Activity of MSNs of the direct pathway leads, via two inhibitory synapses, to disinhibition of the thalamus and thus an increase in positive feedback excitation to the cortex. D1 dopamine receptors found on these direct pathway MSNs increase their excitability and firing, thus enhancing excitatory feedback to the cortex. Medium spiny neurons of the indirect pathway, in contrast, produce a net inhibitory effect on the thalamus. D2 dopamine receptors are found on these MSNs and decrease their activity; thus, activation of D2 receptors *also* increases net excitatory feedback to the cortex. This contrasting regulation of direct and indirect pathways by dopamine provides an explanation for the ability of dopamine-enhancing drugs, such as cocaine and amphetamine, to accelerate both behavior and cognition, and for dopamine deficiency in Parkinson disease to produce slowing and deficits in both domains.

This model of the dynamic relationships between nuclei of the basal ganglia neglects their intrinsic microcircuitry; dysregulation of this microcircuitry is likely to have a central role in the pathophysiology of TS. The inhibitory MSNs make up a large majority of striatal neurons, but critical minority populations of interneurons coordinate, sculpt, and integrate MSN firing and thus critically regulate information flow through

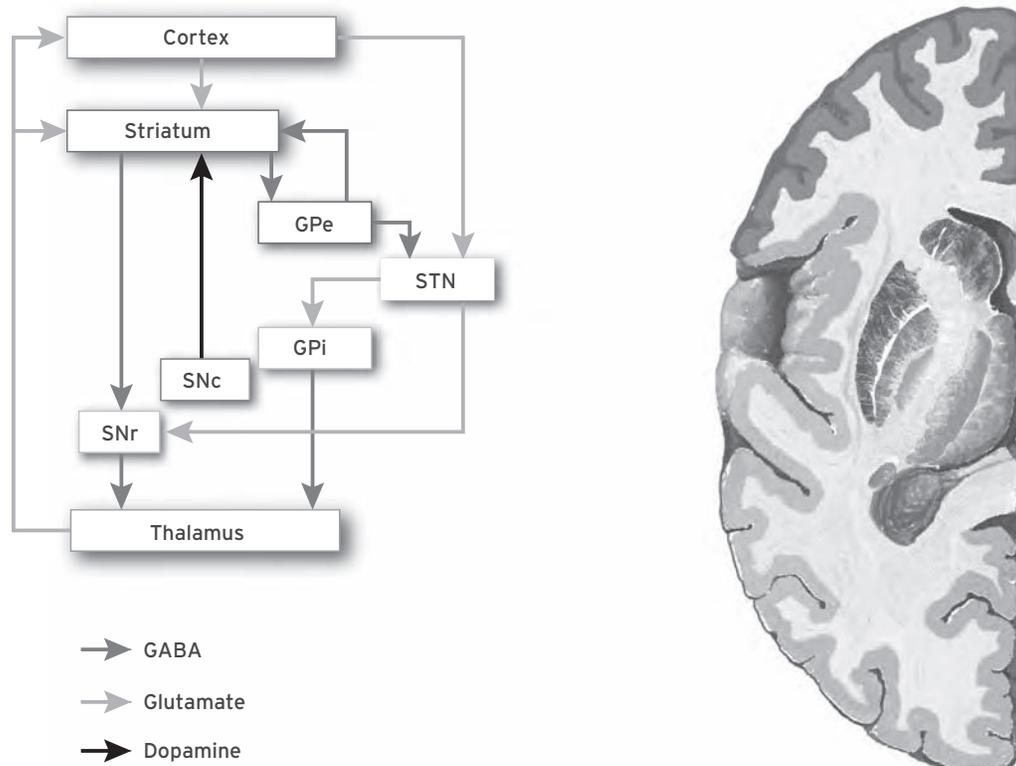

Figure 79.2 Schematic organization of the cortico-striato-thalamo-cortical circuitry. Major structures and connections of the basal ganglia circuitry are shown. GPe, globus pallidus externa; GPi, globus pallidus interna; STN, subthalamic nucleus; SNc, substantia nigra, pars compacta; SNr, substantia nigra, pars reticulata. D1-expressing MSNs in the striatum (the caudate and putamen) project to the SNr; this constitutes the direct pathway. D2-expressing MSNs project to the GPe, constituting the indirect pathway. (Adapted from Pittenger et al., 2001. *Glutamate abnormalities in obsessive compulsive disorder: neurobiology, pathophysiology, and treatment*. *Pharmacol. Ther.* 132, 314–332.)

the basal ganglia (Kreitzer, 2009). Prominent among these are the large cholinergic interneurons, hypothesized to be identical to the electrophysiologically identified tonically active neurons (TANs). These intrinsic interneurons provide the only source of modulatory cholinergic tone in the striatum. As their name suggests, the TANs show rhythmic intrinsic activity in the 5-Hz range; this contrasts with the MSNs, which are rather quiet at baseline. Acetylcholine from the TANs acts on both muscarinic and nicotinic receptors, modulating corticostriatal synaptic plasticity (Shen et al., 2008) and interacting with dopamine to gain behavioral reinforcement (Aosaki et al., 2010). Interestingly, the TANs have also recently been shown to release synaptic glutamate (Higley et al., 2011); the implications of this co-release for striatal information processing remain to be clarified.

There are also several populations of GABAergic interneurons in the striatum. The parvalbumin-expressing fast-spiking interneurons (FSIs) have electrophysiological properties similar to those of parvalbumin-expressing interneurons elsewhere in the brain and are capable of firing bursts in excess of 100 Hz. They are thought to mediate feed-forward inhibition from the cortex and may have a role in the synchronization of MSN output (Berke et al., 2004). This suggests that alterations in FSI firing may lead to disorganized striatal information processing. Consistent with this model, pharmacological inhibition of FSI firing produces dyskinetic movements reminiscent of tics (Gittis et al., 2011).

Modulatory neurotransmitters also play a key role in regulating information flow through the basal ganglia, as they do elsewhere in the brain. The roles of dopamine and acetylcholine have been briefly described in the preceding. Certain serotonin receptors, especially the 5-HT_{1B} receptor, are also densely expressed in the basal ganglia. Histaminergic modulation of the basal ganglia has received relatively little attention until recently. However, as summarized previously, the identification of a rare but highly penetrant mutation in the *Hdc* gene that segregates with TS in a dense pedigree creates new interest in the potential role of abnormalities in histaminergic neurotransmission in the pathophysiology of TS. Histamine receptors are prominent in the basal ganglia. Their specific role is an area of active research.

NEUROIMAGING: SUBCORTICAL STRUCTURES

Neuroimaging studies in patients with TS support the presence of anatomical and functional abnormalities in the basal ganglia circuitry. Neuroimaging in patients with TS can be particularly challenging, as tics can generate problematic movement artifacts. Nevertheless, substantial imaging data have been described over the years. The most robust and replicated findings involve volumetric changes in subcortical nuclei, particularly the caudate nucleus. Three volumetric MRI studies, including one with more than 150 subjects, have reported decreases in the volume of the caudate in TS subjects compared with controls. Moreover, reduced caudate volumes are associated with increased tic and OCD symptoms severity in adulthood (Leckman et al., 2010). Changes in the putamen are less well established. One early study suggested a reduction in the size of the lenticular nuclei,

consisting of putamen and globus pallidus (Peterson et al., 2003), whereas subsequent reports have found increased putamenal volumes (Kassubek et al., 2006; Roessner et al., 2011). Two additional large-scale (>100 TS subjects and controls) MRI studies have reported volumetric changes in the hippocampus, amygdala, and thalamic nuclei (Leckman et al., 2010), although the specific findings have yet to be replicated.

With regard to neurotransmitter systems in these brain regions, three PET studies have reported increased dopamine release in response to amphetamine challenge in striatum, although one study failed to find evidence of abnormal dopaminergic transmission (Rickards, 2009). A SPECT study found increased expression of the striatal dopamine transporter compared with controls, consistent with increased dopamine release and turnover. Finally, significant decreases in GABA_A receptor binding throughout subcortical structures (chiefly the basal ganglia, substantia nigra, thalamus, and amygdala) have recently been reported in TS (Lerner et al., 2012). Viewed as a whole, these studies provide evidence for increased dopaminergic activity in TS and altered neurotransmission in CSTC circuitry.

It is worth noting that the majority of these PET and SPECT studies were performed in symptomatic adults. A majority of children with TS experience a significant decrease in their tic symptoms during adolescence. Therefore, adults with clinically significant tics may represent a specific subset of those diagnosed with TS during childhood. It is possible that the pathophysiology of tics in these adult patients differs from that in individuals whose tics remit or substantially improve during adolescence.

Functional imaging studies convey a similar theme. Four PET studies of regional metabolic activity have found decreased basal activity in the striatum and caudate nuclei in subjects with TS compared with controls. Functional MRI (fMRI), which allows better time resolution, has yielded largely consistent results. Functional fMRI studies of brain activation during voluntary tic suppression have revealed increased activation of the caudate nucleus but decreased activation of the putamen and thalamus. Increased striatal activation has been reported in patients with TS during performance of cognitive control tasks. This increase positively correlates with tic severity (Rickards, 2009). Similarly, two studies of inhibitory control, using the Stroop and Simons tasks, showed greater activation of the putamen and globus pallidus, and poorer performance, in children with TS compared with controls (Raz et al., 2009; Rickards, 2009). An fMRI analysis of a simple, non-tic motor task (finger tapping) in medication-free boys with TS found similar increased activation of the caudate nucleus compared to controls, suggesting a generalized inefficiency of this circuitry in both tic-associated and non-tic-associated contexts (Roessner et al., 2012).

Techniques that probe the integrity of neurons and neuronal connections also indicate the presence of abnormalities in the CSTC circuitry in TS. Magnetic resonance spectroscopy (MRS) measurements of *N*-acetylaspartate (NAA), which is thought to reflect neuronal integrity, revealed reductions in the striatum of TS subjects compared with controls (DeVito et al., 2005). Diffusion tensor imaging (DTI), which measures the

anisotropic diffusion of water molecules to probe the integrity of white matter tracts, has revealed abnormalities in the organization of the internal capsule, basal ganglia, thalamus, and frontostriatal networks (Felling and Singer, 2011; Govindan et al., 2010).

A consistent theme among these studies is the abnormal structure and function throughout the subcortical components of the CSTC circuitry. The details and functional consequences of these abnormalities remain to be elucidated, and it remains unclear which abnormalities are essential components of the pathophysiology of tic symptomatology, as opposed to epiphenomena or compensatory changes. However, the consistency of these findings strongly suggests a role for abnormal CSTC circuit function in the pathophysiology of TS.

NEUROIMAGING: CORTICAL PATHOLOGY IN TOURETTE SYNDROME

Afferent projections to the basal ganglia originate primarily in the cortex and thalamus, and numerous studies have revealed cortical abnormalities in patients with TS. Whether these cortical abnormalities are a primary cause of the subcortical abnormalities described in the preceding or are a consequence of basal ganglia dysregulation is a difficult question to answer. It may be that primary pathology in either region can lead to similar dysregulation of the circuit as a whole and thus to similar symptomatology.

Early postmortem studies identified increased second-messenger enzyme levels in frontal and occipital cortices (Singer et al., 1995), with subsequent findings of increased D_1 , D_2 , and α_2 -adrenergic receptors in the prefrontal cortex of patients with TS compared with controls (Leckman et al., 2010). This later finding is of particular interest because pharmacological treatments for tic disorders are centered upon either dopaminergic or adrenergic modulation.

Neuroimaging provides additional evidence of altered cortical physiology in tic disorders. The most widely replicated findings involve volumetric abnormalities throughout multiple regions of cortex, with cortical thinning in the frontal and parietal cortices, particularly in the sensorimotor regions (Leckman et al., 2010), in adults with TS. These cortical abnormalities appear to follow a specific developmental trajectory, with an *increase* in dorsal prefrontal cortical thickness in children with TS (Peterson et al., 2001), evolving into cortical thinning in adults (Leckman et al., 2010). A similar developmental trajectory of cortical thickness abnormalities has been reported for pre-motor and parieto-occipital cortex, with tic severity inversely correlated to the volume of these structures (Peterson et al., 2001). These findings have been interpreted as suggesting hypertrophied CSTC input in children with TS, with subsequent atrophy of these regions in adulthood. In contrast, the corpus callosum, which interconnects the hemispheres, shows reduced cross-sectional area in children but increased area in adults (Felling and Singer, 2011). An important caveat is that these findings are from cross-sectional studies; no longitudinal studies of cortical thickness or connectivity over time in TS have been reported.

Functional imaging and PET studies complement these structural findings. Studies of resting state connectivity and DTI have identified increased and disorganized connectivity between frontostriatal networks (Felling and Singer, 2011), which has been interpreted as a sign of immature functional connectivity of these neuronal circuits. This finding is congruent with results from task-related fMRI studies, which have repeatedly shown increased recruitment of the frontal cortices during cognitive tasks (Raz et al., 2009; Rickards, 2009), and blink-suppression (Mazzone et al., 2010), in TS subjects compared with controls. Functional imaging during motor tasks has revealed both increased and decreased activation in the sensorimotor and supplementary motor regions during movement when compared with controls (Rickards, 2009; Roessner et al., 2012). However, PET studies have consistently found increased metabolic activity in the premotor and supplementary motor areas in TS subjects, which have positively correlated with tic severity (Felling and Singer, 2011).

In sum, the TS neuroimaging literature—both of cortical and subcortical structures—contains substantial heterogeneity and important open questions, but certain generalizations emerge in which we can have confidence. Multiple cortical areas, especially sensorimotor cortices, are thicker in children but thin over time and are thinner in adults than in matched controls. These same cortical regions appear to be hyperactive at rest and to be more readily recruited during a variety of tasks. The striatum, in contrast, is hypoactive at rest, and the caudate nucleus has a small but significant reduction in volume that correlates with long-term clinical course. In aggregate, these volumetric abnormalities support the hypothesized dysregulation of the CSTC circuitry, although many details remain to be elucidated.

NEUROPATHOLOGY: EVIDENCE FOR BASAL GANGLIA DYSREGULATION IN TOURETTE SYNDROME

Recently, postmortem analysis has provided direct evidence for alterations in striatal interneuron populations in TS (Kataoka et al., 2010). Rigorous quantification of the density of specific populations of interneurons has revealed a significant, approximately 50% decrease in the density of parvalbumin-expressing FSIs throughout the striatum and globus pallidus externa (GPe) of TS subjects when compared with controls (Fig. 79.3). Strikingly, PV+ neurons, although decreased in the GPe, were *increased* by 68% in the adjacent globus pallidus *interna* (GPi) in patients with TS compared with controls. The cholinergic interneurons—the presumptive TANs—were similarly decreased by approximately 50%. These deficits appear specific to the PV+ and ChAT+ interneuron populations, as no differences in total neuronal number or in the density of other, calretinin-expressing interneurons were appreciated. ChAT+ interneurons displayed greater deficits in the sensorimotor and associative regions of the striatum (compared with more ventral limbic regions). There is normally a gradient of TAN density from dorsal to ventral striatum; this regionalized deficit had the effect of abolishing this density gradient seen in control postmortem brains (Kataoka et al., 2010).

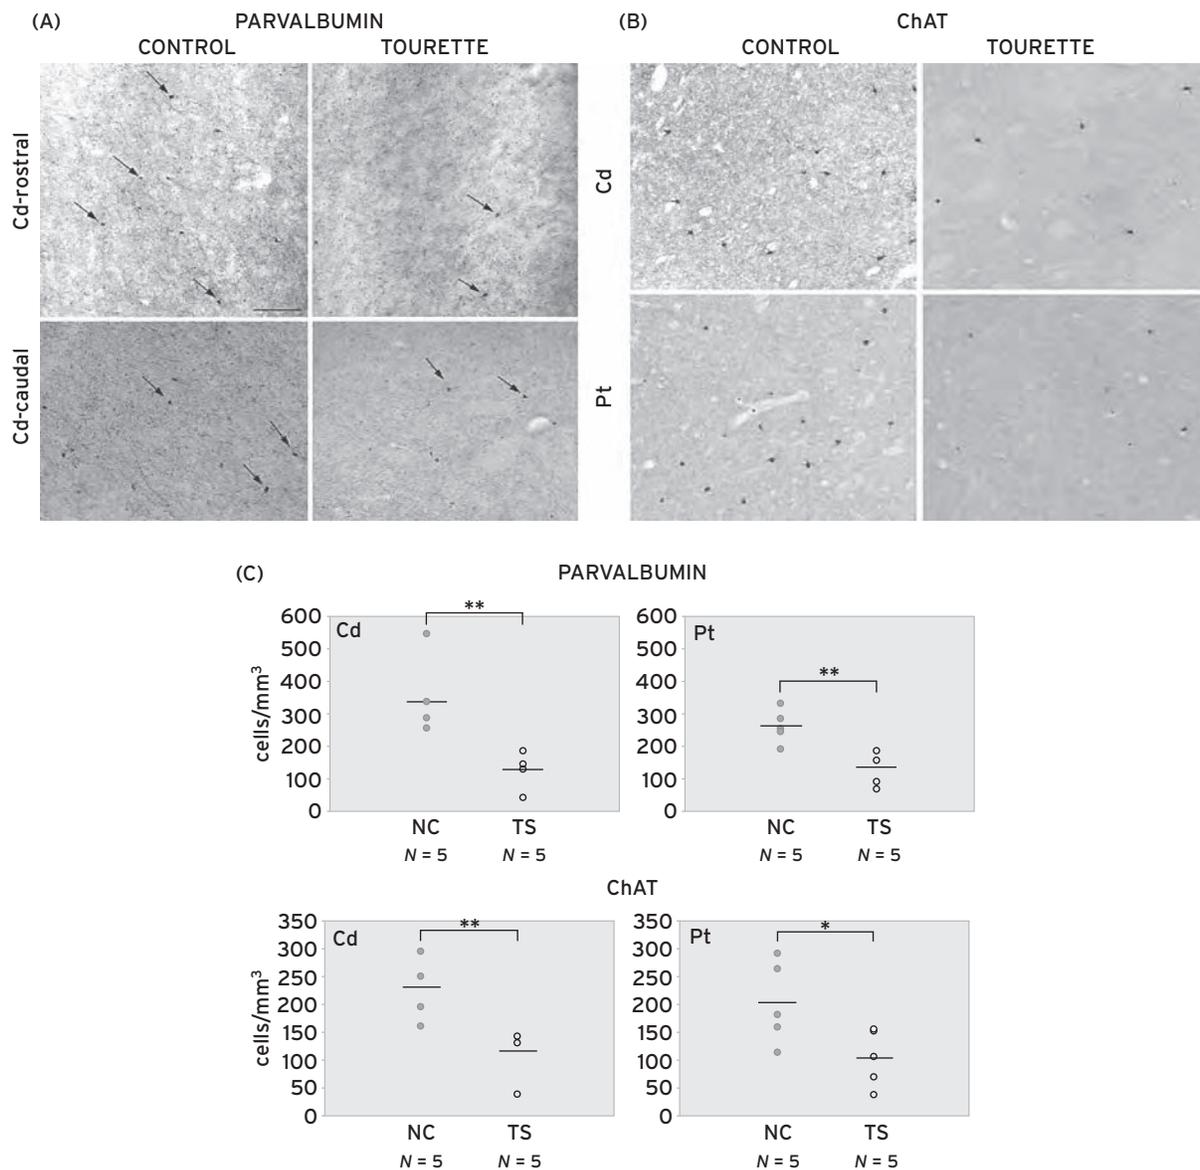

Figure 79.3 Interneuron deficits in postmortem samples from the Tourette syndrome brain. (A) Immunostaining for parvalbumin identifies putative FSI interneurons in postmortem tissue from TS and control brains. (B) Immunostaining for ChAT identifies putative TANs. (C) Both categories of interneuron are reduced in number by approximately 50% in the TS brain throughout the caudate and putamen. (Adapted from Kataoka et al., 2010, with thanks to F. Vaccarino and Y. Kataoka. Decreased number of parvalbumin and cholinergic interneurons in the striatum of individuals with Tourette syndrome. *The J. Comparat. Neuro.* 518, 277–291.)

These important postmortem findings come with some caveats. The total number of TS brains examined remains small (five TS brains and five controls). The subjects were not typical patients with TS. They were adults with lifelong, treatment-refractory disease and had had multiple pharmacotherapy trials. Therefore, it is important to guard against overgeneralizing from these results. Nevertheless, the suggestion that specific interneuron deficits may underlie TS has importantly reoriented the field.

The genesis of the observed deficits in cholinergic interneurons and in PV-expressing interneurons in these postmortem studies remains unclear. In particular, it remains to be established whether these deficits are causal, compensatory, related to the treatment-refractory nature of the particular patients

studied, or an epiphenomenon. It is also unclear whether the reduced interneuronal number is caused by a developmental failure or represents a remarkably specific pattern of degeneration. Two arguments support the former possibility. First, the fact that PV-expressing interneurons are not simply missing but rather are maldistributed, with a decreased density in striatum and GPe but an *increased* density in GPi, suggests dysregulated migration during development. Second, recent studies have revealed that these two interneuronal populations have a shared developmental origin, and their ontogenesis is regulated by an overlapping set of transcriptional regulators (Fragkouli et al., 2009). This suggests the possibility that disruption in a specific developmental program could produce the remarkably specific observed pattern of interneuron deficits. However, any such

proposal remains highly speculative, and many details remain to be worked out.

How might these interneuronal deficits lead to the circuit dysregulation and symptomatology of TS? PV+ interneurons are highly responsive to stimulation from motor and somatosensory cortices (Parthasarathy and Graybiel, 1997) and densely innervate adjacent MSNs (Leckman et al., 2010). They are electrically coupled to one another through gap junctions. *In vivo* recordings in rats suggest that they play a role in synchronizing the firing of MSNs, at least during some behavioral states (Berke et al., 2004); their disruption may lead to dysynchrony of CSTC circuitry. Targeted pharmacological inhibition of PV+ interneurons in the striatum of freely moving mice produces dystonic symptoms, consistent with this prediction (Gittis et al., 2011). Administration of amphetamine has also been shown to increase the firing rates of PV+ interneurons, whereas blockade of the D₂ dopamine receptor decreases firing rates (Wiltschko et al., 2010), suggesting modulation of these neurons from compounds capable of both exacerbating and alleviating tics.

As noted, cholinergic interneurons, identified by their expression of choline acetyltransferase (ChAT), are widely thought to correspond to the sparse tonically active neurons (TANs) found in *in vivo* electrophysiological recordings. These TANs express both D₂ and D₅ receptors and are also highly responsive to afferent dopaminergic projections, as well as to glutamatergic afferents from both cortex and thalamus. Tonically active neurons synapse richly on MSNs and FSIs, as well as on other TANs and on the terminals of both glutamatergic and dopaminergic afferents (Kreitzer, 2009). Tonically active neuron firing and the burst firing of dopaminergic projections have a complex relationship. When dopaminergic afferents fire in response to an unexpected reward, the TANs coincidentally pause their tonic firing (Goldberg and Reynolds, 2011), possibly through the direct action of these dopaminergic afferents on D₂ receptors on the TANs. Recent work suggests activation of ChAT+ interneurons by thalamic afferents may transiently enhance activity of the indirect pathway, inhibiting movement (Ding et al., 2010). It is plausible that dysregulation of this regulatory mechanism leads to impaired indirect pathway activity. However, such interpretations remain highly speculative. The potential consequences of interneuronal dysregulation in TS remain to be clearly elucidated.

ANIMAL MODELS: SUBCORTICAL DYSFUNCTION AND TOURETTE SYNDROME

Both TS and OCD have been associated with dysregulation of the CSTC circuitry. An early mouse model of comorbid TS and OCD sought to recapitulate this hyperactivity by expressing the cholera toxin A1 subunit, which potentiates neuronal activity, under the control of the D₁ dopamine receptor promoter. These animals have chronic activation of D₁-containing neurons throughout the cortex and amygdala (Felling and Singer, 2011). They display repetitive behaviors, with bursts of tic-like movements of the head and limbs, and demonstrate

improvement with both α_2 -agonists and D₂ receptor antagonists. However, these mice also display symptoms outside the scope of TS, such as a reduced seizure threshold, leading to questions regarding the validity of this model.

Another animal model of substantial interest derives from a spontaneous mutation in the Syrian golden hamster: the dystonic or dtsz hamster. These animals display stress-induced facial contortions, hyperextension of limbs, and dystonic posturing; these behaviors are arguably analogous to the symptoms observed in patients with tic disorders. Immunohistochemical analysis revealed a 26% reduction of the PV+ interneuron population in the striatum of mutant hamsters when compared with controls, paralleling what has been described in postmortem human brain, with resultant abnormal burst-firing patterns of globus pallidus neurons recorded using *in vivo* electrophysiology. Remarkably, these mutant hamsters show an age-related decrease in stress-induced dystonias, again analogous to the clinical course of TS, and this improvement of symptoms correlates with an age-related normalization of striatal PV+ interneurons (Leckman et al., 2010).

IMMUNE DYSFUNCTION IN TIC DISORDERS AND TOURETTE SYNDROME

One intriguing hypothesis developed in recent years is that some cases of TS and OCD may derive from autoimmune mechanisms. Proposals along this line have been met with both interest and controversy. One proposed syndrome, termed Pediatric Autoimmune Neuropsychiatric Disorder Associated with Streptococcal infections (PANDAS), hypothesizes that tic disorders in a subset of patients are the result of an autoimmune syndrome initiated by a group A beta-hemolytic streptococcal (GABHS) infection. A more general hypothesis is that more nonspecific inflammatory activity and/or immune dysfunction in the CNS contributes to the pathophysiology of tic disorders more broadly.

PANDAS is characterized by the rapid onset of OCD and/or tic symptoms in a previously healthy child following a recent GABHS infection. This syndrome is conceptualized as a variant of Sydenham chorea, a well-characterized hyperkinetic movement disorder that follows a recent GABHS infection, and shows both radiological evidence of basal ganglia abnormalities and autoimmune antibodies directed against neuronal proteins (Murphy et al., 2010). The clinical scope and diagnostic criteria for PANDAS are defined by an abrupt onset and waxing and waning symptoms associated with GABHS infections.

A thorough discussion of the controversy surrounding the PANDAS diagnosis is beyond the scope of this chapter. Briefly, owing to the lack of biomarkers or diagnostic tools to identify those with PANDAS from children with childhood onset OCD or tic disorder, many investigators have argued that PANDAS represents a spurious association between a ubiquitous infection of childhood (GABHS) and the onset of a common neuropsychiatric disorder (Singer et al., 2011). Cross-sectional studies investigating new-onset diagnoses of TS and GABHS infections, as well as longitudinal studies investigating

symptom exacerbations following GABHS infections, have produced conflicting results (Singer et al., 2011).

However, clinical trials using immunomodulatory therapies for children with PANDAS have shown striking reductions in OCD and tic symptoms, as well as normalization of basal ganglia abnormalities on serial MRI exams (Murphy et al., 2010). Furthermore, antibodies against the D₁ and D₂ receptors have been isolated from children with PANDAS (Brimberg et al., 2012), providing a plausible mechanism for an autoimmune etiology in these patients. Additional support comes from two recent animal studies using immunization with GABHS proteins in mice, demonstrating the generation of perseverative behaviors and motor stereotypies, as well as deposition of autoimmune antibodies throughout the CNS, including the basal ganglia (Hoffman et al., 2004; Yaddanapudi et al., 2010). Continued investigation is needed to clarify the validity of this diagnostic entity. A replication trial of immunomodulatory therapy in the treatment of PANDAS is underway at the National Institute of Mental Health.

Multiple investigations suggest individuals with tic disorders display altered immune function, irrespective of any etiopathological link to specific infections. For example, a recent post-mortem analysis of RNA transcripts in the basal ganglia of four patients with TS (and four controls) found a 6.5-fold increase in MCP-1, a marker of chronic inflammation and immune cell activation. An additional 2.9-fold increase was observed in IL-2, an inflammatory cytokine involved in immune cell proliferation, replicating a similar finding from a previous study of postmortem putamen in TS subjects. Elevations of inflammatory cytokines in patients with TS compared with controls have been documented in small-scale studies, as have abnormalities in immunoglobulin levels (Murphy et al., 2010). Further research is necessary to discern whether these changes are pathophysiologically related to TS or are an epiphenomenon.

INTEGRATIVE MODELS OF TOURETTE SYNDROME PATHOPHYSIOLOGY

Several themes emerge from this summary of recent advances in our understanding of the pathophysiology of TS. Our insight into the pathophysiology of the disorder remains incomplete; but some integration can be attempted and may guide future investigations.

The initial proposal of the direct and indirect pathways (see Fig. 79.2) suggested that a dynamic balance between them regulates relative levels of activation (Albin et al., 1989). A refinement of the direct/indirect pathway concept, focusing on the concept of *action selection*, has cast further light on how dysregulation of this circuitry may produce tics. In any given context, an organism must select from among different possible actions or responses. The direct pathway is hypothesized to be responsible for selecting an action from among different cortical representations. The indirect pathway, in contrast, suppresses other “off-target” actions (Mink, 2001). In this model, reduced activity in the indirect pathway would be predicted to disinhibit off-target movements, a plausible explanation for tics. D2 blockade, which is an efficacious pharmacotherapy for

TS, would disinhibit the indirect pathway and thereby reduce these off-target movements.

How might such a relative hypoactivity of the indirect pathway develop? We can only speculate. The D2 receptor has a higher affinity for dopamine than the D1 receptor and is thought to be more responsive to tonic, rather than phasic, dopamine stimulation. A chronic, mild elevation of striatal dopamine could thus lead to preferential activation of the D2 receptor and suppression of the indirect pathway, with little or no impact on the direct pathway. Interestingly, H3 histamine receptors are found presynaptically on dopaminergic terminals and are thought to suppress dopamine release; it is plausible, therefore, that reduced histamine (e.g., in patients carrying the rare HDC mutation described in the preceding) could lead to disinhibited dopamine release and produce just such an effect. Amphetamine use, which has been clinically reported to worsen tic severity in some cases, could likewise produce a chronic elevation of striatal dopamine and thus reduced indirect pathway tone. The mechanisms whereby autoimmunity may influence this circuitry in PANDAS are not well understood. However, the observation of antibodies against dopamine receptors in some individuals leads to a plausible explanation for an effect on the flow of information through the system.

How might interneuronal pathology fit into this hypothesis? One possibility is that an interneuronal deficit can differentially affect the medium spiny neurons of the direct and indirect pathways. For example, burst-pause firing of the cholinergic interneurons has recently been shown, in brain slice, to produce a differential silencing of the D2-expressing MSNs of the indirect pathway (Ding et al., 2010). A TAN deficit could plausibly impair this mechanism, producing an indirect pathway-specific deficit (at least phasically). An alternative possibility is that interneuronal deficits lead to a disorganization of striatal information processing. For example, parvalbumin-expressing FSIs are thought to play a role in synchronizing MSN firing, at least during some behavioral states (Berke et al., 2004). Disruption of such a coordinating role could plausibly produce local imbalances of direct and indirect pathway tone, thus disinhibiting fragmentary off-target movements.

These speculations address regulation throughout the basal ganglia (the striatum in particular). But individual tics are typically focal and presumably derive from dysregulated firing of a small domain of the basal ganglia circuitry, not the entirety of the striatum. In support of this supposition, small, localized strokes can produce tics (Kwak and Jankovic, 2002), and local disinhibition of the monkey striatum by infusion of a GABA antagonist produces tic-like movements (McCairn et al., 2009). There are three ways such a local effect may arise. First, there may be a truly local pathology, as occurs after a stroke. Second, there may be a disorganization of striatal network activity such that local areas of dysregulation spontaneously emerge through self-organization of a maladaptive network architecture. Finally, neurochemical or interneuronal abnormalities throughout the basal ganglia circuitry may render it susceptible to aberrant responses to particular patterns of cortical input. This last possibility would potentially provide an explanation for the clinical observation that tics can sometimes be triggered by a particular sensory stimulus, such as a cough, but then appear to become autonomous.

TREATMENT

In many cases, TS and other tic disorders do not require intervention. Because the natural history of the disease is waxing and waning and improvement with age is common, tics can often simply be monitored. Treatment is warranted when tics cause significant distress or impact social or occupational functioning. When tics become self-injurious or damaging, aggressive treatment is critical. We end our discussion of the neurobiology of TS with a brief summary of evidence-based pharmacological and neurosurgical treatments, in the context of the previous discussion of TS pathophysiology.

To date, the only medications approved by the Food and Drug Administration (FDA) for the treatment of TS in children are the neuroleptics haloperidol and pimozide, both potent antagonists of the D₂ receptor. Both haloperidol and pimozide have demonstrated efficacy, compared with placebo, in randomized controlled trials, with one trial suggesting a superior effect of pimozide over haloperidol. Risperidone, a second-generation antipsychotic, has also demonstrated effectiveness in the treatment of tics in randomized, double-blinded controlled trials, with a reported 32% reduction in tic severity at eight weeks. Treatment with these agents is often limited by side effects, with extrapyramidal motor side effects and cardiac effects being of greatest concern for the older agents and weight gain for risperidone.

D2 receptors are particularly concentrated in the caudate and putamen, and D2 blockade has marked effects on basal ganglia function and information processing. In particular, D2 blockade will reduce the normal inhibitory effect of dopamine on activity in the indirect (striatopallidal) pathway through the basal ganglia (see Fig. 79.2). It was speculated in the preceding that tics may represent fragmented off-target movements that are insufficiently inhibited by the indirect pathway. Increasing activity in this pathway may therefore represent the mechanism whereby D2 antagonism mitigates symptoms. D2 receptors are also found on striatal cholinergic interneurons. Blockade of these receptors may disinhibit these interneurons, mitigating some consequences of any deficiency in neuronal number or function. However, these proposed mechanisms remain speculative.

The side effect profile of antipsychotic medications decreases the long-term viability of these treatments for many patients. Agonists of the α_2 -adrenergic receptor, clonidine, and guanfacine have shown efficacy in the treatment of tics in double-blind, treatment-controlled studies (Bloch et al., 2011). These medications have a much smaller treatment effect size than the D2 antagonists, but have the benefit of far fewer side effects than the antipsychotics. α_2 -adrenergic agonists are also effective therapies for the management of ADHD, making them attractive candidates for those with tic disorders and comorbid ADHD. One barrier to treatment among α_2 -adrenergic agonists is their short duration of action. A long-acting preparation has recently been approved by the FDA, although to date no trials in TS have been published. Adrenergic innervation of the basal ganglia is sparse; however, modulation of the frontal cortex is substantial. It is therefore likely that the α_2 -adrenergic agonists affect the symptoms of TS by modulating cortical function. Details of this effect remain to be worked out.

We have described the evidence that TS is associated with dysregulation of the CSTC circuitry. This leads to the idea that direct manipulation of activity in this circuit using deep brain stimulation (DBS) may mitigate symptoms in particularly severe, refractory cases. DBS has long been used for Parkinson disease, dystonia, and other movement disorders. In TS, a number of cases and case series of DBS have been described. Targets have included thalamus, globus pallidus, and nucleus accumbens. Reports from these early trials have been promising, with an approximately 60% reduction in tic symptoms across reported studies (Neuner et al., 2009). However, no well-powered placebo-controlled studies have been described to date; therefore, these results must be considered tentative. No consensus exists regarding the optimal structure for stimulation to alleviate tics, and no careful comparison studies have been conducted to date. Further research is needed to identify which targets within the CSTC circuitry give the greatest effect in the DBS treatment of tic symptoms.

CONCLUSIONS

Our understanding of the pathophysiology of TS has advanced remarkably over the past decade, to the point that several specific pathophysiological themes are beginning to coalesce. Multiple strands of evidence from neuroimaging, postmortem, and preclinical studies suggest that abnormalities in the CSTC circuitry are a central component of the neurobiology of TS. Dysregulation of dopaminergic modulation within this circuitry has long been thought to be of central importance. More recent work has focused attention on interneuron abnormalities and potential dysregulation of histaminergic neurotransmission. The genetics of the disorder, long opaque, are now beginning to come into clearer focus, although larger studies are clearly necessary to characterize the contribution of both rare and common genetic variation. Most important, the tools and methodologies necessary to exploit these large samples and clarify the genomic landscape of TS are already in place. Finally, the complex interplay between immunological dysregulation and pathophysiology suggested by the controversial syndrome of PANDAS is a fertile area for ongoing investigation.

Neuropsychiatric diseases are, as a rule, pathophysiologically and genetically complex and heterogeneous. Tourette syndrome is no exception to this generalization, and much work remains to be done before a clear understanding of the genetic and developmental origins, neurobiological correlates, and systems-level abnormalities underlying this fascinating condition can emerge. However, the accelerating pace of discovery in recent years engenders real optimism that the new insights into pathophysiology that emerge will, before long, lead to novel strategies of treatment and prevention.

DISCLOSURES

Dr. Williams is supported by the NIMH (T32MH018268) and the Massachusetts General Hospital Research Fund. He has no real or potential conflicts of interest.

Dr. Bloch is supported by the NIMH (K23MH09124), the Brain and Behavior Research Foundation, the Yale Center for Clinical Investigation (UL1TR000142), and the State of Connecticut through its support of the Abraham Ribicoff Research Facilities at the Connecticut Mental Health Center. He has no real or potential conflicts of interest.

Dr. State is supported by the NIMH and NINDS. He has no conflicts of interest pertaining to the content of this chapter.

Dr. Pittenger's work on this chapter has been supported by the NIMH (K08MH081190; R01MH091861), the Tourette Syndrome Association of America, the Brain and Behavior Research Foundation, and the State of Connecticut through its support of the Abraham Ribicoff Research Facilities at the Connecticut Mental Health Center. He receives research support from Roche Pharmaceuticals for an unrelated project.

80 | NOVEL THERAPEUTICS IN CHILDHOOD ONSET PSYCHIATRIC DISORDERS

DOROTHY E. GRICE, ALEXANDER KOLEVZON,
WALTER E. KAUFMANN, AND JOSEPH D. BUXBAUM

Intellectual disability (ID) and autism spectrum disorder (ASD) are among the more severe and prevalent neurodevelopmental disorders. It is estimated that the majority (>50%) of ID cases are traceable to specific genetic causes, and estimates of heritability in ASD are higher, and among the highest in psychiatric disorders (Devlin and Scherer, 2012; van Bokhoven, 2011). Estimates based on gene discovery efforts place the number of genes involved in ID and ASD at 500 or more, with perhaps 20% of ID genes and 10% of ASD genes identified to date (Betancur, 2011; Neale et al., 2012; van Bokhoven, 2011). Widespread use of chromosome microarray (CMA) and massively parallel sequencing (MPS) accelerate gene and locus discovery in these disorders. Many of the genes and loci identified to date are associated with intermediate to high risk for disease (relative risk of approximately 20 to 200; see, e.g., Neale et al., 2012), which allows for the development of cell and animal models with construct validity. The use of neurobiological approaches to analyze these models in turn provides a means to understand disease pathogenesis and identify neurobiologically based targets for future therapeutic interventions. Although the enormous etiological complexity of these neurodevelopmental disorders is daunting, each identified gene provides an additional tool for understanding pathogenesis, and an additional target for novel therapeutics. In this sense, the very complexity of neurodevelopmental disorders may be an advantage for treatment development, especially if some of the causal genes converge on common pathways.

DIRECT AND INDIRECT INHIBITION OF mGluR SIGNALING IN FRAGILE X SYNDROME AND AUTISM SPECTRUM DISORDERS

Neurobiologically driven clinical trials in fragile X syndrome (FXS) are some of the most advanced in the field (Hagerman et al., 2012; Krueger and Bear, 2011). Mice, flies, and worms with disruptions in *FMRI*, the gene mutated in FXS, show alterations in synaptic function. These studies have shown that the *FMRI* gene product (called the FX mental retardation protein, or Fmrp) regulates translation at the synapse, and loss of Fmrp leads to excess translation. Parallel studies have shown that glutamate signaling through group 1 metabotropic glutamate receptors (mGluR) activate translation at the synapse, a

process linked to long-term depression, with Fmrp providing negative feedback for this process. These findings in turn suggest that the mGluR pathway is a therapeutic target in FXS that could be manipulated either by antagonizing these receptors or using reverse agonists to mGluR. More broadly, reducing glutamate transmission through the use of presynaptic GABA_B agonists might represent another mechanism to counter the molecular deficits in FXS. Both of these approaches have been successful in model systems.

Two randomized controlled trials (RCTs) based on these neurobiological approaches have been reported to date. In the first, AFQ056, an mGluR5 antagonist, was studied in 30 males with FXS (Jacquemont et al., 2011). There were no significant effects of treatment on the primary outcome measure, the Aberrant Behavior Checklist-Community Edition (ABC-C). However, exploratory analyses indicated that those individuals with full methylation of the *FMRI* promoter showed significant improvements in total ABC-C and two subscale scores (ABC-Hyperactivity and ABC-Inappropriate speech). This finding is being pursued in independent studies (Table 80.1).

In the second RCT, STX209, which is a GABA_B agonist also known as arbaclofen, was studied in 63 patients with a full *FMRI* mutation (Berry-Kravis et al., 2012). Once again, there was no significant finding in the primary outcome measure, in this case the ABC-Irritability (ABC-I) subscale. In exploratory analyses, there was a positive effect of treatment in the ABC-Social Avoidance scale, a scale derived from ABC-C factor analyses in FXS (Sansone et al., 2012), both in the entire study population and a subgroup of subjects with more severe social impairment. Convergent evidence was provided as they also observed improvements in complementary measures such as the Vineland II-Socialization raw score. Arbaclofen is currently being further assessed as a clinical treatment in both FXS and idiopathic ASD (see Table 80.1). Because mouse models of FXS also display GABAergic deficiency, particularly in the amygdala (Olmos-Serrano et al., 2010), a region implicated in avoidant behaviors, the effects of arbaclofen may be mediated by a combination of GABA agonism and indirect glutamate antagonism.

The Fmrp-binding protein CYFIP1 (cytoplasmic Fmrp-interacting protein 1) is coded by one of five genes found between breakpoints 1 and 2 in the 15q11 region. Loss of one copy of this chromosome interval is associated with increased risk for, or increased severity of, a number of neurodevelopmental and psychiatric disorders, including ID, ASD,

TABLE 80.1. Examples of compounds in clinical trials for pervasive developmental disorders

COMPOUND	TARGET	DISORDER
PHASE I		
Carbetocin	Oxytocin receptor agonist	ASD
RG1662	Gamma-aminobutyric acid receptor A (GABA _A) reverse agonist	DS
RG7314	Arginine vasopressin receptor 1A (AVPR1A) antagonist	ASD
STX107	Metabotropic glutamate receptor 5 (mGluR5) antagonist	FXS
PHASE II		
Mecasermin	Insulin like growth factor receptor (IGF1R) agonist	RTT, 22q13DS
STX209 (arbaclofen)	Gamma-aminobutyric acid receptor B (GABA _B) agonist	ASD
RO4917523	Metabotropic glutamate receptor 5 (mGluR5) antagonist	FXS
PHASE III		
AFQ056	Metabotropic glutamate receptor 5 (mGluR5) antagonist	FXS
STX209 (arbaclofen)	Gamma-aminobutyric acid receptor B (GABA _B) agonist	FXS

22q13DS, 22q13 deletion syndrome; ASD, autism spectrum disorder; DS, Down syndrome; FXS, Fragile X syndrome; RTT, Rett syndrome.

epilepsy, and schizophrenia (reviewed in Bozdagi et al., 2012). Interestingly, mice with a loss of *Cyfp1* show many of the same features of mice with a loss of *Fmr1*, including enhanced long-term depression that is insensitive to protein synthesis inhibitors, and accelerated extinction of inhibitory avoidance. Furthermore, group 1 mGluR antagonists reverse the deficits in synaptic plasticity observed in these mice (Bozdagi et al., 2012). This suggests that the *Fmr1/Cyfp1* pathway may be disrupted in multiple neurodevelopmental disorders with the potential for common therapeutic approaches.

IGF-1 IN RETT SYNDROME AND 22q13 DELETION SYNDROME

Rett syndrome is a pervasive developmental disorder almost exclusively found in girls that is characterized by regression, cognitive impairment, deficits in communication, and stereotypic movements and is, in most cases, caused by mutations in the methyl CpG binding protein 2 (*MECP2*) gene (Calfa et al., 2011; Neul et al., 2010). *MeCP2* binds to methylated DNA and thereby regulates gene expression. Studies in mouse models of Rett syndrome and human brain tissue have shown that *MeCP2* regulates the expression of insulin-like growth factor binding protein 3 (IGFBP3) and that loss of *MeCP2* leads to enhanced levels of IGFBP3 (Itoh et al., 2007). Because IGFBP3 functions

to sequester insulin-like growth factor 1 (IGF-1), increased levels of IGFBP3 would lead to reduced IGF-1 signaling.

In one study of *Mecp2*-deficient mice, a peptide derivative of IGF-1 including the first three amino acids of the full-length protein, (1-3)IGF-1, was found to reverse many neurological deficits in the mice (Tropea et al., 2009). One caveat with this study is that the mechanism of action of (1-3)IGF-1 is not fully clear. It does not seem to bind directly to IGF-1 receptors, although it does appear to activate some of the same downstream cascades that are activated by the full-length protein (Corvin et al., 2012). More recently, full-length IGF-1 was shown to reverse deficits in neurons prepared from patients with Rett syndrome (Marchetto et al., 2010). Full-length IGF-1 crosses the blood-brain barrier via its interaction with lipoprotein-related receptor 1 (LRP1), and can be selectively targeted to the brain through local neuronal activity (Nishijima et al., 2010); therefore, peripheral administration of full-length IGF-1, already approved for use in children with Laron-type dwarfism, could be useful in neurodevelopmental disorders.

Two phase I trials with full-length IGF-1 have been completed at the time of this writing. In the first, carried out in six girls with Rett syndrome, six months of twice-daily subcutaneous injection of IGF-1 proved to be safe and showed some positive effects on respiration (Pini et al., 2012). In the second, 12 girls with *MECP2* mutations, most of them with Rett syndrome, have been followed to collect pharmacokinetic and safety data and identify potential biomarkers for phase II trials (Kaufmann et al., unpublished). In addition to showing safety of IGF-1 in this vulnerable population, one important finding of this study is that peripherally administered IGF-1 is found in cerebrospinal fluid.

Loss of one copy of the *SHANK3* gene, either through deletion (termed 22q13 deletion syndrome or Phelan–McDermid syndrome) or point mutation, leads to ID, absent or severely delayed language, and ASD (Grabrucker et al., 2011). A mouse model with a heterozygous loss of the *Shank3* gene shows deficits in synaptic development and plasticity, as well as deficits in motor and social behaviors (e.g., Bozdagi et al., 2010; Yang et al., 2012). The mice show evidence for delayed maturation of glutamatergic synapses via several measures, in addition to reduced levels of postsynaptic density protein 95 (PSD-95), a neuronal protein important for synaptic development and plasticity. Synaptic development and function can be enhanced by IGF-1, and PSD-95 expression increased by IGF-1. Two-week treatment of these mice with full-length IGF-1 reversed the deficits in synaptic signaling, synaptic plasticity, and motor performance (Buxbaum et al., unpublished). A randomized controlled trial is currently underway using IGF-1 in patients with 22q13 deletion syndrome or *SHANK3* mutation (Kolevzon, NCT01525901).

The parallel preclinical findings showing beneficial effects of IGF-1 in two very different disorders (Rett syndrome or loss of *SHANK3*) is a basis for some optimism that even in the face of profound etiological heterogeneity there may be therapeutic approaches effective across neurodevelopmental disorders. Increasing evidence demonstrating mammalian target of rapamycin (mTOR) abnormalities in a variety of disorders associated with ID and ASD (Hoeffler and Klann, 2010) supports this approach to common targets.

GABA_A ANTAGONISTS IN DOWN SYNDROME

Although it is relatively easy to conceptualize treating a monogenic disorder, it is more difficult to consider specific interventions for contiguous gene syndromes. There are dozens of recurrent copy number variants (CNV) associated with neurodevelopmental disorders (Betancur, 2011; Cooper et al., 2011), and many of these likely represent contiguous gene syndromes. In addition, there are larger chromosomal abnormalities associated with ID, including trisomy and monosomy of entire chromosomes. One of the most common trisomies is that affecting chromosome 21, called Down syndrome. Murine chromosome 16 contains large regions syntenic to human chromosome 21, and a mouse with a translocation of a large portion of chromosome 16 has been generated (Ts65DN) that is trisomic for about two-thirds of the human chromosome 21 genes. These mice show excess inhibition in the dentate gyrus and systemic dosing with a GABA_A antagonist has demonstrated beneficial effects on synaptic plasticity (reversing deficits in the induction of long-term potentiation) and cognition (reversing deficits in working memory and in object recognition memory) (Fernandez et al., 2007). A phase I clinical trial with an inverse agonist of the GABA_A receptor 5, a subtype of GABA_A receptor relatively abundant in the hippocampus (Rudolph and Knoflach, 2011), is currently being carried out in young adults with Down syndrome by Hoffmann-La Roche (NCT01436955).

CONCLUSIONS

This chapter summarizes several clinical trials in neurodevelopmental disorders. In each case, the clinical trial was based on preclinical, neurobiological studies in model systems. Although it is premature to assess the clinical success of these approaches, we chose these trials to make several points. First, with a given neurobiological finding, such as dysregulation of translation in FXS, there may be several avenues by which it can be remedied, and we highlight the paths of direct and indirect modulation of glutamate signaling. Second, preclinical studies with IGF-1 in the etiologically distinct conditions of Rett syndrome and *SHANK3*-deficiency syndromes raise the hope that multiple disorders may be treatable with the same or similar therapeutics. Third, even in very complex disorders with multi-gene involvement (e.g., Down syndrome), there may be dominant neurobiological abnormalities that have more profound impact on pathobiology and in turn provide optimal targets for therapeutic intervention. Altogether, the increase in novel therapies in neurodevelopmental disorders represents an important and exciting potential advance in the treatment of mental illness.

DISCLOSURES

Dr. Grice has not reported any conflicts of interest to disclose. Dr. Kolevzon receives research support from Hoffmann-La Roche and Seaside Therapeutics.

Dr. Kaufmann receives research support from Novartis and Ipsen.

Dr. Buxbaum has filed a patent on the use of IGF-1 in 22q13 deletion syndrome and mGluR antagonists in CYFIP1 deletion.

81 | DSM-5 OVERVIEW AND GOALS

DAVID J. KUPFER AND SUSAN K. SCHULTZ

This chapter reviews the stages of development of the Fifth Edition of the Diagnostic and Statistical Manual (DSM-5) and addresses the present and future goals of the manual regarding its function in informing both diagnostic decision making and serving as a template for integrating neurobiologic information as the field evolves over time. Specifically we review how the last few decades of research have yielded remarkable findings from genetics, neuroimaging, cognitive science, and pathophysiology that significantly affect the way the field conceptualizes many of the major psychiatric disorders. However, our ability to use these findings to draw diagnostic thresholds and inform diagnostic decision making has not yet been fully realized. Indeed, it was one of the main subjects of extensive discussion at a series of international research planning conferences for DSM-5. Furthermore, the task of harmonizing the manual with the International Classification of Disease (ICD) has been another major focus of attention in the DSM development process, including facilitating the adoption of parallel chapter headings that are consistent between the two classifications. Finally, we look ahead to the nosology that will be informed by the NIMH RDoC research agenda and the ability of a neuroscience-based diagnostic framework to ultimately influence the evolution of DSM-5. We have chosen the Arabic numeral five for the express purpose of permitting a DSM-5.1, DSM-5.2, and so on. In sum, DSM-5 does not by any means reduce the value of DSM-IV and in fact DSM-5 is more similar to DSM-IV than dissimilar, but the overarching goal is to combine the tradition of diagnostic reliability while building in new information from the neurosciences that helps refine the nosology through an understanding of the pathophysiology that may help meaningfully separate disorders to optimally convey prognosis and inform treatment decisions.

THE RESEARCH AGENDAS FOR DSM-5

During the DSM planning process, it was anticipated that the emerging scientific advances of the last several decades would affect the assessment and management of mental disorders. To stimulate international discourse and move closer to the objective of rebuilding DSM-5's scientific base, the American Psychiatric Association (APA) convened three research conferences from 1999 to 2002. From these conferences came a series of six white papers, which were published as two monographs, entitled "A Research Agenda for DSM-V" (*A Research Agenda for DSM-V*, 2002) and "Age and Gender Considerations in

Psychiatric Diagnosis: A Research Agenda for DSM-V" (*Age, Gender Considerations in Psychiatric Diagnosis: A Research Agenda for DSM-V*, 2007). These addressed topic discussions in nomenclature, disability and impairment, developmental approaches, advances in neuroscience, cross-cultural issues, and current gaps in the classification system. During the course of this process, the concern was raised that over the last few decades, researchers who have dogmatically adhered to DSM-IV definitions could have been constrained in a way that may have hindered progress in understanding the pathophysiology of mental disorders. Although no one would question the value of having a well-operationalized and universally accepted diagnostic system to facilitate comparisons across studies, the reification of DSM-IV entities such that they are considered equivalent to diseases may be more likely to obscure than elucidate research findings. Research exclusively focused on refining the DSM-defined syndromes may never be successful in uncovering their underlying etiologies. Consequently another important goal of DSM-5 is to transcend the limitations of the current DSM paradigm and encourage a research agenda that goes beyond current ways of thinking to attempt to integrate information from a wide variety of sources and technologies (*A Research Agenda for DSM-V*, 2002).

FINE TUNING THE CONCEPTUAL FRAMEWORK

Following the initial discussions addressing the overall conceptualization of the DSM-5 disorders and the need for new approaches, a series of international research planning conferences were conducted between 2003 and 2008 to solidify the framework of the DSM-5 research agenda. This international research planning conference series, jointly supported by the American Psychiatric Association, the World Health Organization (WHO), and the National Institute of Health (NIH), was begun in 2003 and spanned five years. The resulting series of 13 conferences was titled, "The Future of Psychiatric Diagnosis: Refining the Research Agenda for DSM-5." These conferences featured nearly 400 international experts in psychiatry and neuroscience from 39 countries. The experts conducted a multiphase global review of psychiatric diagnosis and classification, and formed the foundation for initial recommendations to the DSM-5 Task Force and Work Groups. The purposes of these conferences were several-fold. First, the conferences sought to examine research evidence for phenomena that cut across traditional diagnostic groups.

For example, such phenomena include the construct of psychosis; hence a conference titled “Deconstructing Psychosis” was convened to examine the current evidence regarding the diagnosis and pathophysiology of common syndromes with psychosis, including: schizophrenia, bipolar disorder, major depressive psychosis, and substance-induced psychosis to address broad issues relating to ways in which psychosis cuts across multiple diagnostic categories (Tamminga et al., 2010). Another conference provided a detailed examination of the heterogeneity and overlap among disorders characterized by fear and avoidance, including posttraumatic stress disorder, panic/agoraphobia, social phobia/social anxiety disorder, and specific phobias. Although these disorders are phenotypically heterogeneous, neuroimaging and neuroanatomy data from human and animal model studies suggest a shared membership in a stress-induced and fear circuitry spectrum, which is conceptually and clinically distinct from other anxiety disorders, such as generalized anxiety disorder, obsessive compulsive disorder, and impulse-control disorders (*Stress-Induced and Fear Circuitry Disorders: Refining the Research Agenda for DSM-V*, 2009). These new conceptualizations could provide useful and novel insights for assessment, treatment, and research.

PURSuing HARMONIZATION ACROSS CLASSIFICATIONS

Another goal for the initial DSM-5 research agenda conferences was to move aggressively toward harmonization with the ICD-11 process. One of the international conferences was dedicated specifically to public health aspects of psychiatric diagnosis and uncovered strategies for using DSM-5 to better address global mental health needs (*Public Health Aspects of Diagnosis and Classification of Mental and Behavioral Disorders: Refining the Research Agenda for DSM-V and ICD-11*, 2012). This conference also served as a springboard for the formation of a DSM-5 Study Group on the interface of general medical disorders with psychiatric disorders. The Psychiatric/General Medical Interface Study Group has sought to specifically examine the link between general medical disorders and psychiatric disorders. Given that most patients with mental illnesses are seen by primary care physicians, the study group was formed to ensure that DSM-5 meets the needs of general medical practitioners as opposed to only specialty mental health clinicians. The study group is also developing revision strategies for the forthcoming DSM-5 for Primary Care, or DSM-5PC, which is intended to be used in primary care settings.

ANTICIPATING THE FUTURE OF NEUROBIOLOGICAL CLASSIFICATIONS

Much of the underlying rationale and discussion associated with the DSM-5 development has been articulated in the research agenda for DSM-5 (*A Research Agenda for DSM-V*, 2002). At the time this volume was published in 2002, it was anticipated that the great gains across the neurosciences

addressing pathophysiology and genetics of mental illnesses would affect to a significant degree the diagnosis and classification of mental disorders. However, the anticipation that these research advances would inform psychiatric diagnosis has not evolved to a clinically applicable state as quickly as was expected. It is now clear that findings from genetic, neuroimaging, cognitive science, and pathophysiology will *eventually* be appropriate for DSM documentation, and in fact in some disorders to be discussed later, there is utility to specific biomarker data and validators in diagnostic decision making, but by and large across the manual most disorders await a classification that is fully informed by underlying pathophysiological mechanisms. Consequently, the DSM-5 research planning conferences generated research strategies to identify groups of validators (Andrews, Goldberg et al., 2009; Andrews, Pine et al., 2009; Carpenter et al., 2009; Goldberg et al., 2009; Kendler, 2009; Krueger and South, 2009; Sachdev et al., 2009). As the DSM-5 process has continued, a new research effort, the Research Domain Criteria (RDoC) has been implemented by the NIMH and seeks to classify psychopathology based on dimensions of observable behavior and neurobiological measures (Insel et al., 2010). The NIMH RDoC objective is consistent with the conclusions of the research planning conferences; as described further here, the information that will emerge over time from the RDoC development will likely merge quite well with the template provided by the DSM-5 text structure.

ORGANIZATION OF DIAGNOSTIC CATEGORIES ACROSS DSM-5

The research conferences in the DSM-5 process facilitated an invaluable review of scientific evidence for establishing groups of disorders with shared criteria, and possibly shared etiologies. The dialogue from these conferences prompted a reconceptualization of the process for validating nosologic categories to update the standard originally delineated by Robins and Guze (1970). The new validation process builds on the original concepts to include the following: building a behavioral phenotype of clinical description and course, creating a neurobiological profile, identifying genetic and familial patterns, considering the interaction between biology and environment, and emphasizing treatment response and follow-up studies (Kupfer et al., 2008). Whenever appropriate thresholds for replication have been met, these validators for diagnostic classification have been included.

In addition to a new approach to the assessment of validity, it also became clear during the DSM-5 development process that there was a need for better integration of cross-cutting factors, such as age-related and cultural considerations, which had not been fully addressed in DSM-IV and may have contributed to intradiagnostic variability. One strategy used in the DSM-5 process is actively focusing on overarching themes that may play an essential role in the conceptualization of disease presentation and classification. Such themes include the ways in which diagnoses and symptoms vary across the developmental lifespan and how gender and cultural diversity affect symptomatology. To this end, additional topic-specific study groups

were formed, in addition to the Psychiatric/General Medical Interface described in the preceding. These Study Groups included the following: (1) Diagnostic Spectra, (2) Lifespan and Developmental Approaches, (3) Gender and Cross-Cultural Issues, (4) Impairment Assessment, and (5) Diagnostic Assessment Instruments. Each of these study groups was charged with reviewing the literature on cross-cutting and dimensional issues in their respective areas and disseminating their findings through collaborative interaction with the individual DSM-5 workgroups. This approach may be useful in developing more precise clinical phenotypes to match the neurobiological profiles. Attention to specific cross-cutting issues such as lifespan and development provided an important opportunity to impart key information relevant to age of onset and symptom presentation. Related to this is the concept of how diagnoses change across the lifespan, such as using a developmental approach to elucidate the onset and characterization of pediatric bipolar disorder (Leibenluft and Rich, 2008). The text structure for the individual disorder descriptions in DSM-5 was revised from the DSM-IV format to permit the relevant information such as developmental perspectives to be presented in relevant chapter headings and subheadings. To ensure that these new facets developed within DSM-5 were harmonized with other classifications, discussions with the WHO facilitated the planned adoption of parallel chapter headings that would be consistent across DSM-5 and ICD.

INTEGRATION OF DISORDERS USUALLY FIRST DIAGNOSED IN INFANCY, CHILDHOOD, OR ADOLESCENCE

DSM-5 has implemented a new feature in support of the view that many mental disorders can be viewed as developmental conditions with their roots in childhood or adolescence. DSM-5 does not contain a separate category titled *Disorders Usually First Diagnosed in Infancy, Childhood, or Adolescence* because this category was viewed as creating an artificial distinction among many conditions with strong developmental features. These disorders are now integrated across the manual, some into existing categories and others into new categories. By presenting an overarching lifespan perspective rather than isolating childhood disorders, DSM-5 now aggregates disorders based on similar pathology and emphasizes the salience of development for a broad array of disorders. The reorganization of the childhood disorders permits proximal placement of disorders with the same putative neural substrates in the same section. For example, the separation anxiety disorders are now placed with the anxiety disorders; which optimally reflects their evidence of shared pathophysiology with the anxiety disorders and discordance from other “childhood” disorders, such as attention deficit hyperactivity disorder. This attention to possible shared pathogenesis of disorders may help facilitate future research on diagnostic biomarkers. This approach in DSM-5 provides a template for the role of developmental biology and how it impinges on the manifestation of disease, suggesting that the concept of “developmental validators” may be a useful tool for future use. Data on anxiety disorders and

other mental syndromes emphasize the importance of probabilistic perspectives and a focus on prevention and potential reduction in later morbidity. For example, early problems with anxiety in childhood may constrain patterns of function during adulthood and predict a statistically increased risk for later problems, but they do not invariably predict a chronic, unrelenting pattern of illness from childhood into adulthood (Pine et al., 1998). By facilitating early recognition of risk factors, DSM-5 is positioned to facilitate a focus on early detection and prevention. It is anticipated that the future will hold opportunities for adding relevant developmental biomarkers to the “living” DSM-5 that will be poised to receive ongoing updates as diagnostically useful measures begin to emerge in future research.

THE DEVELOPMENTAL PERSPECTIVE IN DSM-5

Integration of developmental themes for each disorder across the text also provides an opportunity to focus attention on the developmental features of many adult conditions not typically considered to be developmental in nature. For example, major depression did not appear among DSM-IV disorders *Usually First Diagnosed in Infancy, Childhood, or Adolescence*, yet research is increasingly demonstrating that the initial signs of major depression typically arise in adolescence. A complete discussion of these issues has been provided in substantial detail by Pine et al. (2010). The rationale for integrating the childhood disorders across the manual is also supported by the observation that they are more likely to be similar than different in their characteristic features and pathogenesis, and in many cases they likely represent a continuum of the same disorder, as noted by Rutter et al. (2011). It follows intuitively that the end of childhood or adolescence at the age of 18 years does not coincide with resolution of all effects of an illness, and many developmental disorders not only remain persistent into middle and late life but increase in severity as they interact with changing social demands such as parenting, maintaining employment, or entering retirement. In view of this new arrangement, all diagnoses now provide a lifetime perspective with instructions for the ways in which manifestations vary with age.

INTEGRATION OF NEUROBIOLOGICAL, PATHOPHYSIOLOGICAL, AND LABORATORY DATA INTO DSM-5

The text structure of DSM-5 was designed to provide templates for integration of neurobiological information when the data support their diagnostic use. The new text structure DSM-5 includes subheadings that are designed to serve as placeholders or “receptors” for additional subheadings that may not be populated for all disorders in DSM-5, but may be expanded over time as DSM-5.1, DSM-5.2, and so on, evolve. The specific subheadings that may serve as such “receptors” for emerging neurobiological measures and

biomarkers may be found within the DSM-5 text in the *Risk and Prognostic Features* section as well as the *Diagnostic Markers* section. The *Risk and Prognostic Features* heading is further subdivided to include: (1) temperamental, (2) environmental, and (3) genetic and physiological factors. The *Risk and Prognostic Factors* section includes a discussion of features thought to portend the development of a disorder, including temperamental or personality features; environmental risks, including toxicities, traumatic exposures, environmental precipitants, and substance use; genetic and physiological factors (e.g., APOE4 for neurocognitive disorders, and other known, replicated familial genetic risks); as well as familial pattern.

In preparation for DSM-5, the use of neurocognitive measures was also extensively considered. For example, the aggregate literature on cognition and schizophrenia was carefully reviewed and a variety of views were carefully considered (Barch et al., 2003; Daban et al., 2006; Keefe and Fenton, 2007). The possibility of adding cognitive impairment as a characteristic symptom was considered, but the Psychotic Disorders Work Group recommended against doing so because of its lack of diagnostic specificity and limited information about the effect of such a change. However, cognition was still considered an essential aspect of schizophrenic psychopathology, and is recommended as one vital dimension to be measured across patients with a psychotic disorder. Continued research in this area, potentially in combination with other biomarkers, may facilitate an increase in diagnostic certainty via multidimensional measures such that the DSM-5 text may ultimately include specific neurocognitive “biomarkers” that have diagnostic significance for schizophrenia and other disorders.

Integration of diagnostic markers based on pathophysiology is already occurring in DSM-5 in the context of neurocognitive disorder due to Alzheimer’s disease. For example, in the diagnosis of mild neurocognitive disorder, the Alzheimer’s disease (AD) subtype is not commonly diagnosed, however, such a diagnosis is possible if there is evidence of a causative Alzheimer’s disease genetic mutation from either genetic testing or family history. This advance in DSM-5 represents one of the first examples of integration of neurobiological information into clinical diagnostic decision making. Along these lines, the sleep-wake disorders represent another group of conditions that have increasingly well-established pathophysiological markers. In the case of the parasomnias, previously sleepwalking and sleep terror disorder were listed as individual parasomnias, yet they represent variations of a single underlying pathophysiology of wake/NREM sleep admixture; consequently, they were proposed to have a single parasomnia heading of “Non-Rapid Eye Movement Sleep Arousal Disorders” in DSM-5, with subtypes including sleepwalking and sleep terrors. This permits an aggregation of the disorders of arousal owing to their shared NREM features as well as expanded explanation of their shared pathoetiology in the DSM-5 text. In sum, the DSM-5 has begun to move toward a manual based in common pathogenic sources as opposed to simply syndromic coherence.

PUBLIC HEALTH IMPLICATIONS AND THE STRUCTURE OF DSM-5

Beyond keeping pace with the science of psychiatry, many of DSM-5’s proposed changes represent an opportunity to improve the field from a clinical and public health perspective. This includes the new conceptualization of the neurodevelopmental disorders that has led to a proposed singular Autism Spectrum Disorder category that would include current DSM-IV autistic disorder (autism), Asperger’s disorder, childhood disintegrative disorder, and pervasive developmental disorder not otherwise specified. This decision emerged from data suggesting that these disorders share a pathophysiological substrate. The sharing of neurobiological features can clearly lead to new nosology of disorders, but it will happen in an iterative fashion affecting specific clusters of disorders, rather than the entire nomenclature. As the field continues to grow and the RDoC initiative provides increasing evidence for the pathological substrates that may ideally inform a diagnostic classification, the DSM-5 text template is geared to accommodate additional text that may be presented in future iterations of the “living” DSM.

CONCLUSIONS

It is important to emphasize that DSM-5 does not represent a radical departure from the past, nor does it represent a divergence from the long-term goals of the RDoC. As we gradually build on our knowledge of mental disorders, we begin bridging the gap between what lies behind us (presumed etiologies based on phenomenology) and what hopefully lies ahead (identifiable pathophysiological etiologies).

DISCLOSURES

Dr. David Kupfer serves as a consultant for the American Psychiatric Association (in his capacity as Chair of the American Psychiatric Association’s DSM-5 Task Force).

Dr. Schultz has received support from the National Institute of Health (MH086482, CA122934, AG024904, AG021488), Health Resources and Services Administration (HP19054), Agency for Healthcare Research and Quality (HS019355), the Nellie Ball Trust Fund Foundation, and the Alzheimer’s Disease Cooperative Study in partnership with Baxter Healthcare (NCT00818662). She has also received support from the American Psychiatric Association for editorial duties.

STEVEN E. HYMAN

The major diagnostic systems in psychiatry, the Diagnostic and Statistical Manual of Mental Disorders, 4th edition (American Psychiatric Association [APA], 1994) and the closely related International Classification of Diseases, 10th edition (World Health Organization, 1992), chapter on mental and behavioral disorders are currently undergoing revision. Both the general scientific press (Miller and Holden, 2010) and the lay press have focused a great deal of attention on these revisions because the resulting manuals will exert significant influence on the putative boundaries between health and mental illness, the treatments that patients will receive, reimbursement for services, determinations of disability, and even the sentencing of some individuals convicted of crimes. To the credit of the American Psychiatric Association, each subsequent recent edition of the DSM system has included a disclaimer in the front matter. For example, the current DSM-IV-TR (APA, 2000), states that the diagnostic criteria are “offered as guidelines” because “use of such criteria enhances agreement among clinicians and investigators.” The authors of the manual make no truth claims for the classification overall or for any disorder within it. Yet in practice it would be hard to imagine any caveat or disclaimer more widely ignored than this one.

Like any disease classification, the DSM is a cognitive structure imposed on scientific data to make it useful for clinical applications and research. Even the most scientifically useful theoretical frameworks or classification systems eventually outlive their beneficial role. Like Ptolemaic astronomy, a broadly accepted theoretical schema that has outlived its ability to explain emerging data can produce intellectual stagnation by excessively narrowing the focus and even the imagination of investigators (Kuhn, 1962). The DSM system is a central organizer of psychiatric research because it provides a shared language, and more than that, it delineates those specific disorders that can generally be studied within the mainstream psychiatric community. The profound influence of the DSM system grew directly from the success of applying the DSM-III (APA, 1980) to enhance comparability across studies, in marked contrast with the diagnostic free for all (Pope and Lipinski, 1978) that existed before its publication in 1980. Without comparability of subject populations in translational or clinical research, it is simply not possible to replicate results or falsify specific hypotheses with any rigor. The obverse of this benefit is that the DSM system came to dominate thinking about psychiatric disorders at a time when the relevant science was embryonic. Thus the DSM system enhanced the ability of researchers, clinicians, patients, and families to communicate with each other, but also

produced premature intellectual closure—despite the American Psychiatric Association’s disclaimer (Hyman, 2007, 2010).

The DSM-III remains—even with the impending publication of DSM-5—the fundamental current prototype for psychiatric disease classification and diagnosis. The DSM approach has been to delineate a large number of distinct diagnostic categories and to define them based on operationalized diagnostic criteria. Given the early state of psychiatric science, all of the current sets of criteria are perforce comprised of clinical descriptions (i.e., phenomenology). It would be possible to imagine that objective tests and biomarkers could be discovered for the existing categories, and their careful incorporation into current sets of criteria would ultimately lead to a modern descendent of the DSM-III. This chapter argues that in contrast to this hopeful view, much clinical and laboratory evidence suggests that there are fundamental structural problems with the DSM system and that the current diagnostic structure may be impeding progress (Hyman, 2007, 2010). For example, essentially all disease-focused grant applications, if they are to be awarded, must select patient populations based on DSM criteria. Similarly, manuscripts submitted for publication must also categorize patients according to the DSM system. Patients entered in clinical trials almost invariably must meet criteria for specific DSM disorders. Indeed, with respect to development of new treatments, DSM-based diagnoses, which are taken to represent the psychiatric community’s consensus, strongly influence regulators. Thus, for example, the US Food and Drug Administration takes the DSM system into account in deciding what constellation of symptoms represents a valid indication in psychiatry. Deviations from DSM nomenclature may require special efforts before development of a new drug treatment commences (Buchanan et al., 2005). In addition, psychiatry residents and clinical psychology interns often find themselves memorizing the most recent version of the DSM for certification examinations. It is no wonder that, despite the American Psychiatric Association’s disclaimers, the lay press often describes the DSM as psychiatry’s bible.

DSM-III ANTEDATED IMPORTANT DEVELOPMENTS IN THE LIFE SCIENCES

Even today we do not understand the etiology or pathophysiology of depression, bipolar disorder, schizophrenia, autism, or any other major disorder under the purview of psychiatry. There are still no objective medical tests that are sensitive or specific enough to use for diagnoses, and there are no validated

biomarkers for monitoring treatment. Despite this seemingly dismal picture, which contrasts with significant progress in many other areas of medicine, there is good reason to believe that the science of psychiatry is maturing in ways that will prove highly fruitful. The section that follows, illustrating the potential of newer technological and scientific approaches to psychiatric research is not meant to understate the challenges that remain, but to provide examples of major developments in science relevant to psychiatric disorders, and to underscore that all of these emerged in the decades *after* the publication of DSM-III (APA, 1980).

Much has happened in the life sciences since the gestation of descriptive psychiatry in the 1960s and 1970s and its apotheosis with the publication of DSM-III (APA, 1980) in 1980. Molecular biology, perhaps the dominant force in modern biology and medicine only emerged in the mid-1980s following a moratorium on recombinant DNA technology that ended in 1975 (Wade, 1975). Important discoveries about the nervous system date back to the nineteenth century, but modern neuroscience as an interdisciplinary field is relatively new. The first department of Neuroscience was only founded in 1970, and the field only began to involve clinical disciplines effectively in the ensuing decades. One recent subfield emerging from within neuroscience that is highly relevant to the goals of psychiatry is called “connectomics.” This field represents an attempt to provide full descriptions of the brain “wiring diagrams” of both model organisms and humans based on detailed mapping of cells, synapses, and circuits. Beyond a static map, connectomics is also attempting to overlay a dynamic picture of the functional connectivity of the human brain. Because neural circuit function directly underlies thought, emotion, and behavior, in short, the substrate of psychiatric symptoms, the data and understandings that emerge will be critical to understanding psychopathology and ultimately disease classification. Connectomics has become a feasible goal for neuroscientists because of advances in such technologies as microscopy, neuroimaging, computation, and new technologies that utilize molecular tools to study specific neural circuits and their relationship to behavior (Fenno et al., 2011). Noninvasive neuroimaging is giving us important structural and functional views of the human brain. Structural magnetic resonance imaging (MRI) permits the detailed characterization of diverse neural structures; for example, measurements of cerebral cortical thickness or hippocampal volume. Diffusion tensor imaging (DTI) permits the accurate tracing of white matter tracts in the brain. Functional MRI (fMRI) and various modalities of positron emission tomography (PET) make it possible to observe the activation of brain circuits in response to specific tasks and to observe patterns of brain connectivity at rest. PET also permits the labeling and visualization of specific proteins, such as neurotransmitter receptors. To give some historical context, the first published papers using fMRI, now a major contributor to psychiatric neuroscience, only appeared in the mid-1990s.

Genetics is also an important approach to understanding the etiology of mental disorders given that many disorders are highly heritable. Using still-developing technologies motivated by the human genome project (Shendure and Ji, 2008), it has been possible only since 2007 to make significant progress in

discovering specific genetic risk factors involved in the pathogenesis of autism (Neale et al., 2012) schizophrenia (Lee et al., 2012), and bipolar disorder. Also in 2007, induced pluripotent cell technology was developed that has made it possible to transform fibroblasts obtained from small skin biopsies of psychiatric patients and healthy comparison subjects into human neurons that can be studied *in vitro* (Takahashi et al., 2007). This technology is already permitting molecular and cellular investigations into the pathogenesis of psychiatric disorders. The intellectual roots of the DSM system lay in the descriptive psychiatry of the 1960s and 1970s (Robins and Guze, 1970), which in turn dates back to the pioneering nineteenth century work of Kraepelin (1899/1991). Descriptive psychiatry was a critically important intellectual movement that helped free the field from the dominant psychoanalytic approaches of the mid-twentieth century that had little place for biology. It should not be surprising, however, that the institutionalization of descriptive psychiatry mediated by the DSM system has provided a poor lens through which to view modern science.

DESCRIPTIVE PSYCHIATRY

Scientifically mature diagnostic systems are generally based on pathophysiology or etiology rather than clinical description in recognition of the fact that multiple factors related to disease processes, patient adaptations, and environmental context may influence the nature and severity of symptoms, functional impairments, and disability. Beginning in the 1950s, new pharmacological treatments had emerged, including antipsychotic drugs, antidepressants, lithium, and benzodiazepines, creating a significant need for a diagnostic system that would permit the selection of homogeneous groups of patients for clinical trials and facilitate the appropriate matching of patients with treatments. One important hurdle was diagnostic reliability, the ability of different observers to reach the same diagnosis for a given patient. Absent understandings of pathophysiology, lacking empirical knowledge of etiology, and even without objective medical tests, careful clinical description would prove to be the best approach available to psychiatry in the mid-twentieth century. In 1970 Robins and Guze (1970) two investigators at Washington University, argued that it would be possible to achieve reliable and valid psychiatric diagnoses based on clinical description, laboratory studies, exclusion of other disorders, follow-up observations, and family studies. They and their colleagues were inspired by the careful phenomenology of Emil Kraepelin (1899/1991), who had argued that psychiatry could identify specific disorders based on careful description of symptoms, signs, and course of illness. Kraepelin used such methods to distinguish what he called dementia praecox (schizophrenia) from manic-depressive illness (bipolar disorder) in the nineteenth century. Following the lead of Robins and Guze, the St. Louis school produced two sets of diagnostic criteria, the Research Diagnostic Criteria (RDC) and the Feighner criteria (Feighner et al., 1972; Spitzer et al., 1975), which were direct forerunners of the DSM-III (APA, 1980). To enhance inter-rater reliability these diagnostic systems employed operationalized criteria (i.e., criteria that specified

well defined clinical observations). Validation (i.e., providing evidence that a diagnosis identified a verifiable entity in nature) represented an insurmountable problem given the state of the science in the 1970s. Robins and Guze (1970) argued that validity of diagnoses could be established using multiple forms of evidence, such as the stability of a person's diagnosis over the life course, and the transmission of a disorder within families (Robins and Guze, 1970). As will be seen, however, familial transmission would not prove to be a validator as Robins and Guze had hoped: Disorders defined by purely phenomenological criteria do not breed true (Lichtenstein et al., 2009).

One of the original validating criteria listed by Robins and Guze (1970) was delineation of disorders from each other. Across the RDC, Feighner criteria, and the DSM system, psychiatric disorders are conceptualized as bounded categories that are qualitatively different from each other and from health. All of these diagnostic systems treat psychiatric disorders as discontinuous categories in analogy with infectious diseases such as pneumococcal pneumonia or tuberculosis. The mid-century descriptive psychiatrists eschewed an alternative conceptual schema that has turned out to be more consistent with the accumulated data, which would describe psychiatric disorders in terms of quantitative dimensions that are continuous with normal in analogy with hypertension or diabetes mellitus. In dimensional diagnoses, thresholds for illness are determined empirically based on studies of impairment, disability, or longer-term health outcomes (such as risk of stroke given current blood pressure). Evidence that dimensional approaches better capture psychopathology than categories include the inability to discover discontinuities in the distribution of symptoms from healthy to ill people (e.g., in depression; Lichtenstein et al., 2009) and epidemiological studies that find normal distributions of symptoms in the population (e.g., for attention deficit hyperactivity disorder, autism [Kendler and Gardner, 1998], and schizophrenia) with illness representing extremes of the distribution on multiple dimensions.

An important goal of the early Washington University diagnostic systems (Feighner et al., 1972; Spitzer et al., 1975) and the DSM-III (APA, 1980) was to identify homogeneous populations for research and treatment. The DSM-III attempted to achieve this goal by subdividing psychopathology into a large number of narrowly defined categorical diagnoses. This approach goes to the heart of the deep structural problems of the DSM system: It is based on narrow, highly specified (and therefore, it was thought, reliable), discontinuous categories. Far from producing homogeneity, the DSM approach has resulted in a highly infelicitous combination of overlapping categories that are yet, internally heterogeneous. By slicing psychopathology into many narrow silos, the DSM manuals have produced a situation in which a large number of patients receive more than one diagnosis (so-called co-occurrence or comorbidity.). For example, an individual who receives a single DSM-IV diagnosis often meets criteria for multiple additional disorders, and the pattern of often changes over the lifespan (Kessler et al., 1996, 2005). Thus, for example, children and adolescents with one (and often more than one anxiety disorder diagnosis) may receive a diagnosis of major depression in their teens or twenties. Individuals with autism spectrum disorders have high rates of attention

deficit hyperactivity disorder, obsessive-compulsive disorder, and others (Lichtenstein et al., 2010). Of course, disorders could co-occur at random based on their prevalence or, co-occurrence at a higher rate than predicted by prevalence alone could signify that one disorder is a risk factor for another, just as diabetes mellitus is a risk factor for peripheral vascular disease. Within the DSM system, however, many diagnoses co-occur at frequencies far higher than predicted by their population prevalence, and both emerging understandings of pathogenesis (Kendler et al., 2011; Krueger and Markon, 2006; Krueger and South, 2009) and temporal relationships (Kessler et al., 2005) make it unlikely that one disorder is a risk factor for later onset disorders. The most parsimonious explanation for the plague of comorbidity is that it is largely an artifact of the DSM system, resulting from its having divided shared pathological processes into excessively narrow slices (Krueger and Markon, 2006; Krueger and South, 2009).

The excessively narrow diagnostic silos of the DSM system (which produce comorbidity) do not, unfortunately, generate homogeneity within each category. Thus, for example, well-diagnosed schizophrenia does not "breed true"; instead, single families may exhibit schizophrenia schizoaffective disorder, bipolar disorder, and unipolar mood disorders (Craddock et al., 2006; Lichtenstein et al., 2009) even when the etiology of psychopathology appears to rest largely in a single large chromosomal rearrangement (Millar et al., 2000).

Even though, as early as 1967, Gottesman and Shields (1967) recognized that schizophrenia might be polygenic, the Washington University School and the authors of the DSM-III (APA, 1980) understandably did not take this complicating view into account. Had they done so in a sophisticated manner they might have given greater credence to dimensional constructions and might have created a system more tolerant of heterogeneity. What has emerged from family and genetic studies in recent years is that autism (Neale et al., 2012; Sullivan et al., 2012), schizophrenia (Gejman et al., 2011; Lee et al., 2012; Sullivan et al., 2012), bipolar disorder, and indeed all common psychiatric disorders that have been examined (Sullivan et al., 2012), are polygenic. Large numbers of genes contribute to risk of mental disorders in different combinations in different families, where they produce disease phenotypes in combination with stochastic, epigenetic, and environmental factors. In some families genetic risk for mental disorders seems to be caused by many, perhaps hundreds of small variations in DNA sequence (often single nucleotide bases), each causing a very small increment in risk. In other families a copy number variation (CNV), whether a duplication, deletion, or rearrangement of DNA sequence, may play a large role, but still acts against a background of polygenic risk. In some individuals with sporadic autism, rare mutations may occur *de novo*. In others, rare mutations are inherited. In sum, no gene is either necessary or sufficient for risk of a common mental disorder, and genes may produce different symptoms depending on broad genetic background, early developmental influences, life stage, or diverse environmental factors. The DSM myth of narrow homogeneous diagnostic categories seems ready for burial once we recognize the full implications of polygenicity and the variable penetrance and expressivity of many risk genes (Cross-Disorder Group, 2013). Rather than

tightly constrained disorder categories, it might be better, for the near term, to rely on broader clinical diagnoses that likely capture etiologically heterogeneous conditions but that might share essential features of pathophysiology and thus produce related (but not identical) symptoms and course.

The DSM-III was based of necessity on clinical phenomenology, and had many important strengths that must be kept in historical context. What went most wrong with the DSM-III were fairly arbitrary decisions to conceptualize psychopathology as discontinuous categories, as if they were infectious diseases, and then to promulgate a very large number of them. A short-term alternative to the use of individual DSM disorders might be the use of disorder clusters that will be embedded in the organization of the DSM-5 (Hyman, 2010), whereas longer term improvements will require substantially new thinking (e.g., National Institutes of Mental Health, Research Domain Criteria). In the meantime, students who use this textbook should recognize that DSM categories are heuristics based on half-century-old science, and are not to be reified, but rather used pragmatically until better approximations of nature arrive.

EPILOGUE: CLASSIFICATION ACCORDING TO BORGES

These ambiguities, redundancies, and deficiencies recall those attributed by Dr. Franz Kuhn to a certain Chinese encyclopedia called the *Heavenly Emporium of Benevolent Knowledge*. In its distant pages it is written that animals are divided into (a) those that belong to the emperor; (b) embalmed ones; (c) those that are trained; (d) suckling pigs; (e) mermaids; (f) fabulous ones; (g) stray dogs; (h) those that are included in this classification; (i) those that tremble as if they were mad; (j) innumerable ones; (k) those drawn with a very fine camel's-hair brush; (l) etcetera; (m) those that have just broken the flower vase; (n) those that at a distance resemble flies.

"John Wilkins' Analytical Language", translator Eliot Weinberger; included in *Selected Non-Fictions: Jorge Luis Borges*, ed. Eliot Weinberger; 1999, New York: Penguin Books, p. 231. The essay was originally published as "El idioma analítico de John Wilkins," *La Nación*, February 8, 1942.

DISCLOSURE

Dr. Steven Hyman serves on the Novartis Science Board and has advised AstraZeneca within the last year. Both advisory roles focus on early stage drug discovery. His research is funded by the Stanley Foundation.

83 | TOWARD PRECISION MEDICINE IN PSYCHIATRY: THE NIMH RESEARCH DOMAIN CRITERIA PROJECT

BRUCE N. CUTHBERT AND THOMAS R. INSEL

Three events transpired between August 2011 and January 2012 that heralded the future of medicine over the next several decades. In August 2011, the FDA issued the first formal approval of a new drug whose use was contingent upon an authorized companion diagnosis: Vemurafenib (trade name Zelboraf) was shown to be effective in extending survival time for late-stage melanoma patients with the BRAF V600E mutation (FDA, 2011). In January 2012, the FDA issued an approval for ivacaftor (trade name Kalydeco), the first non-cancer compound requiring a companion diagnosis. This agent is highly effective in managing cystic fibrosis for the small minority of patients (approximately 4%) who have the G551D mutation of the cystic fibrosis transmembrane regulator gene (FDA, 2012).

These two events bracketed the release in November 2011 of a major report by the Institute of Medicine (IOM) entitled, *Toward Precision Medicine: Building a Knowledge Network for Biomedical Research and a New Taxonomy of Disease* (Committee on a Framework for Developing a New Taxonomy of Disease, 2011; henceforth referred to as the IOM Committee). This report comprised a major proposal for the development of an Information Commons that can incorporate multiple sets of data (genomics, microbiomics, symptoms, environmental influences) to characterize focal groups of patients. Essentially, the report lays out the roadmap for a network of information that could provide an entirely new structure for the integration of research and personalized health care in the United States. Precision medicine is officially, and indubitably, here.

The ability to identify small groups of patients who can benefit from targeted treatments is necessarily built upon two major factors. First, diagnostic tests are required to identify relevant genetic polymorphisms, biomarkers, and other specific aspects of disorders. Second, new interventions must be developed that are targeted directly to the disease mechanisms identified by the diagnostics. Although companion diagnostics—required tests whose use is mandated in tandem with the new therapeutic—may not always be formally necessary, they represent the epitome of the new approach.

Precision medicine thus far is heavily represented by cancer biology, which is well suited for the identification of genetically related abnormalities that directly mediate the disease process. It is not coincidental that two of the first three therapy/companion diagnostic approvals were issued for particular indications in cancer. In other areas of medicine, disease risk is

often characterized by multiple genes of small effect, and by substantially greater environmental risk factors. Mental disorders clearly fall in this latter category. Even within this group, however, psychiatry has almost no track record so far, even though research on genetics and neural circuits in the central nervous system has accelerated dramatically over the past two decades.

Comparisons with other comparable disorders illustrate this point. Mortality from heart disease in 2007 was only one-fourth the number projected a decade earlier; 1.1 million fewer deaths occurred in 2007 alone than predictions based on earlier trends (National Heart, Lung, and Blood Institute, 2011). In another area of medicine, a recent report indicated that current survival rates for children with acute lymphoblastic leukemia are greater than 90%, compared with a rate of less than 10% in the 1960s (Hunger et al., 2012). The comparable figures for mental illness present a stark contrast. Prevalence rates for common mental disorders have not declined to any degree over the last several years (Kessler et al., 2005). Diagnosis is typically not made until well after the generally accepted time that symptoms and impairment begin. Mortality resulting from suicide, side effects of medications, and medical comorbidities have not decreased. Very few preventive interventions are available. Finally, and most telling, there are virtually no biomarkers or genetic tests that can help point the way toward the kinds of targeted treatments that precision medicine entails.

There are many, varied reasons for this situation. The brain is easily the most difficult organ in the body to access directly for direct examination or tissue samples. The blood-brain barrier frustrates attempts to introduce many new compounds, and only recently have positron emission tomography scans become available to help indicate whether new chemical entities have reached their intended targets. In another domain, the hopelessness and isolation of mental illness discourage people from seeking treatment quickly or accepting the utility of screening and indicated prevention.

In addition to these difficulties, it has been increasingly clear that standard diagnostic systems in psychiatry—for all their advantages in enhancing reliability in an age when the field retreated from the sway of psychodynamic theory—represent a liability at this point in time regarding the urgent need to link diagnostics with cutting-edge brain science in psychiatric research. This chapter describes a new experimental classification system for research developed by the National

Institute of Mental Health (NIMH) that is intended to inform new versions of nosologies that foster precision medicine for psychiatry. The basic rationale for this initiative can be stated as follows: Psychiatry will never have an empirically derived classification system for precision medicine that is based upon neuroscience until a suitable database is available to inform its development; and obviously, such a database will never become available until research is funded that can generate the relevant literature.

The following sections review the development and organization of this initiative, termed the Research Domain Criteria (RDoC) project, with a particular emphasis upon some of the conceptual foundations and the ways that RDoC could apply to current research issues. Although the latter are illustrated with examples drawn particularly from mood/anxiety disorders and psychotic spectrum disorders, the principles pertain to all areas of mental disorders and mental health.

ORIGINS OF THE RDoC PROJECT

The need to consider an experimental system for classification arose during discussions held in 2007–2008 as the Institute considered topics for its then-new strategic plan. Investigators had noted issues in using the DSM (Diagnostic and Statistical Manual for Mental Disorders; American Psychiatric Association, 2000) in research for some time; these include, for example, comorbidity rates well above chance, heterogeneity, and an inconsistent scientific treatment (e.g., Clark et al., 1995). However, another set of problems emerged with the rise of sophisticated new technologies for studying the neurobiology of disorders. Increasingly, genetics and neuroimaging data failed to map onto standard diagnostic categories, frustrating attempts to develop cohesive theories of etiology or biomarkers (e.g., Hyman, 2007). Thus, although the DSM retained its familiar advantages in clinical utility, the diagnostic system was impeding progress toward research on neuroscience-based conceptions of etiology and pathophysiology.

Such problems were readily apparent to the organizers of the DSM-5 (née DSM-V) revision process. The first volume in an extensive series of reports from the research planning conferences for DSM-5 contained a thoughtful review of the issues for neuroscience-based classification (Charney et al., 2002). The participants were keenly aware of the problems, as well as potential solutions:

...there has been too strong a reliance on the DSM-defined symptom clusters and too little on biologically based symptoms that may cut across the DSM-IV-defined disorders. This over-reification of the DSM categories has led to a form of closed-mindedness on the part of researchers and funding sources. For example, researchers involved in new drug development tend to focus their efforts on treatment of DSM-IV-defined categories, despite widespread evidence that pharmacologic treatments tend to be effective in treating a relatively wide range of DSM

disorders. Furthermore, the erroneous notion that the DSM categories can double as phenotypes may be partly responsible for the lack of success in discovering robust genetic markers. Although a move to an etiologically and pathophysiologically based diagnostic system for psychiatry will be extraordinarily difficult, it is nevertheless essential, based on the increasing belief that many, and perhaps most, of the current symptom clusters of DSM will ultimately not map onto distinct disease states. (p. 34)

It should be emphasized that the DSM has become the standard for regulatory approval of new treatments from the Food and Drug Administration, for pathophysiology research conducted with a view to its eventual translation to new drug targets, and thus for research grant applications and editorial guidelines for publishing. Given the centrality of the DSM throughout the entire mental health system of practice and research, dramatic changes are simply not possible until a clear alternative is evident (see Kupfer and Regier, 2011, for a thoughtful discussion of this point). These facts influenced the NIMH in considering an effort that could provide the data that would be needed for future, neuroscience-based revisions.

Another factor contributing to the momentum for a new initiative was the emergent trend in the literature favoring dimensional approaches both in terms of translational research from non-clinical samples (e.g., Clark, 2005) and from psychopathology, with one of the volumes from the DSM-5 conference series exclusively devoted to dimensional approaches (Helzer et al., 2008). Thus, the NIMH included in its strategic plan Strategy 1.4, to “Develop, for research purposes, new ways of classifying mental disorders based on dimensions of observable behavior and neurobiological measures.” (See Table 83.1 for a listing of this aim and the accompanying four-point implementation plan.)

TABLE 83.1. NIMH strategic aim 1.4

<p>Strategy 1.4: Develop, for research purposes, new ways of classifying mental disorders based on dimensions of observable behavior and neurobiological measures.</p>
<ul style="list-style-type: none"> • Initiate a process for bringing together experts in clinical and basic sciences to jointly identify the fundamental behavioral components that may span multiple disorders (e.g., executive functioning, affect regulation, person perception) and that are more amenable to neuroscience approaches.
<ul style="list-style-type: none"> • Determine the full range of variation, from normal to abnormal, among the fundamental components to improve understanding of what is typical versus pathological.
<ul style="list-style-type: none"> • Integrate the fundamental genetic, neurobiological, behavioral, environmental, and experiential components that comprise these mental disorders.
<ul style="list-style-type: none"> • Develop reliable and valid measures of these fundamental components of mental disorders for use in basic studies and more clinical settings.

RDoC ORGANIZATION AND PROCESS

A workgroup of NIMH staff, supplemented subsequently with a small group of external experts, started the implementation process for Strategy 1.4 in early 2009 and completed an organizational framework and process by March.¹ In July 2009 a meeting was convened that included representatives of the ICD and DSM revision efforts, NIMH staff, and external scientists presenting data that illustrated RDoC goals. The meeting, chaired by former NIMH Director Dr. Steven Hyman, facilitated a discussion that served to highlight the respective areas of emphasis among the three projects, and to prompt an ongoing series of collegial meetings among members of the three agencies that has contributed in multiple ways to efforts both for research purposes and for the clinical utility of classification.

The NIMH workgroup crafted the scientific framework for the new scheme on the basis of multiple areas of research. Five major domains (i.e., the Research Domain Criteria) were designated on the basis of both basic science and clinical research into structural models of disorders: Negative Valence Systems (i.e., those for processing aversive situations), Positive Valence Systems, Cognitive Systems, Systems for Social Processes, and Arousal/Modulatory Systems. The specific dimensions were then nested within each of these domains. As discussed in the following, the dimensions that appear in RDoC are formally denoted as constructs. This follows the traditional definition of the term construct in psychology and similar disciplines, indicating its status as a hypothetical entity that is not necessarily observable and not formally computable, but which serves to organize a set of data that accord with its putative function (Cronbach and Meehl, 1955).

To create a visual framework, the domains and their subordinate constructs were placed in the rows of a two-dimensional matrix. The columns of the matrix contained the various “components” (see the third bullet of Table 83.1) that were to be used to measure the various dimensions, and were termed units of analysis.

Three other important, integral parts of the overall RDoC organization could not be represented in the two-dimensional matrix. One very salient aspect concerns developmental processes, seen as critical for multiple reasons. First, events that occur during childhood affect the trajectories of subsequent development throughout the lifespan. Second, the area of childhood nosology has been particularly fraught with confusion and controversy, because of such factors as the difficulty of assessing behavioral and biological variables and the uncertainty as to whether adult-onset disorders can simply be scaled down to childhood. Third, mental illness is increasingly viewed as a set of neurodevelopmental disorders, with its origins partially stemming from epigenetic programs laid down as a result of such early life effects as maternal diet, maternal stress, and exposure to various infectious agents and toxins (Bale et al., 2010). The exploration of all these effects is best

orchestrated by an approach such as RDoC that considers their sequelae in terms of neural circuit development and its associated behavioral activity, given that the most likely outcomes are best represented as dimensions of change in particular areas of functioning.

Environmental influences are a second topic area that could also be represented as another dimension in the matrix. Taken together, development and environmental influences represent one of the most important potential foci of the RDoC effort. Too often, using an infectious-disease model, patients are simply evaluated in terms of their presenting phenomenology so as to provide a diagnosis. Knowledge of past developmental history is sure to be an important step for precision medicine diagnostics.

Third, communicating the dimensionality of a construct (“determine the full range of variation”) is difficult in the two-dimensional matrix structure. For symptoms, of course, this would represent severity. One of the important goals that the continuous-dimension framework fosters is the search for nonlinearities, in which sudden change (particularly in symptoms) may result from a relatively small increment in other systems such as behavior or circuit activity—particularly important as the thresholds for diagnosis in the familiar binary, “disease absent/present” format of the DSM and ICD were determined by clinical judgment rather than quantitative modeling. In sum, it would thus require at least a five-dimensional matrix to represent all the aspects that are important for the overall RDoC scheme.

The RDoC project utilized a series of consensus scientific workshops in which experienced scientists met to decide upon a list of constructs for which sufficient evidence existed. Five major workshops were convened, one for each of the five domains (preceded by a “test run” meeting with a single construct, Working Memory, in July 2010). The workshops were planned on an accelerated timetable to hasten the availability of the entire system, with one workshop scheduled every four months between March 2011 and June 2012.

The workshop process was modeled after the NIMH-sponsored CNTRICS initiative (Cognitive Neuroscience for Translational Research in Cognition in Schizophrenia; Barch et al., 2009), which has been successful in generating constructs in cognition that are relevant to schizophrenia (and in fact, formed most constructs of the Cognitive Processes domain).² The reader is referred to other RDoC papers for details on the workshop process (e.g., Sanislow et al., 2010). Briefly, participants were charged with producing three products: (1) a listing of constructs for the domain; (2) definitions for each construct; and (3) a set of empirically based elements for each construct at each of the several units of analysis. Participants were instructed that new or altered constructs had to meet the same two criteria that the workgroup used in compiling its draft list: (1) there had to be strong evidence for the validity of the suggested construct as a functional entity (see the following); (2) there had to be strong evidence that the suggested construct maps onto a specific biological system, such as a brain or hormonal circuit.

1. The members of the NIMH RDoC workgroup are Bruce Cuthbert (chair), Marjorie Garvey, Robert Heinssen, Michael Kozak, Sarah Morris, Kevin Quinn, Daniel Pine, Rebecca Steiner, Janine Simmons, Rebecca Steiner, and Philip Wang. External consultants are: Deanna Barch, Michael First, and Will Carpenter.

2. Grateful thanks are expressed to Drs. Deanna Barch and Cameron Carter for their time and expertise in consulting about the CNTRICS model and the format of the first RDoC conference.

Figure 83.1 Research domain criteria matrix. The left-hand column shows constructs nested with in domains; the remaining columns show the units of analysis and paradigms.

These twin criteria were one aspect of the workgroup’s goal of constructing an integrative approach to the characterization of the various dimensional constructs. Proceedings of the workshops were drafted by members of the RDoC working group with input from the moderators of the breakout groups, and vetted by the workshop participants before being posted on the RDoC website (<http://www.nimh.nih.gov/research-funding/rdoc/index.shtml>). See Figure 83.1 for a listing of the matrix as of July, 2012 (following the final workshop).

DISTINGUISHING FEATURES OF THE RDoC APPROACH

The basic features of the RDoC initiative are summarized here see Morris and Cuthbert, 2012; Sanislow et al., 2010, for additional details. These points have guided the RDoC project since its inception, and serve to distinguish the RDoC approach from other current nosologies:

1. RDoC takes a strongly translational perspective to mental illness, in which symptoms and disorders are viewed in terms of basic functions (e.g., fear, working memory) and the mechanisms by which their operations become dysregulated in such a way as to eventuate in psychopathology. A keystone of this approach is that these functional dimensions have been found to be implicated in many different disorder categories as currently defined, so

that conducting research on the functions themselves, as they cut across multiple disorders (and often in interaction with other dimensions), is the optimal way to analyze how their operations become abnormal.

2. The RDoC approach to psychopathology is strongly dimensional, not only within the range of psychopathology but in the entire range of functioning that runs the gamut from “normal” to extreme pathology.
3. Related to the prior point, one of the goals of RDoC is to support the developmental of appropriate scales and tasks that can provide valid measurement of the entire range for each construct.
4. To foster research designs that address key questions of interest, investigators are free to use measures from any of the units of analysis as the independent variable (IV) in the design (e.g., circuit activation, cognitive performance, targeted symptoms) and dependent variables (DV) from other units of analysis. To put it another way, circuit activation could be an IV in one study and a DV in another, depending on the study aims. This necessitates a two-stage strategy for ascertaining subjects. The first stage is to determine the “sampling frame” for the study; that is, that set of individuals who will comprise the study sample and whose data will generate a reasonable amount of variance regarding the study question. For instance, a specialized facility might not generate sufficient range to

address questions about relationships of genetic variance to different kinds of task deficits, so a clinic seeing a broader range of patients might be more appropriate for this aim. The second stage of the study is then to determine the values of the independent variable(s) through whatever measurement is necessary. In some situations, the value of the independent variable may not be determined until after the subject has been run (e.g., for neuroimaging studies that require extensive data processing).

5. The RDoC model is intended to be integrative across the various units of analysis. Behavioral or cognitive functioning, and the activity of neural circuits and their component elements, are all considered important in characterizing a construct.
6. Particularly at the outset, the project will concentrate on circuits that have strong evidence for their validity and appear especially promising for clinical research. This approach was taken deliberately to gain experience with the overall system and provide a solid platform for future additions. There is no claim at this point to cover the entire range of symptoms or pathology included in the DSM or the ICD.
7. As an experimental classification project, RDoC is committed to incorporating updates on a regular basis. At the same time, it is recognized that overly facile change can prompt instability in the system and confusion among investigators. The RDoC workgroup is developing a process for evaluating proposed changes to the matrix (which will involve criteria similar to those employed originally) so as to foster the continued growth of the literature in this area.

RDoC: CONCEPTUAL STRUCTURE

As a “clean sheet of paper” design, RDoC is unique in many aspects. Accordingly, the considerations and assumptions that went into the overall scheme must be discussed before turning to an examination of how the system will actually work in practice and the kinds of classification issues that might be addressed. The constructs in RDoC are the heart of the system, representing the functional dimensions that are to be explicated, so some elaboration of the way these are treated is necessary.

CONSTRUCTS

In many areas of medicine, symptoms as such are not impairing (lumps under the skin, high blood pressure levels, elevated cholesterol levels), and serve to call attention to palpable (if occult) underlying pathological processes. The DSM generally follows this medical model. Because any combination of X out of Y possible symptoms (e.g., five out of nine for major depressive episode) can define a disorder, any given symptom per se is not seen as critical in and of itself, but merely as a marker of the underlying disorder (granted that impairment is often part of the overall disorder definition). However, the realization

that relatively specific behaviors, cognitive operations, and affective processes are primarily implemented by particular neural circuits suggests a very different view of symptoms. The impairment/disability represented by symptoms and associated dysfunction in relevant neural circuitry are in fact the primary and proper focus of study—the things that ought to be the targets of assessment and treatment—rather than being simply markers. It is for this reason that Strategy 1.4 refers to “dimensions of observable behavior.” Such a view is in fact the norm in treatment settings, in that practicing clinicians emphasize treatment of particular symptoms rather than disorders. To restate this critical point, a strong implication of precision medicine for mental disorders is to diagnose and treat specific dysregulated functions that are implemented by particular neural circuits (along with their constituent genes, molecules, and cells), rather than broad syndromes. From this perspective, accordingly, it now becomes a high priority to determine precisely what the functions *are*, and what forms their dysfunction may take.

The precise construal and definition of fundamental dimensions of behavior—and brain-behavior relationships—remains a complex issue, starting with common sense and face validity but heavily dependent upon continual revision and refinement through ongoing empirical studies. For instance, the classic conception by Olds and Milner of a “brain reward system” on the basis of self-stimulation studies (1954) was superseded by a more differentiated and anatomically detailed account that accommodated both the consummatory aspects of pleasure and other brain circuits that implement reward-seeking activity (Berridge, 1995); and subsequently by yet more refined parsing of reward-related processes (Treadway and Zald, 2011). Accordingly, the use of the term construct to denote the primary dimensions in RDoC follows the usual denotation of this term in psychology and areas of biomedical science; that is, a hypothetical entity that is inferred on the basis of a set of measurements that converge on its putative characteristics but do not much overlap with characteristics of other potential functions (Cronbach and Meehl, 1955; MacCorquodale and Meehl, 1948).

The term construct validity was first introduced in the late 1940s and early 1950s to establish standards and procedures for psychological testing, and the principles have been extended to other forms of measurement (e.g., neurophysiological measures). In the current context, constructs are further denoted as functional to indicate their significance to the goals, behaviors, and mental operations of the individual. Although characterizing any particular function may seem to be simply a matter of common sense, it is worth recalling that archaic psychodynamic concepts such as id and superego were once regarded as perfectly acceptable constructs. Thus, it is necessary to consider what the criteria might be for deciding that a construct could be posited, and what its function would comprise. Miller and Kozak (1993), in one of the few systematic analyses of functional constructs in emotional states, relate the question to other areas of science: “... this problem of criteria for judging a proposed function may be approached the way one evaluates any theoretical proposal once made. Does it fit the available data? Does the fit survive various means

of convergent validation of the construct?” (p. 41). In other words, various measures that putatively seem to index the hypothesized function should correlate with each other, what Cronbach and Meehl (1955) referred to as the nomological net. These provisions may seem somewhat arcane, but are outlined here because they are directly relevant to the development of the RDoC matrix. One of the two major criteria for including any potential construct in the RDoC matrix held that there must be an adequate body of empirical research validating the construct as a functional entity. As implied by the reward system example in the preceding, the definition and measurement of constructs are subject to continual refinement (or, as for the id, retrenchment) as new data emerge.

“Grain size” for the constructs was a critical parameter that concerned the workgroup from the earliest meetings. As Goldilocks discovered, things needed to be not too big and not too small, but just right. Constructs that were overly large might be vague and ambiguous, and would likely subsume multiple circuits and behavioral functions, resulting in prohibitive theoretical and analytical complexity. Constructs that were overly narrow might suffer from insufficient relevance to clinical issues, have dubious ecological validity, represent undervalued circuits or functions, and render the system unwieldy as a practical classification tool (even for experimental use). Thus, for instance, fear behavior in animal models can include active avoidance and passive avoidance, which may be somewhat *recherché* to translate to the clinic. Similarly, a growing number of subcircuits in the amygdala are being elaborated, but it is not yet feasible to measure them in humans and the clinical significance awaits translation. Both these systems, although finding support in the literature, were not included as constructs.

A critical point concerns the initially privileged status of the constructs that emerged from the rigorous workshop and vetting process. Clearly, as an experimental system, a high priority is placed on the ability of RDoC to update the matrix frequently to reflect advancing science. Critics have already pointed out informally the danger that RDoC constructs could suffer the same fate as their DSM/ICD cousins in becoming reified and resistant to constructive change. More to the point, it is obvious that strong consideration for funding must be given to projects that present well-justified (and well-reviewed) proposals for new or altered constructs, else the system will not obtain the data needed for continual improvement of the matrix. The same point holds for research evaluating the various units of analysis.

What, then, is the status of the constructs and elements in the units of analysis in the current version of the matrix? These comprise areas that a large number of scientists have judged as being of particularly high priority for investigations that can revamp our understanding of mental disorders, and that appear most likely to provide traction in building the database for future nosologies; it is anticipated that a substantial proportion of pressing issues can be addressed with these constructs. A clinical researcher could select a construct (or multiple constructs) that match her or his area of interest and then construct the application using the extant constructs and units of analysis, with the assurance that this will be a priority area of

study. However, a researcher with a strong background in basic or translational research may well generate hypotheses that fall outside the current matrix. Both have the potential for equally strong contributions.

SYMPTOMS

It has been repeatedly pointed out that one weakness of current psychiatric nosologies is reliance upon presenting signs and symptoms (as opposed to clinical tests) to make a diagnosis (e.g., Hyman, 2010). However, in keeping with the different perspective on symptoms and constructs presented in the preceding, the RDoC workgroup maintained a strong emphasis upon symptoms in formulating the list of constructs to be initially nominated in the matrix. Obviously, symptoms are what prompt patients and families to seek out a clinical facility, and what they wish to see ameliorated by treatment. It is not so much the reliance upon symptoms as such, but the inability to connect them to any systematic bodies of neuroscience or behavioral science that poses a critical problem. A shared consensus among the workgroup members was that the DSM/ICD systems contain virtually all the significant symptoms that have been associated with mental disorders; the concern was thus not so much with the symptoms *per se*, but rather the ways in which they are clustered to create disorder definitions—with the familiar problems of heterogeneity, overspecification, and comorbidity (Hyman, 2010; Insel et al., 2010).

That said, a number of problems arise in adapting symptoms into the RDoC framework. A first issue is that the symptoms listed in the DSM vary widely in their specificity—another type of “grain size.” Thus, one of the criteria for major depressive episode is explicitly quantitative, that is, a gain or loss of weight of more than 5% of body weight in a month. With suitable baseline measurement, there is little uncertainty or subjective judgment about this specific criterion. On the other hand, “depressed mood” is a much broader and more vaguely defined entity that invites serious scientific scrutiny in and of itself. Exactly what is meant by “mood” in any sort of scientific sense, and how would it be measured? Experienced clinicians will typically have a “feel” for the clinical sense of this construct. However, operationalizing and quantifying a construct such as mood is much more challenging from an integrative perspective, and in fact “mood” *per se* is not included in the matrix. A similar point can be made for the second criterion of major depression (i.e., markedly diminished pleasure) and for many of the symptoms throughout the DSM.

A second and related difficulty in creating a translational framework for psychopathology is that many symptoms are conceived and couched in terms of everyday language constructs that do not have a demonstrated relationship to specific behavioral or neural systems as derived from empirical research. As discussed, the criteria were derived in an era when such a research literature was not available, so the DSM-III can hardly be criticized for the omission; however, the problems has become increasingly obvious as relevant data continue to accumulate three decades later. An example of this problem is given by the “diminished interest or pleasure” criterion for MDE. As has now been noted repeatedly, studies have shown

that reward-seeking, the experience of reward, and other processes with respect to appetitive functions can be dissociated on the basis of behavioral and neural systems studies (e.g., see the Positive Valence systems proceedings at the RDoC website: <http://www.nimh.nih.gov/research-funding/rdoc/index.shtml>). The realization that these functions are distinct to varying degrees has prompted an increasing number of experiments to explore their clinical ramifications and significance (e.g., Treadway and Zald, 2011).

The obvious implication of such considerations is that the nature of a “symptom” must be altered for the RDoC framework, from “a problem that the patient reports or exhibits with respect to traditional feeling-state notions of disorders” to “an abnormality of some degree that can be expressed quantitatively with respect to its deviation from the usual operation of the function(s) attributed to the construct.” In some cases, this may be quite close to a DSM symptom (sleep problems), and in others (low mood) not. In some cases, the nature of such an abnormality and its clinical significance will be quite salient. In others, it may be somewhat ambiguous in the early going as to exactly how particular circuit-based dysfunctions relate to an overall clinical picture. (For instance, some investigators have commented that psychosis “looks like a black box” in RDoC, an instance of an invigorating translational question; but see Gold, 2011, for a good example of how relating neural system activity and behavior to reported hedonic states can shed light on an important clinical problem in schizophrenia.) Another way of putting this is that the workgroup members envision a grain size for symptoms that unequivocally reflects clinical level dysfunction, but is sufficiently specific to bear a reasonably strong relationship to the relevant construct both in terms of its function and its neural circuitry. Thus, rather than “low mood,” the RDoC symptoms for a particular patient (i.e., in an individuated assessment) might be different combinations of, for example, approach motivation, reward learning, and working memory.

The RDoC workgroup members were mindful of clinical relevance in nominating constructs, and this task will represent one of the challenges facing the enterprise as RDoC moves forward. It may appear in this context that such a shift is unnecessary and needlessly confusing to clinical researchers, accustomed as they are to the current lists of symptoms. The rejoinder is that such change is imperative to fulfill the promise of RDoC; that is, to delineate more sharply the relevance of genetics, neural systems, and behavioral science to an understanding of patients’ psychopathology, and in particular, the individual differences in the operation of these systems that can accommodate assessment and intervention in a precision medicine environment. Thus, although it remains unclear as to how well these more empirically derived constructs will relate to the familiar symptoms in the DSM, the long-range goal is that clinicians and researchers alike will perceive the advantage of viewing disorders in terms of fundamental biobehavioral systems.

Yet a third problem involves the lack of tasks and scales to measure “the full range of variation” in dimensions of interest; that is, a range from one extreme to the other. Most scales of characteristics or performance in behavioral science

and psychiatry are designed either for normal range traits or clinical symptoms. The result is that either type of assessment lacks sensitivity at the other end. Such scales are now starting to appear with the growing interest in translational research for psychopathology. An excellent example is provided by a scale for the measurement of externalizing spectrum behavior developed by Krueger et al., 2007. These investigators used item-response theory modeling and diverse non-clinical and forensic samples to create an inventory that assesses externalizing behavior along a spectrum ranging from “normal” out to prisoners incarcerated for serious crimes. It is pertinent to quote the authors’ conclusions about this dimensional approach.

Comorbidity among mental disorders has been an impediment to progress because researchers are forced to make a number of confusing choices regarding fundamental issues in research design. For example, in work on the etiology of alcohol use and problems, should persons with antisocial features be included or excluded? The Externalizing Spectrum Model resolves these problems by reconceptualizing the targets for clinical inquiry in a manner derived directly from data on the empirical organization of externalizing phenotypes. (Krueger et al., 2007: p. 661)

Such research will gain increasing priority as the RDoC project advances.

RDoC AND CURRENT DISORDER SPECTRA MOOD AND ANXIETY DISORDERS

Marked progress has occurred in the science of anxiety disorders (e.g., Ressler and Mayberg, 2007) and mood disorders (e.g., Berton et al., 2012) over the past several years. In spite of this scientific progress, diagnostic and treatment approaches have not changed fundamentally. The essential structure defined by the DSM-III in 1980 remains static, and cognitive-behavioral therapies and drugs acting on monoaminergic systems remain the standard treatments. It has become increasingly clear that the current categorical system poses a variety of obstacles to developing more precise diagnoses and treatments for the anxiety disorders (e.g., Fyer and Brown, 2009) and mood disorders (e.g., Berton et al., 2012). A brief overview of these problems provides a basis for discussing an approach that might be taken from an RDoC perspective.

Extensive co-morbidity represents one of the most substantial problems in investigating the so-called internalizing disorders (Nemeroff, 2002). This is true at both conceptual and practical levels. At the practical level, analyzing co-morbidity in experimental designs is daunting. Although patterns of co-morbidity vary across disorders—e.g., GAD is often observed in conjunction with other diagnoses, but specific phobia much less—myriad combinations are observed. If one were to take the eight major adult anxiety disorders, it would require 246 distinct combinations to account for all possible co-morbidities among these disorders (ranging from two to

seven co-morbid conditions). With major depressive episode and dysthymia added to the mix, an investigator would need more than 1,000 categories to account for all potential co-morbidities.

The conceptual problems of co-morbidity are perhaps more knotty, suggesting fundamental mechanisms that are obscured by the lens of categories. The relationships among different internalizing disorders are not random. For more than a decade, structural analyses of disorder co-morbidity in epidemiological and other large samples have revealed two broad classes of so-called internalizing disorders, “fear” versus “distress” or “anxious-misery” (e.g., Krueger, 1999). Such studies have resulted in proposals for a re-alignment of the disorders to reflect this hierarchical arrangement (e.g., Watson, 2005). However, for the most part, the general acknowledgment of this structure has not led to widespread changes in how research grants are funded, or in journal articles, or therapeutic development.

A further complicating factor is the assumption that all patients with a given diagnosis have exactly the same disorder in terms of abnormal psychological or biological functioning. Thus, there are innumerable papers regarding “the” pathophysiology of posttraumatic stress disorder (PTSD), major depression, and so forth. However, as Fyer and Brown conclude regarding heterogeneity in anxiety disorders:

...categorizing [the anxiety disorder categories] by genetic data creates one set of groupings; using age at onset creates a second set; and latent-class analysis creates a third. There is also considerable within-disorder heterogeneity. These observations suggest that the DSM anxiety categories do not map neatly onto simple, consistent, and distinct etiological pathways. (2009: p. 132)

For example, a recent review of neuroimaging data during symptom provocation in PTSD reported two distinct patterns of response. One pattern was the anticipated hyperarousal but the other was a blunted response that the authors interpreted as dissociative, leading the authors to conclude that “grouping all PTSD subjects, regardless of their different symptom patterns, in the same diagnostic category may interfere with our understanding of posttrauma psychopathology” (Lanius et al., 2006).

Similarly, McTeague and Lang (2012) reported that PTSD patients with a single traumatic event responded with the largest fear-potentiated startle responses (i.e., the difference between fear and neutral images) of several anxiety disorders groups in a symptom-provocation emotional imagery paradigm, whereas patients with PTSD experiencing numerous traumatic events and/or a chronic course showed the smallest startle potentiation of all the groups, with responses during fear not significantly different from those during neutral images. Over the entire sample, patient groups with greater distress and longer chronicity showed consistently smaller startle potentiation. Moreover, startle responses were further attenuated in patients with co-morbid depression. (“Baseline” startles evoked during rest periods did not differ among the groups.) In spite of the marked difference in startle response across groups, patients

in all groups reported high subjective arousal during imagery with virtually identical mean scores, an instance of the desynchrony among response systems often noted in emotion research (e.g., Miller and Kozak, 1993).

These results from Lanius et al. (2006) and McTeague and Lang (2012) indicate that a consideration of the “fear circuit dimension” in psychopathology must address not only the canonical notion of hyperreactivity, but also developmental histories that eventuate in a failure to engage appropriate motivational circuits—an important condition both clinically and mechanistically. Beyond anxiety per se, the data further suggest diminished affective responding in patients with overall greater distress (including those with co-morbid depression). Although many recent studies have reported enhanced amygdala activity in depressed patients (e.g., Suslow et al., 2010), others have found various forms of blunted responding during depression (e.g., Vizueta et al., 2012).

A recent intriguing study of monozygotic twins examined those who were discordant for depression (on the basis of epidemiological survey test scores), as well as those who were high- or low-risk concordant (Wolfensberger et al., 2008). For the discordant pairs, high-risk twins showed increased amygdala responses to anxious/angry faces compared to their low-risk sibling. In contrast, concordant high-risk pairs showed blunted amygdala reactivity compared with low-risk pairs. The results indicate that very complex combinations of genetic and environmental risks may affect amygdala reactivity, including interactions with such factors as baseline amygdala activity (as the authors suggest) and with ventromedial prefrontal cortical structures known to modulate amygdala efferents dynamically.

Even such a very brief review serves to indicate that there is significant variability in the types and degrees of dysregulation observed within and across disorders. Integrating the findings across experiments in this area is extremely difficult for several reasons. First, patients are virtually always studied in a particular paradigm with single DSM groups, so that it is impossible to assess the extent to which the same patterns might be present in other groups. Second, reported conclusions for a single diagnosis may differ depending on whether a relatively larger proportion of hyperreactive versus hyporeactive patients happen to be included in the sample (e.g., for PTSD, as discussed). Third, the single-group experimental approach precludes the necessary studies that examine the interactions of the various motivational circuits directly (e.g., the amygdala, vmPFC, areas of the cingulate cortex, nucleus accumbens, HPA axis) across a range of disorders so as to provide a comprehensive accounting of the activity within and among these various systems. To put it more directly, it is only by studying the activity of the neural circuits and relevant behaviors themselves, rather than their variation as a function of one or another diagnosis, that a complete explanation can be sought. A thorough analysis at the systems level also needs to explore carefully the nature of responding as a function of the intensity and temporal characteristics of the stimuli. Many studies of depression have employed very brief and affectively mild face stimuli, whereas other studies employ symptom provocations or other challenges of high intensity. Finally, a developmental perspective

is absolutely essential to study the trajectories of the systems as maturation interacts with various kinds of life events.

How might an RDoC paradigm be designed to sort out these various considerations? A simple example is given in the top half of Figure 83.2, following roughly the McTeague and Lang (2012) paradigm studied in the preceding. The sampling frame for the study would be all patients seeking treatment at an anxiety disorders clinic, most of whom would receive a primary anxiety disorders diagnosis but with small numbers of patients with depression or personality disorders. The hypothesis of the study would be that magnitude of fear-potentiated startle (or, alternatively, amygdala activation) would predict (inversely) overall symptomatic distress and chronicity, confirming the relationship observed using diagnostic group means. A second aim would predict that patients with elevated startle reactivity would respond well to exposure-based therapies (owing to the presence of a robust response that can be habituated), whereas patients with blunted reactivity would largely fail to profit from exposure. In addition, the independent variable of startle response might be stratified by a genetic factor, for example, the BDNF polymorphism that has been shown to affect extinction learning in normal subjects (Soliman et al., 2010).

Extending the simple example, a longitudinal component might be added to determine the kinds of trajectories that lead to disorder. For example, the Wolfensberger et al. (2008) data (with exaggerated versus blunted amygdalar response in discordant and in concordant high-risk twins, respectively) clearly raise the possibility that some individuals have blunted affective reactivity from an early age, whereas others may be highly reactive initially but then transition to a nonreactive pattern owing to stress-related neuroplastic changes occurring over time. The genetic and epigenetic factors involved with these two patterns would likely be very different, and characteristics that may promote resilience would no doubt modulate these trajectories as well (Southwick and Charney, 2012; Tsankova et al., 2007).

Although an actual study of this type would of course be considerably more complex, the example is deliberately simple to emphasize the point that the main focus of the research is the neural circuits themselves, as modulated by genetic factors and as their activity relates to specific symptoms and behaviors reflecting stress, distress, avoidance, and so forth, but divorced from the procrustean categories that can distort the actual relationships and mechanisms. The reader may readily infer the implications of such work for generating more precise new assessments and intervention tactics.

PSYCHOTIC SPECTRUM DISORDERS

An exciting step forward in biotechnology as applied to mental disorders occurred in May 2011 with the first publication involving the use of human induced pluripotent stem cells (hiPSCs) to study schizophrenia (Brennan et al., 2011). The authors reprogrammed fibroblasts from four patients into hiPSCs, and then differentiated them into neurons. The results revealed nearly 600 genes that showed up- or down-regulated expression compared with control neurons, many of them in areas that had previously been implicated in schizophrenia, such as glutamate, cAMP, and WNT signaling.

This study was justifiably hailed as a first step showing the promise of the still-evolving hiPSC technology to provide information about disorders. The eminent psychiatric geneticist Michael Owen, however, cautioned that it was premature to conclude that the observed differences necessarily underlie schizophrenia: "These disorders are not really disorders. There's no such thing as schizophrenia. It's a syndrome. It's a collection of things psychiatrists have grouped together" (quoted in Callaway, 2011). This viewpoint represents perhaps the extreme of a wide range of opinions as to how psychotic-spectrum disorders should be conceptualized in the current age of genetics and neurobiology. Although the classical Kraepelinian dichotomy between schizophrenia and bipolar disorder has increasingly been questioned since the advent of DSM-III, the issue

has risen to the forefront with genetics studies showing a common risk for both disorders, and accumulating findings about the heterogeneity within both disorders.

In spite of the extensive discussion and awareness in the field about such data, the large majority of etiological studies and trials continue to treat both schizophrenia and bipolar disorder as though they are each unitary diseases, each with a common etiology and pathophysiology. Even allowing for the fact that current publications reflect studies initiated seven to ten years ago or more, this seems a remarkable disjunction.

What might a different model look like, and how might it be tested? In an audacious theoretical integration, Craddock and Owen (2010) first reviewed the literature on genetic risks that are shared in common between schizophrenia and bipolar disorder and then considered the comparably large number of copy number variants (CNVs) and familial co-morbidity that are observed in schizophrenia, intellectual disability, and autism. This leads to a model positing an extended gradient of serious mental illness reflecting the extent of neurodevelopmental pathology, ordered as follows (from most to least severe): mental retardation, autism, schizophrenia, schizoaffective disorder, and bipolar/unipolar mood disorders. A second gradient of affective pathology is proposed that is inversely related to the neurodevelopmental gradient (i.e., increasing in intensity toward the bipolar/unipolar end), although the authors acknowledge that this is an oversimplification for presentation purposes. The model roughly resembles the RDoC matrix rotated 90 degrees to the left, with genetic variation underlying the entire gradient; DNA structural variants range from mental retardation through schizoaffective disorder, and SNPs are seen throughout, consistent with the recent literature. Genetic variation contributes to low-level biological systems that, in turn, feed in various ways into neural modules that interact with environmental influences and stochastic variation to eventuate in various forms of cognitive and affective psychopathology across the two gradients.

The implications of this model are far reaching. Rather than discrete entities, the various disorders are seen as differing ranges along an extended spectrum of severe neurodevelopmental pathology. The current interest in exploring relationships between schizophrenia and bipolar disorder, in this model, is constrained to only one segment of the entire spectrum. The challenges of testing such a model are daunting, but even a partially successful explication would go a very long way toward fulfilling the goal of precision medicine in mental illness.

How would one set about testing this model? From an RDoC perspective, the first principle is to examine the data as a function of particular dimensions of interest, rather than as a function of DSM diagnosis. The speculations that Craddock and Owen (2010) offer are quoted at length here, as one could hardly improve upon their statements in framing an RDoC approach to unpacking their complex theories:

...we need to prepare ourselves to move towards more complex and biologically plausible models of illness rather than clinging on to the biology-free models based on clinical empiricism that have been the

tradition of psychiatry.... There is a pressing need to characterise the neurocognitive disturbances that underlie the major domains of psychopathology if we wish to develop a more refined taxonomy of mental disorders as well as better entities for genetic and other aetiological studies. It is to be hoped that more fundamental phenotypes might emerge from studies of the biological systems implicated by genetic and other biological findings. A combination of these top-down and bottom-up approaches might ultimately allow us to trace the links between genotype and phenotype. These efforts will require greater integration between different research modalities, including genetics, psychopathology, and cognitive and affective neuroscience, together with insights from systems biology. This should be complemented by consideration of social and other relevant environmental variables, and include a developmental perspective.

Keshavan et al. sound a similar note in discussing the schizophrenia spectrum (2011):

One way ahead is to replace categorical thinking by a continuum model. In such a model, each patient may be placed on a unique location in the multi-dimensional "disease space" along the tripartite coordinates of the patient's genomic and environmental risk/ resilience factors and disease expression (at molecular, physiological and behavioral levels). Doing so is the central tenet of personalized medicine; charting person-specific hallmarks of a complex disorder will not only offer novel targets for future pathophysiological and therapeutic research, but will also help optimize diagnosis and treatment for each individual patient.

Fortunately, good examples of this approach are becoming available in the literature, albeit still within single DSM disorders. For example, Wessman et al. (2009) conducted an unsupervised cluster analysis on the basis of clinical and neuropsychological data, examining a large number of patients diagnosed with schizophrenia as well as affected and unaffected family members. The cluster analysis revealed (aside from a group of unaffected family members) one cluster whose symptoms appeared to be "core schizophrenia" and who showed severe impairment, and a second cluster with a more "psychosis spectrum" pattern (including affective symptoms, although the modal diagnosis was schizophrenia) that showed only mild neurocognitive impairment. A subsequent association study of candidate genes revealed a significant association with the DTNBP1 gene for the former and with DISC1 for the latter. The RDoC sample design in the lower half of Figure 83.2 is somewhat similar to this study, except that the sampling frame would include a broader range of pathology. The IV comprises a neurocognitive task (working memory), and an association study would be conducted on candidate genes (i.e., as a DV). The additional DV in the example might represent, for example, fMRI analyses

of dorsolateral prefrontal cortex to examine how circuit activation varies as a function of task performance.

More recently, investigators created sets of genes according to their shared synaptic function (e.g., cell adhesion) and then conducted association studies on the sets of “functional gene groups” rather than individual genes (Lips et al., 2012). The total group of genes encoding synapse-relevant proteins was highly associated with risk for schizophrenia, as compared with a set of matched control genes. Three subgroups of synaptic functioning genes accounted for the most variance: intracellular signal transduction, excitability, and cell adhesion and trans-synaptic signaling. The implications for an RDoC approach are clear, with obvious promise for exploring a greater span of the neurodevelopmental gradient. An obvious hypothesis would predict that different points along the spectrum would be associated with differing total amounts, and/or different types of synaptic group abnormalities. Confirmation would offer systematic inroads toward a mechanistic approach to drug development (e.g., Insel, 2012). Similarly, Brennand et al. conclude from their hiPSC results that “Our data support the “watershed model” of SCZD [schizophrenia] whereby many different combinations of gene malfunction may disrupt the key pathways affected in SCZD. We predict that, as the number of SCZD cases studied using hiPSC neurons increases, a diminishing number of genes will be consistently affected across the growing patient cohort. Instead, evidence will accumulate that a handful of essential pathways can be disrupted in diverse ways to result in SCZD” (Brennand et al., 2011: p. 223). Obviously, as with the Lips et al. study, the results of the Brennand et al. approach could readily be applied to a study of patients across the neurodevelopmental gradient of pathology.

With such powerful tools emerging to make overarching new theories possible, the hope of the NIMH is that RDoC can provide a framework for investigators to use as they explore the daunting new terrain of etiology and precision diagnosis. It is, as yet, somewhat difficult to envision how the diagnostic system of the future will handle these complexities, but direct explorations of the relevant neural systems will provide the kind of database that can inform these future decisions.

RDoC IN TREATMENT

The time frame for the RDoC startup was paralleled by the beginning of a marked withdrawal from central nervous system drug development by pharmaceutical companies (e.g., Miller, 2010). As with any such trend, the reasons are complex; fundamentally, however, the companies regarded central nervous system drug development as an economic liability given recent failures in this area and the lack of good targets for development.

The problems, as well as the opportunities, for precision medicine are outlined by a group of industry scientists: “On average, a marketed psychiatric drug is efficacious in approximately half of the patients who take it. One reason for this low response rate is the artificial grouping of

heterogeneous syndromes with different pathophysiological mechanisms into one disorder.” However, the potential is that “...by increasing the mechanistic understanding of disease and matching the right treatments to the right patients, one could move from one-size-fits-all to targeted therapy and increase the benefit-risk ratio for patients.” They conclude that multi-target, trial-and-error development will be necessary “...until clinical trial design and patient segmentation can improve to the point of matching disease phenotype to circuit-based deficits...” (Wong et al., 2010).

In response to these exigencies, the NIMH has moved to develop a new policy for treatment development that emphasizes an experimental medicine paradigm. New candidate treatments are moved into humans more quickly than in the past, with an emphasis on early trials to demonstrate that the treatment engages its intended target successfully. In the case of compounds, this would ideally involve a PET ligand, but failing that, another measure such as electroencephalography or neurocognitive performance to show that the drug has reached the brain and exerted some effect. Signals of the latter type are also essential for new interventions involving devices or behavioral/psychological treatments. In other words, these very early trials are seen more as probes of target engagement, so that candidate interventions that fail at this step can be shelved quickly (“fast-fail”; see Paul et al., 2010). When target engagement is demonstrated, then the goal is then to move quickly toward early signs of efficacy.

The NIMH has moved forward to implement this new strategy with a slate of contracts for drug development. Termed FAST (for fast-fail), three nearly identical contracts for mood-anxiety spectrum, psychotic disorders spectrum, and autism spectrum disorders were awarded in September 2012 (see the summary at Fedbizopps, 2011). Although still very early in development, RDoC constructs have been integrated into these new trials to provide clinical targets in the form of validated intermediate phenotypes that are closer to the relevant mechanisms (see Meyer-Lindenberg and Weinberger, 2006). The idea is to foster more efficient treatment development by testing a new intervention specifically against the mechanism for which it was developed, rather than a heterogeneous grouping for which the mechanism might be relevant in half or less of the patients. The other function of RDoC would be to provide the measures, in the form of new scale development, that can serve as measures of clinical target engagement and possibly as end points in trials. As yet, the availability of such assessments varies across the domains and constructs, but prior projects have already provided some validated examples and set a model for further developments (e.g., Gold et al., 2012).

In addition to evaluating studies incorporating a fast-fail, experimental medicine approach, these trials will provide the Institute with an opportunity to gain experience with the RDoC dimensional constructs in clinical trials. In addition, this program will no doubt inform the larger RDoC development effort in developing the matrix and the experimental classification scheme.

CONCLUSIONS

This chapter has attempted to provide the reader with a fuller understanding of the conceptual and scientific background for the RDoC project. Such a radical departure from traditional ways of conferring diagnosis in psychiatry necessarily involves many changes, some of them obvious but others more nuanced and subtle. All are equally important to how the system was designed, and to its prospects for generating successful translational research. We have included extensive quotations from scientists with differing areas of expertise to demonstrate the consensus that has grown for developing an experimental system that can inform a nosology for precision medicine in psychiatry.

It is noteworthy that the DSM-5 is moving toward the same goals, albeit from a milieu in which clinical utility and stability are necessarily high priorities. As the leaders of the DSM-5 recently stated:

It is important to emphasize that DSM-5 does not represent a radical departure from the past, nor does it represent a radical separation from the goals of RDoC. As we gradually build on our knowledge of mental disorders, we begin bridging the gap between what lies behind us (presumed etiologies built on phenomenology) and what we hope lies ahead (identifiable pathophysiological etiologies). (Kupfer and Regier, 2011: p. 673)

Although the leaders of the ICD-11 revision process must place an even higher priority on clinical utility owing to their international mandate, they also reiterate that clinical practice is ultimately dependent upon validity (e.g., International Advisory Group for the Revision of ICD-10 Mental and Behavioural Disorders, 2011).

It is thus apparent that all the current efforts in psychiatric nosology are converging around a shared direction for precision medicine in psychiatry—toward classifications organized around empirically based conceptions of neural systems that implement particular behavioral functions. Specifying and integrating the various elements of these systems will be an extraordinarily difficult task, as many commentators have noted. However, an emerging consensus indicates that this direction is indeed the way forward for precision diagnoses that lead to tailored treatments. As Craddock and Owen concluded in their review, “At the end of the 19th century, it was logical to use a simple diagnostic approach that offered reasonable prognostic validity. At the beginning of the 21st century, we must set our sights higher” (Craddock and Owen, 2010: p. 95).

DISCLOSURES

Drs. Insel and Cuthbert report no biomedical financial interests or potential conflicts of interest.

ACKNOWLEDGMENTS

Grateful thanks are expressed to Dr. Michael Kozak for his insightful comments on an earlier draft of this paper.

84 | THE NEUROBIOLOGY OF PERSONALITY DISORDERS: THE SHIFT TO DSM-5

M. MERCEDES PEREZ-RODRIGUEZ, ANTONIA S. NEW, AND LARRY J. SIEVER

Investigations into the neurobiology of psychiatric disorder increasingly focus on dimensions or domains of psychopathology across diagnoses (as exemplified by the Research Domain Criteria initiative [RDoC]; Insel et al., 2010) and their underlying circuitry problems. Neuropeptides and neurotransmitters then modulate these critical circuits. Gene by environment interactions are a focus for investigating these domains.

Although the study of personality disorder had traditionally been the province of psychoanalytic or behavioral models, there is an emerging neurobiology of personality disorders grounded in altered neurocircuitry associated with individual differences and dimensions such as affective dysregulation (affective instability and negative affectivity), disinhibited aggression, anxiety/avoidance, cognitive/perceptual dysregulation, and social detachment/isolation. Thus, these new directions in psychiatry neurobiological research converge with efforts to identify the neural basis of stable traits in the personality disorders. The Five Factor Model of personality has identified core traits, such as neuroticism, which are stable and quite heritable. Extremes of these traits, expressed in the symptom dimensions, crystallize to the prototypic personality disorders as, for example, borderline personality disorder with affective instability, disinhibition/aggression, and social cognitive/interpersonal impairment. Schizotypal personality disorder is comprised of social isolation/detachment and cognitive/perceptual disorganization. Avoidant personality disorder is characterized by detachment and negative affectivity, whereas obsessive compulsive personality disorder is characterized by negative affectivity and conscientiousness. The cluster of traits that place an individual at risk for the development of a personality disorder also places him or her at risk for other psychiatric illnesses, such as depression and anxiety disorders particularly, accounting for the high rate of co-morbidity with personality disorders. Neurocircuits implicated in the affective instability (negative affectivity) and disinhibition of borderline personality disorder are related to limbic structures such as amygdala and insula as regulated by prefrontal regions including the orbitofrontal cortex (OFC). The cognitive disorganization of schizotypal personality disorder may be related to alterations in the dorsal lateral prefrontal cortex and temporal cortex, whereas deficiencies in ventral striatum dopamine systems may be related to the detachment/anhedonia. The biological underpinnings of avoidant and obsessive compulsive personality disorders are less well understood and

because there is not a substantial body of research on these disorders, they are not reviewed in detail in this chapter.

The study of the neurobiology of personality disorders provides a gateway to understanding relationships between brain and behavior building on individual variation in anxiety threshold, affective regulation, social cognition, and inhibition/aggression, and thereby can help us understand the circuitry underlying these critical domains. These specific circuits are modulated by neurotransmitters such as serotonin or norepinephrine for prefrontal cortex, neuropeptides particularly for limbic regions, and these modulators tune the sensitivity and response characteristics of these circuits. The study of the genetics of personality disorders can identify critical genes that regulate the structure of these circuits and their connectivity as well as the modulators that regulate them. Because personality disorders evolve from the interaction of genetics and environment throughout the course of development, understanding the neurobiology of these disorders allows for the characterization of gene by environment interactions as well as the mechanisms by which these interactions unfold in the course of development. Environmental influences also may influence the expression of the genome through epigenetic factors and these are beginning to be investigated in the personality disorders. Finally, through identifying genetic variation and their epigenetic regulation as well as functional aspects of specific neurocircuitry, the molecular mechanisms underlying these differences in personality disorders can be characterized.

CATEGORIES VERSUS DIMENSIONS IN PERSONALITY DISORDERS

Both dimensional and categorical approaches can be used to assess and diagnose personality disorders. There has been controversy about which approach is more valid and a hybrid system utilizing both was proposed for the fifth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5) (Rationale for the Proposed Changes to the Personality Disorders Classification in DSM-5: <http://www.dsm5.org/ProposedRevision/Pages/proposedrevision.aspx?rid=17#>). The final approved version of DSM-5 will maintain the categorical model and criteria for the 10 DSM-IV personality disorders, and will include the newly proposed trait-specific classification system in a separate area of Section 3.

There has been skepticism about the categorical nature of personality disorders (Eaton et al., 2011; Widiger et al., 2009) based in part on the high levels of co-morbidity among personality disorders and between personality disorders and psychiatric diagnoses categorized in DSM-IV on Axis I. This has led a number of investigators to favor a dimensional model based on elements of the Five Factor Model scales (Costa and Widiger, 2002). Other approaches incorporating a dimensional model include large-scale twin studies, which have supported a different model for personality disorders, suggesting four factors: internalizing, externalizing, anhedonic/introversion, and cognitive/relational disturbance (Kendler et al., 2011a; Roysamb et al., 2011); however, according to this model, the division between Axis I and II in DSM IV is called into question. For example, antisocial personality disorder is more closely linked to Axis I substance abuse disorders, and dysthymia is more closely linked to such disorders as avoidant and dependent personality disorders.

Some have argued that the best way to address the dimensions versus categories controversy for personality disorders classification is to adopt a hybrid dimensional-categorical model (Trull et al., 2011).

Borderline personality disorder (New et al., 2008b), ASPD (Patrick et al., 2009), and STPD (Siever and Davis, 2004) have been studied most comprehensively from a neurobiological vantage point and have the largest empirical evidence of clinical utility and validity among PDs (Skodol et al., 2011). In this chapter, rather than reviewing all of the DSM-IV PDs, we review findings in these three PDs.

Research on the metastructure of comorbidity among common mental disorders suggests that mental disorders can be considered indicators of latent dimensional propensities to two types of psychopathology: internalizing or externalizing (Hasin and Kilcoyne, 2012; Krueger, 1999; Krueger et al., 2002). The externalizing dimension is characterized by antisocial personality disorder and alcohol, nicotine, and drug dependence. The internalizing dimension includes two subdimensions, one involving distress (major depression, dysthymia, generalized anxiety) and the other involving fear (panic, social phobia, specific phobia) (Hasin and Kilcoyne, 2012).

BORDERLINE PERSONALITY DISORDER

The DSM-IV characterizes BPD as a pervasive pattern of instability of interpersonal relationships, self-image, and affects, and marked impulsivity beginning by early adulthood and present in a variety of contexts, as indicated by at least five of nine criteria: (1) frantic efforts to avoid real or imagined abandonment; (2) a pattern of unstable and intense interpersonal relationships characterized by alternating between extremes of idealization and devaluation; (3) identity disturbance: markedly and persistently unstable self-image or sense of self; (4) impulsivity in at least two areas that are potentially self-damaging (e.g., spending, sex, substance abuse, reckless driving, binge eating); (5) recurrent suicidal behavior, gestures, or threats, or self-mutilating behavior; (6) affective instability resulting from a marked reactivity of

mood (e.g., intense episodic dysphoria, irritability, or anxiety usually lasting a few hours and only rarely more than a few days); (7) chronic feelings of emptiness; (8) inappropriate, intense anger or difficulty controlling anger (e.g., frequent displays of temper, constant anger, recurrent physical fights); and (9) transient, stress-related paranoid ideation or severe dissociative symptoms (APA, 2000). DSM-5 will maintain the same diagnostic criteria, and will include the newly proposed trait-specific classification system in a separate area of Section 3. In Section 3 of the DSM-5, the diagnosis of BPD is characterized by impairments in personality (self and interpersonal) functioning and the presence of pathological personality traits, including negative affectivity (characterized by emotional lability, anxiousness, separation insecurity, and depressivity), disinhibition (characterized by impulsivity and risk-taking), and antagonism (characterized by hostility).

The proposed traits included in Section 3 of the DSM-5 are based on the Five Factor Model (FFM) of personality (Costa and Widiger, 2002), and arise from the psychology literature. The relation between FFM traits and DSM-IV PDs is supported by considerable data (Samuel and Widiger, 2008). The traits that characterize BPD according to Section 3 of the DSM-5 (negative affectivity, disinhibition, and antagonism) are closely related to the core BPD traits of impulsive aggression and affective dysregulation, which are supported by validating data (Siever and Weinstein, 2009).

EPIDEMIOLOGY

The prevalence of BPD as defined in DSM-IV ranges between 0.5% and 5.9% in epidemiological studies of adults in the general US population (Grant et al., 2008; Leichsenring et al., 2011), making it as prevalent as schizophrenia and bipolar I disorder. This represents a wide range of prevalence, which may reflect the different approaches employed in the studies, although the largest sample of subjects interviewed directly from a community sample reports a lifetime prevalence of 5.9% (Grant et al., 2008). Torgersen et al. (2001) calculated a median prevalence of 1.35%, pooling results from 10 studies. Although earlier research supported a higher prevalence of BPD among women, as reflected in the 3:1 female to male ratio reported in the DSM-IV-TR (APA, 2000), more recent data suggest that there are no sex differences in the prevalence of BPD (Grant et al., 2008).

Borderline personality disorder seems to be less stable over time than expected for personality disorders, with high rates of remission reported in follow-up studies (Skodol et al., 2005; Zanarini et al., 2006) and an inverse relationship between age and prevalence of BPD in the general population (Grant et al., 2008).

COMORBIDITY, ILLNESS BURDEN, AND TREATMENT UTILIZATION

Borderline personality disorder is highly comorbid with both Axis I and II disorders (Grant et al., 2008; Lenzenweger et al., 2007; Skodol et al., 2005): 84.5% of patients with BPD met criteria for one or more 12-month Axis I disorders, most frequently mood disorders, anxiety disorders, and substance use

disorders (Grant et al., 2008; Lenzenweger et al., 2007; Skodol et al., 2005). There appear to be gender differences with regard to Axis I comorbidity, with men having higher rates of substance abuse, whereas women are more likely to suffer eating, mood, anxiety, and posttraumatic stress disorders (Grant et al., 2008; Sansone and Sansone, 2011). About one-third of patients with BPD meet criteria for posttraumatic stress disorder (PTSD) during their lifetime (Grant et al., 2008): 73.9% patients with BPD meet criteria for another lifetime Axis II disorder, most frequently schizotypal, narcissistic, and obsessive compulsive PDs (Grant et al., 2008). Men with BPD are more likely than women to have antisocial personality traits (Grant et al., 2008; Sansone and Sansone, 2011). This high comorbidity rates may reflect a common vulnerability for Axis I and II disorders within the externalizing spectrum (Kendler, Aggen et al., 2011).

Individuals with BPD are higher users of mental health resources than patients with major depression (Bender et al., 2006), and they are overrepresented in clinical populations, with a prevalence of greater than 9% of all psychiatric outpatients (Zimmerman et al., 2005).

Borderline personality disorder is associated with severe and persistent functional impairment (Grant et al., 2008; Lenzenweger et al., 2007; Skodol et al., 2005; Skodol et al., 2005). Most—but not all—subjects with BPD have worsening levels of functioning over time, and never regain their initial level of functioning (Zanarini et al., 2006). They also have a high risk of suicide, with a mortality rate around 8% to 10% (Oldham, 2006).

THE ROLE OF TRAUMA

Patients with BPD report many childhood adverse events (e.g., trauma, neglect) and more negative life events than patients with other personality disorders (Bierer et al., 2003; Golier et al., 2003; Yen et al., 2002). However, no strong association between these experiences and the development of psychopathological changes in adulthood has been found (Fossati et al., 1999; Leichsenring et al., 2011). It appears that the interaction between biological (e.g., temperamental) and psychosocial factors (e.g., adverse childhood events) is likely what underlies the development of BPD (Wagner et al., 2009; Wagner et al., 2010).

PATHOPHYSIOLOGY

The neurobiological factors contributing to the genesis of BPD may be conceptualized in relation to core traits of the disorder (affective instability and impulsive aggression).

THE AFFECTIVE DYSREGULATION AND IMPULSIVE AGGRESSION DIMENSIONS

There is considerable support for the model of reduced medial prefrontal modulation of limbic structures (especially the amygdala), which appear to be hyperactive in patients with BPD, and results in dysregulation of emotions and aggression (Bohus et al., 2004; Mauchnik and Schmahl, 2010; New et al., 2012; New et al., 2008a).

One of the most consistent findings in patients with BPD compared with healthy individuals is a decrease in volume (especially gray matter volume) particularly in the anterior cingulate gyrus (ACG) (Hazlett et al., 2005; Minzenberg et al., 2008; Soloff et al., 2008; Tebartz van Elst et al., 2003), which may be especially pronounced in men with BPD (Soloff et al., 2008; Vollm et al., 2009). Other structural abnormalities in BPD include volume reduction in hippocampus (Brambilla et al., 2004; Irle et al., 2005; Nunes et al., 2009; Ruocco et al., 2012; Tebartz van Elst et al., 2003; Zetzsche et al., 2007), orbitofrontal cortex (OFC) (Tebartz van Elst et al., 2003), and amygdala (Nunes et al., 2009; Ruocco et al., 2012; Tebartz van Elst et al., 2007). However, some, but not all studies (de-Almeida et al., 2012) have raised the possibility that the smaller volumes in BPD may relate to comorbidity with PTSD or history of serious trauma for hippocampal volume (Nunes et al., 2009; Schmahl et al., 2009; Weniger et al., 2009) and the effect of comorbid MDD for amygdala volume remains unclear (Zetzsche et al., 2006).

Diffusion tensor imaging (DTI) studies examining white matter tract integrity suggest that there may be decreased fractional anisotropy (a measure of tract coherence) in the OFC in BPD (Grant et al., 2007) and diminished interhemispheric structural connectivity between both dorsal ACGs in BPD (Rusch et al., 2010).

In adolescent BPD, like adult BPD patients, ACG (Goodman et al., 2010; Whittle et al., 2009) and OFC gray matter volumes (Brunner et al., 2010; Chanen et al., 2008) are reduced compared with age-matched controls. One study showed that ACG volume correlated negatively with number of suicide attempts and BPD symptom severity, but not depressive symptoms (Goodman et al., 2010), suggesting that this volume reduction in ACG is related specifically to BPD pathology. This evidence of structural changes in ACG and nearby OFC is consistent with a model of a disruption in frontolimbic circuitry in BPD. This circuit has been studied with functional neuroimaging.

Multiple studies have reported decreased activation of prefrontal areas involved in emotion control in BPD. Early PET imaging studies showed decreased activity of OFC and ACG in BPD compared with controls (Goyer et al., 1994; Leyton et al., 2001; New et al., 2002; Siever et al., 1999; Soloff et al., 2000). A more recent PET study of laboratory-induced aggression using the Point Subtraction Aggression Paradigm found that BPD patients with impulsive aggression showed increased relative glucose metabolic rate in OFC and amygdala in response to provocation, but not in more dorsal brain regions associated with cognitive control of aggression (New et al., 2009). In contrast, during aggression provocation, healthy individuals showed increased relative glucose metabolic response in dorsal regions of prefrontal cortex, involved in top-down cognitive control of aggression, and, more broadly, of emotion (New et al., 2009). Poor connectivity between OFC and amygdala has also been reported in association with aggression (New et al., 2007).

Most functional magnetic resonance imaging (fMRI) studies using emotional stimuli have shown similar results of decreased prefrontal activation in BPD, with some exceptions

(Minzenberg et al., 2007; Schmahl et al., 2006; Schnell et al., 2007). Most studies in BPD have shown less activation (or more deactivation) of frontal areas involved in top-down control of emotions, including OFC and ACG, in BPD compared to healthy controls in response to emotional probes (Koenigsberg et al., 2009b; Minzenberg et al., 2007; Schmahl et al., 2003; Silbersweig et al., 2007; Wingenfeld et al., 2009), although some studies showed heightened prefrontal activation to emotional pictures in BPD (Minzenberg et al., 2007; Schnell et al., 2007) and to unresolved conflicts (Beblo et al., 2006).

Because of its role in emotion encoding and regulation, the amygdala is another region of interest for the study of affective dysregulation in BPD. Several but not all structural studies of BPD have shown volume reduction in the amygdala (Nunes et al., 2009; Tebartz van Elst et al., 2007).

Functional neuroimaging studies also point to abnormalities in the amygdala in BPD patients. Several studies have shown increased amygdala activation to emotional probes (e.g., emotional pictures and faces) (Beblo et al., 2006; Donegan et al., 2003; Koenigsberg et al., 2009b; Schulze et al., 2011). However, the amygdala appears to become deactivated in response to painful stimuli in BPD (Kraus et al., 2009; Niedtfeld et al., 2010; Schmahl et al., 2006), although one study suggests that this finding may be specific to BPD patients with comorbid PTSD (Kraus et al., 2009).

In summary, it seems that in BPD patients, prefrontal brain regions that normally put the brakes on expressions of emotions and more broadly of aggression (e.g., the OFC and ACG) may fail to become activated during emotional provocation, whereas the amygdala appears to hyperrespond to emotional probes.

However, it is important to note that many of the circuits implicated in BPD (including a model of decreased ACG/OFC response with an associated hyperresponse of amygdala) appear to be implicated in other psychiatric disorders, including MDD (Davidson et al., 2003), bipolar disorder (Blumberg et al., 2003), and PTSD (Shin et al., 1999), indicating potential lack of specificity.

Several laboratory psychophysiological tasks also point to abnormal emotional processing in BPD. A study by Hazlett et al. (2007) showed that patients with BPD exhibited larger startle eye blink during unpleasant but not neutral words, interpreted as an abnormality in the processing of unpleasant stimuli.

Studies on the serotonergic system suggest that the putative imbalance between prefrontal regulatory control and limbic responsivity described in the preceding may relate to impaired serotonergic facilitation of “top-down” control. Early cerebrospinal fluid studies on serotonin metabolites found low cerebrospinal fluid 5-hydroxyindolacetic acid in individuals with a history of suicide attempts (Asberg and Traskman, 1981; Asberg et al., 1976) or impulsive aggressive behavior (Coccaro, 1989). Since then, numerous studies have investigated the role of serotonin in BPD. Studies employing a wide variety of methods have replicated decreases in serotonergic responsiveness in disorders characterized by impulsive aggression, such as BPD (Coccaro et al., 1989; Dougherty et al., 1999;

O’Keane et al., 1992), including neuroimaging using pharmacological probes of serotonin (Leyton et al., 2001; New et al., 2002; New et al., 2004; Siever et al., 1999; Soloff et al., 2000). Recently, patients with personality disorders and impulsive aggression showed reduced serotonin transporter availability, as measured by the PET ligand, [11C]McN 5652, in the ACG compared with healthy subjects (Frankle et al., 2005). Moreover, metabolic activity in OFC and ACG in impulsive aggressive individuals is enhanced with fluoxetine treatment (New et al., 2004).

In summary, abnormalities in the serotonergic system may underlie the putative imbalance between prefrontal regulatory influences and limbic responsivity.

Genetics of Impulsive Aggression and Affective Dysregulation

Twin studies of BPD show substantial heritability scores of 0.65 to 0.76 (Distel et al., 2008; New et al., 2008a; Torgersen et al., 2000). A moderate heritability has been reported for dimensional BPD traits (Torgersen et al., 2008). However, there is considerable disagreement about what specific underlying trait or traits predispose to BPD. Some studies have suggested that one highly heritable factor underlies the symptom domains in BPD (Kendler et al., 2011a) and this factor is closely related to affective instability. This same study also describes strong genetic correlations between BPD traits and elements of the five factor personality components, especially neuroticism, and inversely with conscientiousness and agreeableness. Other studies have suggested that the Five Factor Model has more convergent and discriminant validity than the DSM-IV diagnostic criteria for BPD (Samuel and Widiger, 2010) based largely on the superior convergence between self-report and other assessment modalities (e.g., interview, informant interview). The particularly poor ability of BPD patients to describe their own symptoms based on poor ability to mentalize may underlie some of the confusion in the field. The proper approach to describing the underlying neurobiology of BPD symptoms is an active area of investigation and is among the goals of the RDoC’s effort through the NIMH. This is important not only for elucidating what underlies BPD and whether new therapeutics might be developed with better neurobiological understanding of this illness, but it also is important because BPD features predispose individuals to other serious disorders, especially treatment-refractory depression (Kornstein and Schneider, 2001).

Candidate genes for impulsive aggression and emotional dysregulation include those that regulate the activity of neuromodulators, such as serotonin and catecholamines, as well as neuropeptides (Siever, 2008; Siever and Weinstein, 2009).

NEUROPEPTIDE MODEL

Neuropeptides are another recent area of interest in BPD. Oxytocin has anxiolytic and prosocial effects (Macdonald and Macdonald, 2010), and it reduces amygdala activation in response to a variety of emotional stimuli in healthy individuals (Meyer-Lindenberg, 2008). However, there have been very

few studies in BPD and none involving brain imaging. The two empirical studies of oxytocin administration in BPD have shown that oxytocin modestly decreased the subjective anxiety resulting from the Trier Social Stress Test in BPD (Simeon et al., 2011), but it decreased the level of cooperative behavior in BPD (Bartz et al., 2011). We have found that a polymorphism of oxytocin is associated with anger dyscontrol in BPD patients (Siever et al., unpublished data). This association is increased by trauma.

Opioids are also involved in social attachment. One recent imaging study measured μ -opioid receptor binding, by using the μ -opiate ligand [^{11}C] carfentanil, in patients with BPD during induction of neutral and sad sustained emotional states (Prossin et al., 2010). They found greater baseline μ -opioid receptor availability in BPD, interpreted as a deficit in endogenous circulating opioids. Their results also suggest that BPD patients enhance endogenous opiate availability more than controls during sad mood induction, which might reflect a compensatory response and is consistent with lower levels of endogenous opioids in self-injurers (Stanley and Siever, 2010; Stanley et al., 2009). We have found that polymorphisms of the μ -opioid receptor may be associated with affective instability and BPD (Siever et al., unpublished data). These associations also seem exacerbated by trauma, underscoring the interactive effects of genetics and environment.

One theory about self-cutting, a behavior common in BPD, is that it represents a method of releasing endogenous opioids, to compensate for an intrinsic opioid deficit (New and Stanley, 2010; Stanley and Siever, 2010). The interpersonal difficulty that is central to borderline pathology might also be linked to a deficit in endogenous opiates.

A FOCUS ON FUNCTIONAL NEUROIMAGING OF INTERPERSONAL PROCESSES

Very little empirical work has been done on factors underlying interpersonal disruptions in BPD. Several studies have focused on recognition of facial emotional expression in BPD. Borderline personality disorder patients appear to have a heightened ability to identify emotional expressions correctly compared with healthy controls; however, they tend to interpret neutral faces as more angry than controls do (Donegan et al., 2003; Lynch et al., 2006; Wagner and Linehan, 1999). The data suggest that ambiguous stimuli or contexts including time constraints particularly trigger dysfunctional emotional processing in BPD (Dyck et al., 2009). Difficulties in interpreting social affective stimuli also seem to arise when BPD patients are presented stimuli from multiple sensory modalities (Minzenberg et al., 2006).

Even fewer studies have examined more complex social tasks in BPD. One study using a Theory of Mind task during brain imaging found that BPD patients had less activity in superior temporal areas than controls during a task that involved inferring what someone in a picture was feeling, and they had increased activation of anterior insula during a task probing their own responses to emotional pictures (Dziobek et al., 2011). This supports the disturbances of “self” and “other” described in BPD psychopathology (Bender and Skodol, 2007).

A seminal study of complex social interactions showed that BPD patients had difficulty maintaining cooperation in a version of the Trust game (King-Casas et al., 2008). Behaviorally, BPD patients were unable to maintain cooperation, and were impaired in their ability to “repair broken cooperation” when their partner offered a “coaxing” bid. Neurally, healthy individuals activated anterior insula in relation to cooperative “offers” from their partner, whereas BPD patients activated the insula (a brain region predominantly involved in interoception and to a degree social cognition) in relationship to how much the patient him- or herself offered to the other. In a similar version of the Trust game, BPD subjects responded with greater *self*-criticism when given adverse monetary offers from a putative partner (Franzen et al., 2010).

BRAIN IMAGING OF DELIBERATE EMOTION REGULATION IN BORDERLINE PERSONALITY DISORDER

Because psychotherapeutic strategies that enhance emotion regulation skills have proven effective in BPD, another area of growing interest involves the investigation of regional brain activity in response to deliberate emotion regulation (Koenigsberg et al., 2009a; Lang et al., 2012; Schulze et al., 2011). There has also been interest in whether changes in neurocircuitry in response to successful psychotherapeutic treatment can be detected in BPD (Lai et al., 2007). One very small study showed that in dialectical behavior therapy responders, there was a decrease in amygdala activation measured with fMRI in response to emotional stimuli (Goodman et al., unpublished data).

ANTISOCIAL PERSONALITY DISORDER

The DSM-IV characterizes antisocial personality disorder (ASPD) as a pervasive pattern of disregard for and violation of the rights of others that has been occurring since the age of 15 years, as indicated by at least three of seven criteria: (1) failure to conform to social norms with respect to lawful behaviors as indicated by repeatedly performing acts that are grounds for arrest; (2) deceitfulness, as indicated by repeated lying, use of aliases, or conning others for personal profit or pleasure; (3) impulsivity or failure to plan ahead; (4) irritability and aggressiveness, as indicated by repeated physical fights or assaults; (5) reckless disregard for safety of self or others; (6) consistent irresponsibility, as indicated by repeated failure to sustain consistent work behavior or honor financial obligations; (7) lack of remorse, as indicated by being indifferent to or rationalizing having hurt, mistreated, or stolen from another (APA, 2000). DSM-5 will maintain the same diagnostic criteria, and will include the newly proposed trait-specific classification system in a separate area of Section 3. In Section 3 of the DSM-5, the diagnosis of ASPD is characterized by impairments in personality (self and interpersonal) functioning and the presence of pathological personality traits, including disinhibition (characterized by irresponsibility, impulsivity, and risk-taking) and antagonism

(characterized by manipulateness, deceitfulness, callousness, and hostility).

Antisocial personality disorder is distinct from psychopathy, a construct characterized by pronounced problems in emotional processing (reduced guilt, empathy, and attachment to significant others; callous and unemotional traits) and increased risk for displaying antisocial behavior (Cleckley, 1941; Hare, 2003). The DSM-IV definition of ASPD has been criticized for focusing on the behavioral outcome such as criminality, and ignoring the core personality features such as affective deficits. Despite its association with ASPD, psychopathy is a distinct disorder: Whereas most of those who are diagnosed with psychopathy will also meet criteria for antisocial personality disorder, only about 10% of those with antisocial personality disorder meet criteria for psychopathy (NCCM 2010; Table 84.1).

Another essential difference between ASPD and psychopathy is the type of aggression characteristic of each disorder. Two types of aggression have been described, which are given various names in the literature (e.g., proactive or instrumental vs. reactive; premeditated vs. impulsive; predatory vs. defensive). These two types differentiate aggressive behavior that is controlled/planned and serves an instrumental, goal-directed end (i.e., a planned robbery to obtain the victim's money) versus aggressive behavior that is more retaliatory/impulsive (i.e., road rage), occurs in response to a threat or perceived threat and is associated with negative affect (i.e., hostility or anger; Dolan, 2010; Ostrov and Houston, 2008). Reactive aggression has been associated with a lack of impulse control (e.g., in

ASPD, intermittent explosive disorder and BPD), whereas instrumental aggression has been uniquely linked to psychopathic features (Blair, 2010; Dolan, 2010; Ostrov and Houston, 2008).

EPIDEMIOLOGY

The 12-month prevalence of antisocial personality disorder (ASPD) was recently estimated to be 3.6% in a nationally representative general population survey (Grant et al., 2004). Antisocial personality disorder is more common in men, who are also more likely to have a persistent course of antisocial behavior when compared with women (NCCM, 2010).

Antisocial personality disorder is associated with a high risk of disorders within the externalizing spectrum, mainly alcohol, nicotine, and drug dependence (Hasin and Kilcoyne, 2012; Hasin et al., 2011). It has been postulated that this high comorbidity suggests common underlying biological contributors (Krueger et al., 2002).

Antisocial personality disorder is also frequently comorbid with other cluster B PDs. This is thought to result from both common genetic and environmental influences. Research suggests that, etiologically, ASPD and BPD are more closely related to each other than to the other cluster B disorders, with both ASPD and BPD showing a second genetic and non-shared environmental factor above and beyond the genetic factor influencing all cluster B disorders (Torgersen et al., 2008).

TABLE 84.1. Items in the Hare Psychopathy Checklist-Revised

FACTOR 1: INTERPERSONAL/AFFECTIVE	FACTOR 2: SOCIAL DEVIANCE
1. Glibness/superficial charm	3. Need for stimulation/ prone to boredom
2. Grandiose sense of self-worth	9. Parasitic lifestyle
4. Pathological lying	10. Poor behavioral controls
5. Conning/manipulative	12. Early behavioral problems
6. Lack of remorse or guilt	13. Lack of realistic long-term goals
7. Shallow affect	14. Impulsivity
8. Callous/lack of empathy	15. Irresponsibility
16. Failure to accept responsibility for own actions	18. Juvenile delinquency
Additional items	19. Revocation of conditional release
11. Promiscuous sexual behaviour	20. Criminal versatility
17. Many short-term marital relationships	

(Hare, R.D. (2003). *Hare Psychopathy Checklist-Revised*, edn 2. Toronto, Multi-Health Systems.)

DEVELOPMENT AND CHILDHOOD ANTECEDENTS

Longitudinal, epidemiological studies have identified several risk factors for antisocial behavior, including maltreatment, harsh and coercive discipline, smoking during pregnancy, divorce, teen parenthood, peer deviance, parental psychopathology (including depression, antisocial behavior, and alcohol use problems), and social disadvantage (including poverty and neighborhood disadvantage; Jaffee et al., 2012), with varying support for causal effects.

Antisocial symptoms with onset in childhood often persist into adulthood and are associated with decreased functioning in educational, employment, interpersonal, and physical health domains (Jaffee et al., 2012).

THE DIMENSION OF IMPULSIVE AGGRESSION IN ANTISOCIAL PERSONALITY DISORDER AND PSYCHOPATHY

Impulsive aggression is believed to be the core dimension underlying ASPD, and is also seen in all the Axis II cluster B PDs, most typically in BPD. The present review will focus on the pathophysiology of impulsive aggression.

REACTIVE AGGRESSION

Reactive aggression is common in ASPD (Blair, 2010; Dolan, 2010; Ostrov and Houston, 2008).

Animal research suggests that reactive aggression is part of a graded response to threat: Distant threats induce freezing, closer threats induce flight, and very close threats in which escape is impossible induce reactive aggression. This progressive response to threat is mediated by a threat system that involves the amygdala, the hypothalamus, and the periaqueductal gray. It is believed that this system is regulated by medial, orbital, and inferior frontal cortices (Blair, 2007, 2010). According to this threat system, those individuals at increased risk of showing reactive aggression should show heightened amygdala responses to emotionally provocative stimuli and reduced frontal emotional regulatory activity (Blair, 2010).

INSTRUMENTAL AGGRESSION

Instrumental aggression is characteristic of psychopathy (Blair, 2010; Dolan, 2010; Ostrov and Houston, 2008). Instrumental aggression is hypothesized to be mediated by the motor cortex and the caudate, like any other form of motor response (Blair, 2007). An individual can choose among several available choices of motor response (e.g., instrumental aggression vs. more prosocial behaviors) based on the costs and benefits associated with each choice. For most individuals, the costs of instrumental aggression (e.g., harm to the victim or oneself, risk of punishment) outweigh the benefits, and more prosocial behaviors are chosen instead of instrumental aggression. However, it is believed that individuals with psychopathy initiate instrumental aggression because of dysfunctional representation of the costs of the behavior, related to amygdala and orbitofrontal cortex (OFC) dysfunction (Blair, 2010).

The amygdala is critical for stimulus reinforcement learning and feeding reinforcement expectancy information forward to the OFC to allow good decision making. Because of the hypothesized dysfunction in amygdala and OFC, individuals with psychopathic traits have difficulty socializing (related to dysfunction in stimulus reinforcement learning) and make poor decisions (because of the OFC dysfunction). According to this model, individuals with psychopathic traits should show reduced amygdala and OFC responses to emotional provocation and during emotion-based decision-making tasks (Blair, 2007, 2010).

Research suggests that healthy individuals are predisposed to find distress cues from others aversive and that we learn to avoid behaviors associated with distress cues (i.e., acts that harm others), which is critical for the development of morality. Distress cues from the victim are believed to act as an inhibitor of aggression (Blair, 1995), but this inhibitory mechanism appears to be defective in psychopathy (Blair, 2007).

NEUROIMAGING OF AGGRESSION IN ANTISOCIAL PERSONALITY DISORDER AND PSYCHOPATHY

Although the data strongly support a disruption of amygdala and prefrontal cortex functioning—specifically, in the OFC, ACG, and dorsolateral prefrontal cortex—in individuals with psychopathic traits and/or antisocial behavior, the data for ASPD itself is less conclusive (Nordstrom et al., 2011; Yang and Raine, 2009). This may be because of the heterogeneity of the ASPD diagnosis itself and of the samples and control groups

analyzed (e.g., different demographic groups, psychiatric comorbidities). The majority of the studies and metaanalyses focus on broadly defined antisocial constructs, including individuals with ASPD with or without psychopathy, psychopathy with or without ASPD, antisocial behavior, conduct disorder, oppositional defiant disorder, disruptive behavior disorder, criminals, violent offenders, or aggressive individuals (Yang and Raine, 2009). There is a paucity of studies focusing on ASPD specifically, and even fewer studies assessing the effect of comorbid psychopathy on neuroimaging findings in ASPD subjects (Boccardi et al., 2010; Gregory et al., 2012; Tiihonen et al., 2008).

Structural Findings in Antisocial Personality Disorder

Prefrontal abnormalities

Laakso et al. (2002) observed reductions in volume of the dorsolateral, medial frontal, and orbitofrontal cortices in subjects with ASPD. However, after controlling for substance use and education, they concluded that the observed volume deficits were related more to alcoholism or differences in education rather than the diagnosis of ASPD.

Other authors did find reduced prefrontal volumes in ASPD, even after controlling for the effects of substance use (Dolan, 2010; Raine et al., 2000, 2003; Tiihonen et al., 2008). Raine et al. (2010) observed that individuals with cavum septum pellucidum (CSP), a marker of limbic neural maldevelopment, had significantly higher levels of antisocial personality, psychopathy, arrests, and convictions compared with controls, even after controlling for the effects of potential confounders including prior trauma exposure, head injury, demographic factors, or comorbid psychiatric conditions.

Other abnormalities

Antisocial personality disorder subjects have been reported to have smaller temporal lobes (Barkataki et al., 2006; Dolan et al., 2002), smaller whole brain volumes (Barkataki et al., 2006), larger putamen volumes (Barkataki et al., 2006), larger occipital (Tiihonen et al., 2008) and parietal lobes (Tiihonen et al., 2008), larger cerebellum volumes (Tiihonen et al., 2008), decreased volumes in specific areas of the cingulate cortex, insula, and postcentral gyri (Tiihonen et al., 2008), and cortical thinning in medial frontal cortices (Narayan et al., 2007). Raine et al. (2003) found that psychopathic, antisocial subjects had a longer, thinner corpus callosum with overall increased volume compared with healthy controls.

However, other studies (Gregory et al., 2012) found no differences in gray matter volumes between offenders with ASPD without psychopathy and healthy controls.

Functional Neuroimaging in Antisocial Personality Disorder

Most of the few functional neuroimaging studies with subjects diagnosed with ASPD suggest a dysfunction in brain regions involved in emotional processing and learning (Dolan, 2010). The first functional neuroimaging study in ASPD showed that, compared with healthy controls, subjects with BPD or ASPD

activated different neural networks during response inhibition in a go/no-go task (Vollm et al., 2004). Although controls mainly activated the prefrontal cortex—specifically the right dorsolateral and the left OFC—during response inhibition, BPD and ASPD patients showed a more bilateral and extended pattern of activation across the medial, superior and inferior frontal gyri extending to the ACG (Vollm et al., 2004).

Some of the studies suggest that at least part of the neural abnormalities found in ASPD subjects may not be specific to this disorder, but rather associated with aggressive traits that are associated with a tendency to violent behavior. For example, Barkataki et al. (2008) found that both violent ASPD subjects and violent schizophrenia patients, but not nonviolent schizophrenia patients showed reduced thalamic activity, in association with modulation of inhibition in a go/no-go task. However, another study by the same group suggests that, although there are neural alterations related to violence found both in violent schizophrenic and violent ASPD patients in occipital and temporal regions, there are interesting differences specific to ASPD and schizophrenia, respectively. Specifically, they found that the violent ASPD subjects showed attenuated thalamic–striatal activity during later periods in a “threat of electric shock” task—whereas in the violent schizophrenic subjects there was hyperactivation in the same areas (Kumari et al., 2009). This suggests that, although there is a shared biological deficit, violent behaviors may arise from different mechanisms according to the specific disorder.

NEUROCOGNITIVE FUNCTION AND AGGRESSION IN ANTISOCIAL PERSONALITY DISORDER AND PSYCHOPATHY

Previous research investigating whether subjects with ASPD have impaired cognitive functioning has yielded inconsistent findings (Crowell et al., 2003; Morgan and Lilienfeld, 2000). Although some authors have found a broad range of deficits in planning ability and set shifting, response inhibition and visual memory, likely mediated by dorsolateral prefrontal cortex and ventromedial prefrontal cortex function in subjects with ASPD (Dolan and Park, 2002), others have only found circumscribed deficits in processing speed (Barkataki et al., 2005) or response inhibition (Barkataki et al., 2008) in ASPD subjects. Moreover, a metaanalysis of 39 studies including 4,589 participants found that, although antisocial behaviors in general were significantly associated with a large effect size for executive dysfunction, the effect size for executive function deficits among subjects with ASPD was statistically significant but negligible (Morgan and Lilienfeld, 2000), and others could find no differences in executive function between ASPD and healthy or psychiatric controls (Crowell et al., 2003). It should be noted that some authors have studied ASPD samples with high rates of psychopathy. Therefore, it is impossible to tease apart the contributions of psychopathy and ASPD respectively to the deficits reported. For example, Dinn et al. (2000) studied 12 ASPD patients, 11 of whom fulfilled criteria for psychopathy. They found that ASPD subjects showed greater deficits on measures of orbitofrontal dysfunction, but not on classical measures of

executive function, in comparison with controls (Dinn and Harris, 2000).

Psychopathy has also been associated with executive function deficits as reported in the metaanalysis described in the preceding (Morgan and Lilienfeld, 2000). However, a more recent study found that among offenders with ASPD there was no significant association between executive function impairment and scores on a measure of psychopathy (Dolan, 2011).

GENETIC VULNERABILITY OF AGGRESSION AND ANTISOCIAL PERSONALITY DISORDER

Family, twin, and adoption studies suggest that antisocial spectrum disorders and psychopathy are heritable, with heritability ranging from 0% to 80% in individual studies, and estimated at around half of the variance in most studies and a metaanalysis of antisocial behavior (Rhee and Waldman, 2002; Viding et al., 2008), and even higher when studying externalizing disorders more broadly (Gunter et al., 2010; Krueger et al., 2002) or for certain subtypes, such as those with callous/unemotional traits (Viding et al., 2008).

In the last decade, considerable scientific energy has been focused on identifying specific genetic factors involved in the development of aggressive behavior, as a trait observed in antisocial spectrum disorders and psychopathy. However, despite the great advances in the field, behavioral genetics has yet to elucidate specific genetic pathways that lead to the genesis of the disorders, or develop molecular genetic tests that may inform diagnosis or treatment (Gunter et al., 2010). Association studies on single candidate genes have not yielded any loci with a major effect size. It has been suggested that examining gene by environmental interactions, performing detailed whole genome association studies, functional imaging studies of genetic variants, and examining the role of epigenetics may provide valuable new targets for research (Craig and Halton, 2009).

One of the challenges of the existing research is the heterogeneity of the phenotypes analyzed in different studies, including individuals with ASPD with or without psychopathy, psychopathy with or without ASPD, antisocial behavior, conduct disorder, oppositional defiant disorder, disruptive behavior disorder, criminals, violent offenders, or aggressive individuals, with only a handful of studies focusing on ASPD specifically (Gunter et al., 2010).

Genome-Wide Linkage and Association Studies

Several genome-wide linkage and association studies have suggested possible genomic locations in chromosomes 1, 2, 3, 4, 9, 11, 12, 13, 14, 17, 19, and 20 for antisocial spectrum disorders, but must be interpreted with caution because very few findings reach genome-wide significance, and even fewer have been replicated (Gunter et al., 2010). These studies have focused on diverse phenotypes, including conduct disorder with or without substance use disorders or attention deficit hyperactivity disorder (ADHD), suicidal behavior as a marker of impulsive aggression, or personality traits of psychoticism and neuroticism (Gunter et al., 2010). Of note, only one of these studies specifically included subjects with a diagnosis of ASPD, and found several regions of interest in the genome

(Ehlers et al., 2008). An interesting question for future studies would be to assess whether other constructs (including dimensional personality approaches) may be closer correlates of the underlying genetic factors than the construct of ASPD itself as currently described in the DSM-IV (APA, 2000).

Candidate Genes

The most widely studied genes in antisocial spectrum disorders have been those related to serotonergic and dopaminergic systems, including catechol-*O*-methyl transferase (COMT), monoamine oxidase A (MAOA), dopamine beta hydroxylase (DBH), tryptophan hydroxylase 1 and 2 (TPH 1 and 2), dopamine receptor D2 (DRD2), dopamine receptor D4 (DRD4), serotonin receptor 1B (5HTR1B), serotonin receptor 2A (5HTR2A), serotonin transporter (5HTT), and dopamine transporter (DAT). Other targets include androgen receptors (AR), based on the gender differences in frequencies of antisocial spectrum disorders, and novel sites such as SNAP25, which was identified as a region of interest in genome-wide studies (Gunter et al., 2010). Currently, the strongest evidence available points to the MAOA and 5HTT genes in antisocial spectrum disorders (Gunter et al., 2010).

In the decade since the seminal study by Caspi et al. (2002) suggesting that MAO genotypes can moderate children's sensitivity to environmental insults, the analysis of gene-environment interaction has received much attention. Some but not all studies have replicated gene-environment interactions in antisocial spectrum disorders (Gunter et al., 2010).

Other interesting avenues of research are those of analysis of gene expression and epigenetic modification of gene expression via methylation and histone modification, but data on the antisocial spectrum are still very scarce (Gunter et al., 2010). Only one study so far has analyzed the impact of epigenetic mechanisms on the development of ASPD symptoms. Beach et al. observed that the degree of methylation at 5HTT mediated the impact of childhood sex abuse on symptoms of ASPD (Beach et al., 2011).

In summary, there is compelling evidence that genes involved in the serotonergic system are implicated in impulsive aggression.

SUMMARY AND FUTURE DIRECTIONS

The ASPD diagnosis comprises a heterogeneous population, limiting neurobiological research efforts. However, considerable progress has been made in the understanding of impulsive aggression, a core dimension of antisocial spectrum disorders and psychopathy, including the roles of the prefrontal cortex, the amygdala, and neurocognitive deficits. The strongest genetic evidence points to the MAOA and 5HTT genes, and promising new approaches include genome wide analyses, epigenetics, gene expression, and neuroimaging genetics.

Using an interdisciplinary research team and a systems approach to the biology of complex illnesses such as antisocial spectrum disorders and psychopathy may help to shed light on the interplay among genetic factors, neural networks, and behavior (Gunter et al., 2010).

SCHIZOTYPAL PERSONALITY DISORDER

Schizotypal personality disorder (STPD), the prototypic schizophrenia personality disorder, is part of the schizophrenia spectrum disorders, characterized by the presence of attenuated symptoms typically present in chronic schizophrenia. The investigation of STPD offers an opportunity to elucidate the pathophysiological mechanisms giving rise to schizophrenia, in a less impaired and less heavily medicated population.

Schizotypal personality disorder is defined by DSM-IV-TR as "a pervasive pattern of social and interpersonal deficits marked by acute discomfort with, and reduced capacity for, close relationships, as well as by cognitive or perceptual distortions and eccentricities of behavior, beginning by early adulthood and present in a variety of contexts," and requires five or more of the following criteria: (1) ideas of reference (excluding delusions of reference); (2) odd beliefs or magical thinking that influences behavior and is inconsistent with subcultural norms (e.g., superstitiousness, belief in clairvoyance, telepathy, or "sixth sense"; in children and adolescents, bizarre fantasies or preoccupations); (3) unusual perceptual experiences, including bodily illusions; (4) odd thinking and speech (e.g., vague, circumstantial, metaphorical, overelaborate, or stereotyped); (5) suspiciousness or paranoid ideation; (6) Inappropriate or constricted affect; (7) behavior or appearance that is odd, eccentric, or peculiar; (8) lack of close friends or confidants other than first-degree relatives; and (9) excessive social anxiety that does not diminish with familiarity and tends to be associated with paranoid fears rather than negative judgments about self (APA, 2000). DSM-5 will maintain the same diagnostic criteria, and will include the newly proposed trait-specific classification system in a separate area of Section 3. In Section 3 of DSM-5, STPD is characterized by impairments in personality (self and interpersonal) functioning and the presence of pathological personality traits, including psychoticism, detachment, and negative affectivity (<http://www.dsm5.org/proposedrevision/Pages/proposedrevision.aspx?rid=15#>).

EPIDEMIOLOGY

The median prevalence of STPD had been estimated at 0.7% in the general population (Torgersen et al., 2001); however, recently a lifetime prevalence of 3.9% was reported in a large, nationally representative US community sample (Pulay et al., 2009). Schizotypal personality disorder is more frequent among males than females (Pulay et al., 2009).

More than 80% of those with STPD also suffer other comorbid personality disorders, especially BPD (Pulay et al., 2009) and narcissistic PD (Pulay et al., 2009). Lifetime comorbidity with Axis I disorders is high as well: 67% of individuals with STPD have at least one mood disorder, greater than 70% have at least one anxiety disorder, and greater than 65% have a substance use disorder (Pulay et al., 2009).

Schizotypal personality disorder is one of the DSM-IV PDs most strongly associated with reduced functioning (Pulay et al., 2009) with significantly worse levels of impairment than

among patients with other PDs or major depressive disorder (Skodol et al., 2002).

PUTATIVE ETIOLOGIC FACTORS AND PATHOPHYSIOLOGY

The neurobiological factors underlying the genesis of STPD may be conceptualized in relation to each of the core traits of the disorder (psychotic-like symptoms and cognitive organization disturbances). In this way, disturbances in cognitive organization and information processing may contribute to the detachment, desynchrony with the environment, and cognitive/perceptual distortions of STPD and other schizophrenia spectrum personality disorders (Siever and Weinstein, 2009).

PSYCHOTICISM DIMENSION

Psychotic-like symptomatology is characteristic of STPD patients. Like in schizophrenia, increased dopaminergic neurotransmission is associated with more prominent psychotic symptoms, and the dimension of psychotic-like perceptual distortions has been correlated with measures of dopaminergic activity. The fact that STPD patients have less prominent psychotic symptoms than patients with schizophrenia is believed to be caused by better buffered subcortical dopaminergic activity (Siever and Davis, 2004; Siever and Weinstein, 2009). The results of functional and structural imaging and neuroendocrine challenge studies support this hypothesis. This better buffering system may result in less responsiveness to stress by subcortical dopaminergic systems, which may protect against psychosis (Mitropoulou et al., 2004; Siever and Davis, 2004; Siever and Weinstein, 2009).

It has been suggested that dopaminergic activity can be relatively increased or decreased, depending on the predominance of psychosis-like (hypervigilance and stereotypic cognitions/behaviors) or deficit-like (deficits in working memory, cognitive processing, and hedonic tone) symptoms (Siever and Davis, 2004).

Dopaminergic candidate genes including the dopamine D4 receptor and the dopamine β -hydroxylase gene have been found to be associated with psychosis-like symptomatology (Siever and Davis, 2004; Siever and Weinstein, 2009).

In summary, STPD patients share some of the dopaminergic abnormalities underlying psychotic-like symptoms found in schizophrenia, but in a more attenuated form, likely because of better buffered subcortical dopaminergic activity.

COGNITIVE IMPAIRMENT DIMENSION/ DEFICIT SYMPTOMS

Research data suggest that patients with STPD suffer cognitive impairment, likely related to structural brain abnormalities, especially in the temporal cortex, similar to those seen in patients with schizophrenia. Despite these similarities, STPD patients differ from schizophrenia patients in that they have less impaired executive function—likely owing to greater reserves in prefrontal function (Siever and Davis, 2004; Siever and Weinstein, 2009).

Specifically, patients with STPD have increased ventricular volumes, and frontotemporal volume reductions similar but

milder than those seen in schizophrenic patients, with sparing of some key regions (Hazlett et al., 2008).

Specific cognitive dimensions found to be impaired in STPD include attention, visual and auditory working memory, verbal learning and memory, and STPD individuals perform poorly on executive function tasks. However, the more generalized intellectual deficits found in schizophrenia are not observed in STPD (McClure et al., 2007; Siever and Weinstein, 2009).

These cognitive deficits may contribute to the impairments in social rapport and inability to read social cues seen in STPD patients. Actually, deficits in working memory have been correlated with interpersonal impairment (Mitropoulou et al., 2005).

Decreased dopaminergic and noradrenergic activity in the prefrontal cortex may contribute to the cognitive impairment in STPD. This is consistent with functional studies showing decreases in frontal activation during executive functioning tasks in STPD subjects. However, unlike schizophrenic patients and normal subjects, STPD subjects appear to activate other compensatory regions during executive function tasks (Koenigsberg et al., 2005).

Working memory has been shown to improve after pharmacological interventions with guanfacine, an α_2 adrenergic agonist, and pergolide, a D1/D2 agonist (McClure et al., 2007, 2010).

Schizotypal personality disorder subjects also suffer deficits in information processing, reflected in physiological impairments seen in the schizophrenia spectrum. These include deficits in prepulse inhibition (PPI) of the acoustic startle response, the startle blink paradigm, the P50 evoked potential paradigm, or smooth pursuit eye movement among others (see Siever and Davis, 2004, for a review).

In summary, STPD subjects show cognitive and physiological impairments that seem to be partially caused by reduced prefrontal dopaminergic function and that can be partly reversed with dopamine agonists and partially compensated by activation in other brain areas not used by healthy controls.

GENETIC VULNERABILITY

Schizotypal personality disorder is partly heritable (Kendler et al., 2006), and its genetic factors overlap with those for schizophrenia and other schizophrenia spectrum disorders (Fanous et al., 2007; Siever, 2005). It has been suggested that positive and negative symptoms of STPD represent two distinct heritable dimensions. Thus, in disorders of the schizophrenia spectrum, a set of genetic factors expressed as social and cognitive deficits (spectrum phenotype) might be transmitted independently from a second genetic factor set related to psychosis (psychotic phenotype) (Siever and Davis, 2004).

A polymorphism of catechol-*o*-methyl-transferase (COMT), which metabolizes dopamine and regulates its activity in the frontal cortex, has been associated with working memory deficits and other cognitive deficits both in schizophrenic and schizotypal subjects (Ma et al., 2007; Smyrnis et al., 2007).

A recent study on a risk for psychosis haplotype of the proline dehydrogenase gene found that, in healthy controls, the psychosis variant was associated with PPI and verbal memory

deficits as well as higher anxiety and schizotypal personality traits (Roussos et al., 2009).

In a large cohort of young healthy individuals, Stefanis et al. showed an association between common variants in G-protein signaling 4 (RGS4) and D-amino acid oxidase (DAAO) genes with negative schizotypal personality traits; dysbindin (DTNBP1) variants were associated with positive and paranoid schizotypy measures (Stefanis et al., 2007, 2008).

Finally, preliminary results from our group using the custom Consortium on the Genetics of Schizophrenia (COGS) 1,536-SNP chip found a strong association between polymorphisms in ERBB4, NRG1 and genes involved in glutamate, dopamine, GABA and serotonin receptors signaling, as well as cell signal transduction, with categorical clinical diagnosis (STPD vs. healthy controls) and dimensional quantitative phenotypes of STPD, including cognitive impairment, interpersonal deficits, and paranoia (Siever and Roussos, unpublished data).

In summary, several genetic variants have been associated with STPD traits and/or dimensional quantitative phenotypes of STPD, including cognitive impairment symptoms, opening promising avenues for research and pharmacological targets.

CONCLUSIONS

Increasing evidence suggests that several of the personality disorders that have been most studied including BPD, STPD, and ASPD have distinct neurobiological substrates that emerge from genetic susceptibilities, that are beginning to be identified, interacting with the environment. These categorical personality disorders can also be mapped into dimensions that extend across personality disorders and may even extend into normal personality.

A better understanding of the neurocircuitry underlying the personality disorders and their modulation by neuropeptides and neurotransmitters may help us intervene pharmacologically and even provide a base for predictors of outcome and a mechanism of action in the brain for psychosocial treatments for these disorders.

DISCLOSURES

Dr. Perez has no conflicts of interests to disclose. She is funded by the Department of Veterans Affairs (VISN3) Mental Illness Research, Education, and Clinical Center (MIRECC).

Dr. Siever has no conflicts of interest to disclose. His salary comes from the Peters VA and Mt. Sinai Medical school.

Dr. New has no conflicts of interest to disclose. Her salary comes from the James J Peters VA and Mount Sinai School of Medicine.

R. JAMES R. BLAIR

Aggression, here defined as any form of behavior directed toward the goal of harming or injuring another living being who is motivated to avoid such treatment, is a natural and adaptive phenomenon. However, it can become maladaptive if it is exaggerated, persistent, or expressed out of context (Nelson and Trainor, 2007). As such it is a serious social concern as well as a considerable economic burden on society. Indeed, aggressive and antisocial behaviors are the leading cause of all child and adolescent referrals to mental health clinicians (Berkowitz, 1993). Moreover, each antisocial individual costs society up to ten times more than their healthy counterparts in aggregate health care and social service expenditures (Nelson and Trainor, 2007). An increased risk for aggression can be seen in a variety of psychiatric disorders, including but not limited to mood and personality disorders. Understanding the neurobiology of aggression is thus of considerable importance.

TAXONOMIES OF AGGRESSION

Work with animals has distinguished several forms of aggression (Gregg and Siegel, 2001). We briefly consider the two that, according to the current literature, might be most directly applied to understanding human aggression. These are predatory and reactive aggression.

PREDATORY AGGRESSION

Predatory aggression occurs during food seeking in certain omnivorous and carnivorous species. It involves methodological stalking, well-directed pouncing, and quiet biting attack. If predatory aggression is induced through stimulation of the brain, there will be attacks on live prey but also bites of dead prey. However, attacks on conspecifics will not be initiated. Electrical stimulation of a circuit including dorsolateral hypothalamus and the ventral half of the periaqueductal gray (PAG) has been shown to initiate predatory aggression in both rats and cats (Panksepp, 1998).

REACTIVE AGGRESSION

Animals demonstrate a graded and instinctual response to threat. Distant threats induce freezing, and then, as the threats draw closer, they induce flight, and finally reactive aggression when they are very close and escape is impossible (Blanchard et al., 1977). As such, reactive aggression involves unplanned,

enraged attacks on the object perceived to be the source of the threat or frustration. The animal exhibits piloerection, autonomic arousal, hissing, and growling during their attack. Reactive aggression appears to be mediated via a circuit that runs from the medial amygdala downward, largely via the stria terminalis to the medial hypothalamus and from there to the dorsal half of the PAG (Gregg and Siegel, 2001; Lin et al., 2011; Nelson and Trainor, 2007; Panksepp, 1998;). There have been suggestions that this is a social behavior network from which aggressive behavior is an emergent property (Nelson and Trainor, 2007). However, more recent data suggest rather that overlapping but distinct neuronal subpopulations are involved in different social behaviors such as fighting and mating (Lin et al., 2011). It has also been argued that orbitofrontal cortex (OFC) has an inhibitory impact on this network (Nelson and Trainor, 2007), a claim that will be considered in greater detail in the following.

HUMAN AGGRESSION

In work on human aggression, a fundamental distinction is drawn between instrumental (proactive/planned) and reactive (affective/defensive/impulsive) aggression. This distinction has been made for some time (Crick and Dodge, 1996) even if consideration of the implications of this distinction for the neurobiology of human aggression is only more recent (Blair, 2001).

Instrumental aggression involves the planned execution of aggression. It can involve both overt and covert actions executed with forethought and a degree of planning. The anticipated outcome is positive as seen from the viewpoint of the aggressor: acquisition of territory or goods, improvement of social status, gratification of a perceived need. Typically, there is a relative absence of intense emotion.

In humans, reactive aggression is unplanned aggression that can be most often characterized as impulsive. These acts are often overt, explosive, and involve the active confrontation of the victim. Accompanying emotions are almost always negative (fear of retaliation, anger, sadness, frustration, and irritation). One notable feature distinguishing human reactive aggression from that studied in animals is that it has been associated with frustration (Berkowitz, 1993). Frustration occurs when an individual continues to do an action in the expectation of a reward but does not actually receive that reward (Berkowitz, 1993).

Instrumental and reactive aggression cluster differentially in confirmatory factor analyses with moderate correlations

between the two dimensions (Crick and Dodge, 1996). Studies indicate that approximately 10% of children show elevated levels of instrumental *and* reactive aggression, 3% show elevated instrumental aggression only, and 6% show elevated reactive aggression only (Dodge et al., 1997). Instrumental and reactive aggression have distinct trajectories. (Those with both forms followed a pattern similar to those with instrumental aggression only.) Thus, Dodge and colleagues (1997) observed that children with reactive aggression had an earlier onset (4.5 years vs. 6.5 years for proactive), were more likely (21%) to have experienced physical abuse or aversive parenting, had poorer peer relations, and inadequate problem-solving patterns. The instrumentally aggressive children were more likely to have had aggressive role models in the family and to view aggression positively (Dodge et al., 1997). Similarly, different psychiatric conditions are associated with risks for different forms of aggression. Thus, patients with mood and anxiety conditions (e.g., bipolar disorder and posttraumatic stress disorder, as well as patients with intermittent explosive disorder and borderline personality disorder [BPD]) are at risk for increased reactive aggression. In contrast, individuals with the personality disorder psychopathy show an increased risk for instrumental aggression coupled with an increased risk for reactive aggression (Frick et al., 2005).

It should be noted that the instrumental–reactive dichotomy of aggression has received significant criticism (Bushman and Anderson, 2001). Specifically, whether individual aggressive acts can be reliably classified as reactive or instrumental has been questioned. This criticism may be overstated. Most would agree that the aggression of an individual punching a person who has startled him or her is different from that of an individual pointing a gun at another person and demanding his or her wallet. Moreover, there are identifiable differences in the neural circuitry mediating reactive and instrumental aggression, as detailed in the following. But the criticism of the dichotomy was not without merit. How should one classify the aggression of the person who shoots someone five days after discovering the victim had been having an affair with the shooter’s spouse? There is a clear reactive component (anger, frustration, and confrontation), and yet the action is planned and, by using a gun, definitively instrumental. In short, it may be necessary to consider forms of aggression beyond the instrumental–reactive dichotomy such as aggression in which the functional contributions of the neural systems engaged in instrumental and those engaged in reactive aggression are both involved.

INSTRUMENTAL AGGRESSION

There have been suggestions that the animal work on the neurobiology of predatory aggression may provide information on human instrumental aggression (Gregg and Siegel, 2001). However, this appears unlikely. Instrumental aggression is a flexible way of achieving an individual’s goals rather than an instinctual response to the presence of a prey animal. It is flexible and highly influenced by the individual’s learning environment; for example, environmental factors play a

large role in determining the choice of weapons from fists to pistols. In contrast, whereas predatory aggression in animals may serve the goal of providing the animal with food, it is an instinctual motor program initiated by the presence of prey in the environment that occurs in a relatively fixed fashion; that is, ending with a bite to the neck. Moreover, predatory aggression in animals is not displayed to conspecifics. In contrast, instrumental aggression in humans is almost always displayed to conspecifics. As such, it appears unlikely that most instrumental aggression in humans recruits the subcortical circuits identified in animal work that mediate predatory aggression. Instead, when considering the neurobiology of instrumental aggression in humans, we are considering the neurobiology of instrumental motor responding generally (regions implicated include, e.g., premotor cortex, striatum, and the cerebellum) and, critically, the emotional learning and representational systems that allow the selection of one action over another.

There is only one *clinical* condition associated with an increased risk for *instrumental* aggression: conduct disorder (CD) in childhood and antisocial personality disorder (ASPD) in adulthood. However, it is important to remember that youth with CD and adults with ASPD are not considered to be homogeneous groups (Blair, 2001). Specifically, individuals differ according to their level of callous–unemotional (CU) traits (i.e., the degree to which they show reduced guilt and empathy). Level of CU traits in individuals with CD/ASPD have been shown to modulate BOLD responses within the amygdala to social cues (Marsh et al., 2008; White et al., in press) and within the amygdala and ventromedial frontal cortex (vmPFC) during moral reasoning (Marsh et al., 2011). Callous–unemotional traits are inversely related to mood and anxiety symptoms (Patrick, 1994) and it is individuals with elevated CU traits who are at particular risk for instrumental aggression (Frick et al., 2005).

Instrumental aggression can be adaptive. A starving individual who pushes someone over and takes his or her money is not making a poor decision from that person’s own perspective (whatever its value from a societal perspective). The benefit of the soon-to-be purchased food will significantly outweigh the costs of causing (minor) injury to the victim/risking jail. However, an individual who stabs another to death for \$80 to purchase a mobile phone is going to be considered, by most individuals, to be making a poor decision. The aggression is maladaptive. The benefits should be represented as significantly less than the costs. An increased risk for (maladaptive) instrumental aggression can emerge *following the specific forms of decision-making impairment seen in individuals with elevated CU traits*.

There are three clear components necessary to make a good decision. The individual must: (1) learn the value of the options to be chosen among; (2) successfully represent this value information so the options *can* be chosen among; and (3) successfully choose among the options. Individuals with elevated CU traits appear to have particular difficulties with at least the first two of these components.

Learning the value of options to be chosen among requires stimulus–reinforcement learning. The individual must associate

a reinforcement value with the stimulus. A classic measure of stimulus-reinforcement learning is aversive conditioning—the individual learns that a particular stimulus is associated with threat. Individuals with elevated CU traits show marked impairment in stimulus-reinforcement learning. Indeed, an individual's ability to perform aversive conditioning at 15 years has predictive power regarding whether that individual will display antisocial behavior 14 years later (Raine et al., 1996). Considerable animal and human work shows that the amygdala is critical for aversive conditioning (LeDoux, 2007). Individuals with elevated CU traits show reduced amygdala responses during aversive conditioning (Birbaumer et al., 2005).

A critical cue for reinforcement based learning is the prediction error; that is, the difference between the reinforcement the individual expects to receive and that which he or she does receive. According to learning theory, the greater the prediction error, the faster the learning should occur (Rescorla and Wagner, 1972). Regions implicated in prediction error signaling include the caudate and vmPFC (O'Doherty et al., 2003). Youth with CD and elevated CU traits (requisite studies in adult samples have not been conducted) show indications of impaired prediction error signaling within both the caudate and vmPFC (Finger et al., 2008, 2011).

As the individual learns to associate reinforcement with an object or action, it acquires an expected value. Good decision making by definition involves the selection of an action/stimulus with the highest expected value. vmPFC is critically involved in the representation of expected value (Glascher et al., 2009). Youth with CD show disrupted representation of expected value within vmPFC (Finger et al., 2011).

A critical form of reinforcement for human social interactions involves emotional expressions (Blair, 2003). An individual can show distress by displaying pain, fear, or sadness.

To learn to avoid actions that harm others, one must appropriately represent the distress of others. Youth and adults with elevated CU traits show: (1) reduced autonomic responses to the pain of others (Aniskiewicz, 1979); (2) reduced recognition of fearful and sad expressions (for a metaanalysis, see Marsh and Blair, 2008); and (3) reduced amygdala responses to these expressions (Marsh et al., 2008). The amygdala is thought to allow the individual to associate the distress of others with actions/objects that have caused that distress—this is considered the basis for human socialization (Blair, 2007). Indeed, recent animal work has confirmed that the amygdala is critical for this form of learning (Jeon et al., 2010). In line with their expression processing impairments, the presence of CU traits has been shown to interfere with the child's ability to be socialized using standard parenting techniques (Wootton et al., 1997).

In summary, Figure 85.1 depicts the integrated systems that are dysfunctional in individuals with elevated CU traits and that, through their dysfunction, increase the risk for instrumental aggression. The caudate and vmPFC are involved in prediction error signaling; detecting when a reward or punishment is greater or lesser than expected. Prediction error signals trigger reinforcement learning—they signal to the system that the current reinforcement expectancies are inadequate. If prediction error signaling is disrupted, as data suggest it is in individuals with elevated CU traits, learning about the value of actions and objects will be impaired. The amygdala is involved in stimulus-reinforcement learning allowing the individual to associate reinforcement expectancy values with objects and actions. Again if stimulus-reinforcement learning is disrupted, as data suggest it is in individuals with elevated CU traits, learning about the value of actions and objects will be impaired. A critical type of reinforcement for human social

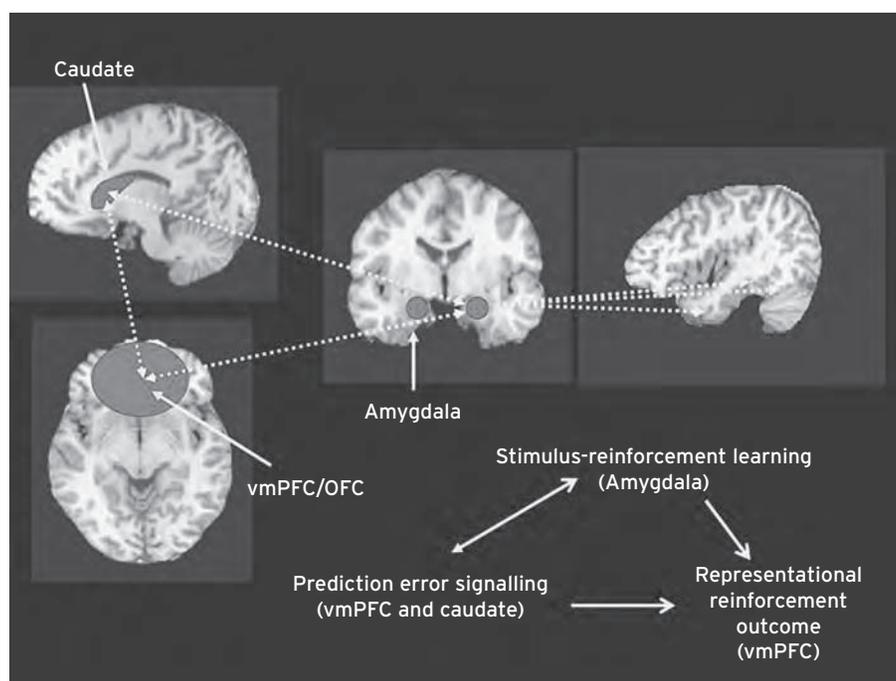

Figure 85.1 The neurobiology of callous-unemotional traits.

interaction is provided by emotional expressions. To learn to avoid actions that harm others one must associate the aversive qualities of the other individual's distress with the object/action that caused this distress. The amygdala is critical for this form of stimulus-reinforcement learning, which again appears disrupted in individuals with elevated CU traits. This learning process is critical for socialization; if disrupted, it will interfere with socialization. Individuals with elevated CU traits show significantly less impact of standard socialization practices than typically developing youth. Poorer stimulus-reinforcement learning and responsiveness to the distress of others lead to an individual who represents more poorly the expected value of objects and actions (including the aversiveness of harmful consequences for others). The vmPFC is critical for the representation of expected value. This representation is also disrupted in individuals with elevated CU traits, further contributing to their decision-making impairment. One manifestation of this decision-making impairment is the selection of maladaptive instrumental aggression/antisocial behavior; that is, choosing antisocial behaviors with inadequate representation of both their potential rewards and their potential aversive consequences.

REACTIVE AGGRESSION

As noted, reactive aggression is considered to be an automatic response to extreme threat that animal work shows is mediated via a circuit that runs from the medial amygdala downward, largely via the stria terminalis to the medial hypothalamus, and from there to the dorsal half of the PAG (Gregg and Siegel, 2001; Panksepp 1998). This circuitry is assumed to mediate reactive aggression in humans also (Blair, 2001) and to be regulated via frontal cortical regions, particularly vmPFC and potentially regions of anterior cingulate cortex (ACC).

There are two main ways that reactive aggression has been investigated in work with humans, by: (1) examining the pathophysiology of patients at increased risk for reactive aggression; and (2) conducting studies with healthy adults performing putative analogues of reactive aggression.

Several psychiatric conditions show a particularly marked increase in the risk for reactive aggression; for example, intermittent explosive disorder, BPD, and severe mood dysregulation in childhood (Coccaro et al., 2009). In addition, Raine and colleagues have done some work with a population of spouse abusers whose aggression was carefully characterized as reactive rather than instrumental (Lee et al., 2008).

Given the animal literature on reactive aggression, it can be predicted that individuals with a heightened risk for the display of reactive aggression will show heightened responsiveness of regions implicated in reactive aggression to emotional provocation (Blair, 2001); that is, the amygdala, hypothalamus, and PAG (Gregg and Siegel, 2001; Lin et al., 2011; Nelson and Trainor, 2007; Panksepp 1998). In line with this suggestion, patients with intermittent explosive disorder and BPD and reactively aggressive spouse abusers all show increased amygdala responsiveness to threatening stimuli relative to

comparison individuals (Coccaro et al., 2007; Lee et al., 2008; New et al., 2009). Patients with BPD have also been found to show an increased amygdala response to interpersonal provocation (New et al., 2009). However, none of these studies reported either increased responsiveness of the hypothalamus or the PAG—although this lack likely reflects methodology, neither region is typically investigated in current functional magnetic resonance imaging work.

What about the regulatory role of frontal cortex? Certainly at least some patients with OFC lesions are at increased risk for reactive aggression (Grafman et al., 1996). This is in line with animal work that shows that lesions of the OFC can increase aggression (Izquierdo et al., 2005).

But what is the nature of this regulatory role? The dominant view is that the OFC inhibits (“puts the brakes on”) the aggressive responses mediated by the amygdala, hypothalamus, and PAG (Heinz et al., 2011; Nelson and Trainor, 2007), but this view is probably wrong. If the OFC was having an inhibitory effect on systems engaged in threat behavior, one might assume that all threat related behavior would be increased following OFC lesions. In contrast, macaques while showing an increase in mild aggression following OFC lesions showed a significantly *decreased* fear reaction to novel threat stimuli (Izquierdo et al., 2005). Moreover, there are data showing that OFC lesions lead to a reduction in amygdala activity in the context of decision-making paradigms (Schoenbaum and Roesch, 2005).

Work with psychiatric patients at increased risk for reactive aggression is often assumed to support the frontal inhibitory position. It is assumed that patients at risk for reactive aggression will show disruption in the ability to recruit OFC in response to emotional provocation. However, data supporting this hypothesis are notably sparse.

There was a report of reduced activation in spouse abusers proximal to the right ACC and left middle frontal gyrus during the emotional Stroop test (Lee et al., 2008). However, it should be noted that these indications of hypofrontality were not seen in a second study by the same group on this population. Moreover, those from the first study involved a region that was white rather than gray matter and thus must be considered with caution. Similarly, data on patients with BPD have been mixed. For example, although some studies report reduced ACC activity during emotional provocation (New et al., 2009), others do not (Herpertz et al., 2001).

In short, it appears probable that the relationship of vmPFC to the amygdala is not simply suppressive. Animal work clearly demonstrates that lesions of vmPFC do not lead to disinhibited/increased amygdala responding as the “brakes type” regulatory view predicts. Lesions of vmPFC/OFC *decrease* amygdala responding (Schoenbaum and Roesch, 2005) and decrease fear reactions to novel threat stimuli (Izquierdo et al., 2005). Work with patients does not consistently support the view of decreased vmPFC/OFC activity in response to emotional provocation in patients at risk for heightened levels of aggression.

It is perhaps important to consider a core function of vmPFC/OFC outlined in the preceding section (i.e., its role in the representation of the value of an object or action) and

the integrated nature of the role with the functioning of the amygdala and caudate. According to this view of integrated functioning, vmPFC/OFC dysfunction should reduce, not increase, amygdala responsiveness (cf., Schoenbaum and Roesch, 2005) and should consequently lead to a reduction, not an increase, in fear reactions to novel threat stimuli (cf., Izquierdo et al., 2005). Within this view, lesions of vmPFC/OFC will increase reactive aggression not because the aggressive response is disinhibited but rather because the costs and benefits of engaging in reactive aggression are not properly represented. Of course, this view places an instrumental slant on many occasions of reactive aggression; that is, although reactive aggression may be an automatic response to an extreme threat, it may also be a selected response (as fear reactions to novel threat stimuli are too; Izquierdo et al., 2005). In this regard, it is notable that the aggression shown by primates following OFC lesions correlates highly with the aggression shown to the primate by other primates (Bachevalier et al., 2011). As such, the increased aggression may be just one reflection of poorer behavioral choices in the primate following the OFC lesion. This point is returned to in the following.

The second main ways that reactive aggression has been investigated in humans involves subjects performing putative analogues of reactive aggression; for example, the Taylor Aggression Paradigm (TAP; Taylor, 1967) and the Point Subtraction Aggression Paradigm (PSAP; Cherek et al., 1997). In the TAP, subjects are instructed that they are playing successive competitive reaction time trials against opponents. They are told that whoever lost a trial would be punished by the opponent with aversive thermal stimulation. Opponents can be predetermined, for example, to differ in provocation (i.e., the amount that they punish the subject). The subject's aggressive responses (retaliatory punishments of the opponent) are a function of provocation level. The similar PSAP examines the subject's responses to the subtraction of points worth money that he or she is accumulating during a testing session in which losses are attributed to the responding of another person. At each moment, the subject can choose to press button A (pressing 100 times earns money), button B (that will take points away from the fictitious person), or button C (that will protect the subject's point total for a set number of trials). Work has demonstrated that increases in provocation by the fictitious player increase retaliatory "aggressive" B responses in the subject (Cherek et al., 1997; New et al., 2009).

Relatively little functional imaging studies have been conducted with these paradigms. There have been reports of increased responding within dorsomedial prefrontal cortex, anterior insula cortex (AIC), and caudate to highly provoking confederates relative to less provoking confederates (Kramer et al., 2008). However, in none of this work was amygdala, hypothalamus, or PAG implicated, with the exception of a study investigating the response of individuals with psychopathy (there was no comparison group; Veit et al., 2010). This study reported that inflicting high relative to low punishments to the competitor was associated with increased activity within the AIC, amygdala, and hypothalamus (extending proximal to the PAG).

The literature on the TAP and PSAP shares interesting similarities with the more extensive literature on social exchange paradigms. In social exchange paradigms, a proposer suggests an allocation of resources and typically the subject decides whether or not to accept this allocation and/or punish the proposer for the unfairness of his offer. As such, social exchange paradigms can be considered social provocation paradigms like the TAP and PSAP. Notably unfair offers are associated with anger, and likely aggression, in the receiving party (Sanfey et al., 2003).

Unfair offers by proposers during social exchange paradigms have been found to elicit activity in subjects within both AIC/inferior frontal cortex (IFC), dorsomedial frontal cortex (dmFC), and striatum (Sanfey et al., 2003; King-Casas et al., 2008; White et al., in press). There have been suggestions that activity within these regions reflects anger elicited by unfairness to the self (Sanfey et al., 2003) or that they play a critical role in detecting and reacting to social norm violations (King-Casas et al., 2008). Indeed, it has been argued AIC/IFC responds to anger/expectations of anger (including in response to norm violations) and organize a behavioral response (Blair and Cipolotti, 2000). In this regard, it appears that part of this organization involves the recruitment of the PAG (e.g., White et al., in press). Decisions to reject the proposer's unfair offers, like decisions to punish another's provocation on the TAP (Veit et al., 2010), are associated with increased activity within dmFC, AIC/IFC, and striatum as well as the PAG (White et al., 2013).

It is interesting in this regard that dmFC and AIC/IFC also show increased activation following unexpected punishments during, for example, reversal learning tasks (e.g., Budhani et al., 2007). Again the assumption is that dmFC responds to the expectation violation (Alexander and Brown, 2011)—in this case the unexpected punishment—and that AIC/IFC organizes a behavioral response. This might involve a change in behavior but it also, as a definitively frustrating event, might involve the initiation of a frustration based reactive aggression episode.

It was argued in the preceding that reactive aggression can be a selected response and that vmPFC lesions increase reactive aggression because the costs and benefits of engaging in reactive aggression are not properly represented. This is important to remember when considering the literature on the PSAP, TAP, or social exchange literature. These paradigms are not modeling an instinctual response to threat or intruders but rather a planned response to another individual's provocative behavior. As successful as these models have been of "reactive aggression," they would appear to be rather more applicable to cases of "instrumental reactive aggression" mentioned in the preceding.

In summary, Figure 85.2 depicts the neural systems involved in the expression of reactive aggression (amygdala, hypothalamus, and PAG) as well as systems implicated in modifying the probability that reactive aggression will be expressed (vmPFC, AIC, and dmFC). Increasing emotional provocation by threat will increase activity in amygdala, hypothalamus, and PAG until, at sufficient strength, reactive aggression will be displayed. Anxiety and mood disorders are associated with an increased

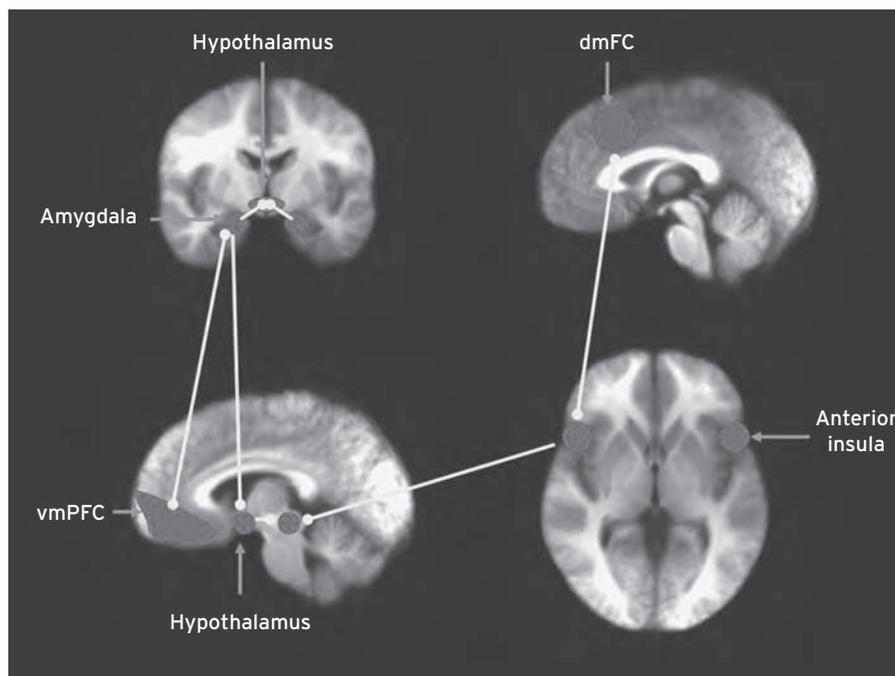

Figure 85.2 The neural systems involved in the expression of reactive aggression.

risk for reactive aggression because they involve an increase in the underlying responsiveness of at least parts of this circuit. Emotional regulation, even if it does not involve vmPFC placing the brakes on the amygdala, will reduce responsiveness and thus decrease the probability that reactive aggression will be displayed.

The dmFC and AIC show increased responses to provocation in the context of reactive aggression paradigms (Kramer et al., 2008) and in response to unfair offers in social exchange paradigms (King-Casas et al., 2008; Sanfey et al., 2003; White et al., 2013). They also show increased responses to frustration as initiated by an unexpected punishment for an action expected to result in reward (e.g., Budhani et al., 2007). Retaliatory responses are also associated with dmFC and AIC activity as well as the PAG (White et al., 2013). The suggestion is that the anger initiated by the expectation violation of the other's inappropriate behavior (delivering shocks or making unfair offers) corresponds to expectation violation signaling and behavioral control mediated by dmFC and AIC. The suggestion would be that this activity could be maintained, or at least reinitiated, whenever the individual considers the provocation and this could potentially lead to an angry aggressive response that will have instrumental components (in that it may be planned; e.g., the person goes home to obtain a weapon before attacking the victim).

The vmPFC allows the representation of the value of an object or an action. The suggestion is that vmPFC's role in reactive aggression corresponds to its role in action selection. If it is impaired, reactive aggression may be more likely to be expressed. (The individual may have generated anger following provocation but did not represent the aversive consequences of the expression of this anger to themselves or others.)

MOLECULAR MECHANISMS

Some work has indicated that antisocial personality disorder and aggression are heritable. Reviews have suggested that a genetic effect could account for up to 50% of the variance in aggression (Miles and Carey, 1997). Unfortunately, almost all of the literature has failed to consider the heterogeneity within aggressive individuals. There have been indications that CU traits are highly heritable and that aggression only appears to be highly heritable in those with elevated CU traits (the suggestion has been made the aggression of aggressive individuals with low CU traits is more environmentally determined; Viding et al., 2005). However, it is perhaps unlikely that only CU traits, and not the emotional lability underlying the selectively increased risk for reactive aggression, are under genetic influence. Indeed there is molecular evidence that genetic polymorphisms associated with increased emotional reactivity are associated with an increased risk for reactive aggression (Brunner et al., 1993; Heinz et al., 2011). Given this, an attempt will be made here to filter the existing genetic literature though what is known about the neurocognitive architectures mediating different forms of aggression.

SEROTONIN

Serotonin has long been implicated in the regulation of aggression, particularly reactive aggression. Generally, experimental manipulations that increase 5-HT receptor activation have been found to decrease aggression, whereas those that decrease receptor activation have been found to increase aggression (Heinz et al., 2011).

Some of the most dramatic work indicating a relationship between serotonin and aggression has been molecular genetic

work. Prominent among this work are studies examining the gene that encodes monoamine oxidase A (MAOA, a catabolic enzyme that breaks down biogenic amines including serotonin). In a seminal study, a single mutation in this gene was associated with criminal/antisocial behavior (Brunner et al., 1993). Although the human functional knockout is rare, there are common polymorphisms in MAOA. The most studied of these is a variable-number tandem repeat (VNTR) polymorphism in the upstream region of the gene, known as the MAOA uVNTR. Certain alleles in this region are associated with higher MAOA expression (MAOA-H alleles), whereas others are associated with lower expression (MAOA-L alleles) (Heinz et al., 2011). MAOA-L subjects (compared with MAOA-H subjects), like other individuals at increased risk for reactive aggression (see the preceding), show heightened amygdala responsiveness to threat stimuli such as angry and fearful faces (Heinz et al., 2011). Moreover, MAOA-L variant subjects are at increased risk for the display of reactive aggression particularly if the individual has been exposed to abuse (Caspi et al., 2002).

Polymorphisms of the 5-HTT gene (*5-HTTLPR*) also appear to increase risk for reactive aggression particularly if the individual has been exposed to abuse (Reif et al., 2007). Similarly, the common polymorphism of the 5-HTT gene (the *5-HTTLPR* S allele) is associated with increased amygdala activation in response to aversive pictures and with a higher risk of experiencing negative mood states when exposed to traumatic life events (Heinz et al., 2011). The suggestion would be that both these MAOA and *5-HTTLPR* polymorphisms and abuse increase responsiveness of the basic threat circuitry (amygdala-hypothalamus-PAG). It appears that the effects of these stressors are interactive rather than simply cumulative; genetic load predisposes the individual to be considerably more impacted by stressful events, considerably increasing the risk for reactive aggression.

DOPAMINE

Considerable animal work has shown that dopamine decreases the threshold for aggressive reaction in response to external stimuli, although an excess of these hormones increases the vulnerability and the risk of uncontrolled responses against stress (Volavka et al., 2004). Much of the human work has considered the involvement of the dopaminergic system in impulsivity rather than aggression. However, there has been some particularly interesting work examining the relationship of the catechol-O-methyl transferase (COMT) gene in aggression.

Many studies evaluating the impact of COMT to the genetics of aggression focused on the characterization of the Val158-Met polymorphism. This polymorphism is interesting functionally as there is almost a two fold decrease in the enzymatic activity of the Met158 variant compared to the Val158-encoding allele. In line with animal work showing that heterozygous COMT-deficient male mice exhibited increased aggressive behavior (Heinz et al., 2011), the allele Met158 of COMT has been found to be associated with aggressive personality traits and a propensity for aggression in humans (Rujescu et al., 2003). Importantly, the data again,

for the most part, indicate that individuals with the Met allele show increased amygdala responsiveness to emotional provocation (e.g., Smolka et al., 2005).

γ-AMINO BUTYRIC ACID

Alcohol and benzodiazepines have been consistently shown to increase aggression (Fish et al., 2001). Both have an inhibitory effect on cortical activation, by inducing GABA release and stimulating GABA type A (GABAA) and GABAB receptors and their aggression-heightening effects can be potentiated by their co-administration (Fish et al., 2001).

Acute alcohol use is implicated in approximately one-half of all violent crimes and sexual assaults, and also confers risk for intimate partner violence. Treatment with benzodiazepines has been shown to increase the risk of aggression (Gardner and Cowdry, 1985).

It has been suggested that aggression may result from acute alcohol effects that impair prefrontal cortex mediated executive functions and disinhibit limbic processing of threatening stimuli, and elicit reactive aggression (Heinz et al., 2011). However, current data are rather inconsistent with this view—at least with respect to the disinhibition of limbic responsiveness. Thus, administration of alcohol leads to a *reduction*, rather than an increase, in the amygdala's response to threatening stimuli (Gilman and Hommer, 2008) as does administration of diazepam (Del-Ben et al., 2012). In other words, acute administration of both alcohol and diazepam *inhibits* rather than *disinhibits* limbic responsiveness.

Alcohol is thought to disrupt decision making in that it increases the probability of maladaptive risk-taking behavior, including risky sexual activity, unsafe driving, and aggression (for a review, see Hommer et al., 2011). However, relatively little work has formally demonstrated decision-making deficits following alcohol ingestion. Somewhat more work has examined reward sensitivity in alcoholics, in which there does appear to be reduced reward sensitivity (Hommer et al., 2011).

In summary, there is a growing literature on the molecular mechanisms underpinning aggression, with some of the most provocative data being provided by molecular genetics. Serotonin decreases the risk for reactive aggression, whereas dopamine increases it. Both alter the sensitivity of the basic threat circuitry (particularly the amygdala). Polymorphisms of serotonin (e.g., MAOA and *5-HTTLPR*) and dopamine (e.g., COMT) genes that are associated with an increased risk for aggression are also those polymorphisms associated with increased amygdala responsiveness.

The relationship between alcohol (and probably the benzodiazepines) and aggression appears rather different though. Ingestion of either reduces, rather than increases, amygdala responsiveness to emotional stimuli. Moreover, ingestion of alcohol appears to lead to decision-making impairments (although the precise computational basis of these impairments has not yet been well specified). As such, ingestion of alcohol appears to induce a state of increased CU (although the similarities can only be really determined when the details on the decision-making impairment are specified).

CONCLUSIONS

Considerable progress is continuing to be made in understanding the neurobiological basis of human aggression. The neurobiological circuits distinguishing instrumental from reactive aggression continue to be further specified. However, it is becoming clearer that these circuits can overlap in function. Thus, for example, the expression of rage- and frustration-induced reactive aggressive episodes can come under the control of systems involved in the representation of reinforcement value (vmPFC) that are critical for understanding instrumental aggression.

Instrumental aggression is mediated by the same cortical circuits that mediate other forms of instrumental behavior (e.g., premotor cortex and the cerebellum). Individuals may choose to engage in instrumental aggression if their representations of the benefits of the action outweigh their representations of the costs of the action (particularly if no other more beneficial action is available). Instrumental aggression can be considered maladaptive if the individuals have failed to learn the appropriate reinforcements associated with the action; that is, they have an inadequate representation of the distress of the victim, show impairment in stimulus-reinforcement learning, and show impairment in the representation of reinforcement expectancies. These capacities are reliant on the functional integrity of the amygdala, caudate, and vmPFC. Impairments in these capacities are seen in individuals who show elevated CU traits, individuals who are at risk for increased levels of instrumental aggression.

Reactive aggression involves a motor response driven by the amygdala, hypothalamus, and PAG that is modulated by the vmPFC's role in the representation of reinforcement value. It represents an ultimate response to threat and is displayed to high level threats and (in humans) also to frustration. If the threat or frustration is sufficiently intense the reactive aggression may be relative automatic. However, it is becoming clearer that in humans and other primates that reactive aggression is under considerable modulation by vmPFC. The individual, anticipating displaying reactive aggression, will represent likely future expected reinforcement values of this action; for example, the value associated with the satisfaction of retaliating to the provoker versus that associated with potential jail time.

Although various neurochemical systems are implicated in the expression and modulation of reactive aggression, the roles of serotonin, dopamine, and GABA are perhaps the best understood. Polymorphisms of serotonin (e.g., MAOA and 5-HTTLPR) and dopamine (e.g., COMT) genes that are associated with an increased risk for aggression are also those polymorphisms associated with increased amygdala responsiveness to threat; that is, they increase the responsiveness of systems involved in the expression of reactive aggression. The ingestion of alcohol, in contrast, reduces amygdala responsiveness to distress and leads to decision-making impairments; that is, it proximally induces a state of increased CU.

These are the neural systems that are dysfunctional in individuals with elevated CU traits and that, through their dysfunction, increase the risk for instrumental aggression. The caudate and vmPFC are involved in prediction error signaling; detecting

when a reward or punishment is greater or lesser than expected. Prediction error signals trigger reinforcement learning—they signal to the system that the current reinforcement expectancies are inadequate. If prediction error signaling is disrupted, as data suggest it is in individuals with elevated CU traits, learning about the value of actions and objects will be impaired. The amygdala is involved in stimulus-reinforcement learning allowing the individual to associate reinforcement expectancy values with objects and actions. Again if stimulus-reinforcement learning is disrupted, as data suggest it is in individuals with elevated CU traits, learning about the value of actions and objects will be impaired. A critical type of reinforcement for human social interaction is provided by emotional expressions. To learn to avoid actions that harm others one must associate the aversive qualities of the other individual's distress with the object or action that caused this distress. The amygdala is critical for this form of stimulus-reinforcement learning, which again appears disrupted in individuals with elevated CU traits. This learning process is critical for socialization and if disrupted will interfere with socialization. Individuals with elevated CU traits show significantly less impact of standard socialization practices than typically developing youth. Poorer stimulus-reinforcement learning and responsiveness to the distress of others will lead to an individual who represents more poorly the expected value of objects and actions, including the aversiveness of harmful consequences for others. The VmPFC is critical for the representation of expected value. This representation is also disrupted in individuals with elevated CU traits, further contributing to their decision-making impairment. One manifestation of this decision-making impairment is the selection of maladaptive instrumental aggression/antisocial behavior; that is, choosing antisocial behaviors with inadequate representation of both their potential rewards and their potential aversive consequences.

These neural systems include those responsible for the basic response to threat (amygdala, hypothalamus, and PAG), which when sufficiently activated by sufficient threat will initiate reactive aggression. In addition, they include the dmFC and AIC. The DmFC responds to expectation violations, whether the expectation violation involves another's provocative behavior or the failure to receive an expected reward following task completion. The suggestion is that it organizes potential behavioral responses through AIC, including reactive aggression expressed through the PAG. Finally, they also include vmPFC. The VmPFC allows the representation of the value of an object or an action. The suggestion is that the vmPFC's role in reactive aggression corresponds to its role in action selection. If it is impaired, reactive aggression may be more likely to be expressed. The individual may have generated anger following provocation or experiencing a frustrating event but not represent the aversive consequences of the expression of this anger to him- or herself or others.

ADAM S. SMITH, KELLY LEI, AND ZUOXIN WANG

Social attachment is a dynamic process, involving multimodal socially relevant sensory information as well as neural systems for attraction, motivation, social recognition, and other cognitive processes to act discriminately in select social environments. Attachments are not simply the absence of social neglect, but these two constructs are not mutually exclusive. Thus, understanding the neurobiological mechanisms underlying social attachment improves knowledge of the neural substrates that govern bond-related behavior, and would provide insight into the etiology of socially related mental disorders. Surprisingly, although social attachments are imperative to survival and success in human and most mammalian societies, the neurobiology behind various bond-dependent behaviors and social attachment itself is only recently coming to light.

The behavioral components of social attachments are highly complex. However, these behaviors that engender infants to bond to their caregivers or two people to fall in love are not beyond appraisal by neurobiological evaluation. In fact, the newly emerged field of social neuroscience (Decety and Cacioppo, 2011) has identified relevantly simple and robust molecular and cellular mechanisms that regulate certain social interactions that propagate social bonding, such as reproductive behavior or parental care (Insel and Fernald, 2004). The form and importance of social attachment depend on the social system. For mammals, mothers are the most vital, if not the only caregiver; thus, reciprocal infant–mother attachments are often crucial to the infant’s survival. In monogamous species, two additional attachments emerge, paternal–infant bonds in bi-parental species and pair bonding between committed partners, to dictate the successful navigation of the social environment. These bonds are coupled to species perpetuation and, therefore, have biological function with decisive evolutionary importance. Several observations have highlighted the role of various monoamines and neuropeptides in regulating bond-dependent behaviors, but there is a larger discussion to be had to understand how various neural systems function in concert to govern social attachments. It is the goal of this chapter to describe the current knowledge of the neurobiology behind each of these social attachments by uncoupling the neurochemistry and neuroanatomy of individual bond-related behaviors, reconstructing uniformed neural systems, and correlating these findings to our understanding of human analogues.

PERSPECTIVES ON A SOCIAL BRAIN

Most mammalian species, especially humans, live in highly complex social systems. Integrating social information to

develop proper behavioral responses is vital to the survival and success of an individual as well as the ability to successfully form social bonds. In understanding the neurobiology of social attachments, it is first worth determining whether there are governing modules in the brain—neural systems dedicated to categorical information—for social behavior.

The social brain hypothesis suggests that behavioral adaptation to ever-increasing complex social society has contributed to the development of neural systems, brain mass, cognitive abilities, processing social information, social communication, and emotionality (Dunbar, 1998). Appropriate behavior during interactions with a conspecific depends on a number of variables associated with the nature of the relationship with the conspecific. For example, the dominant male gorilla (genus *Gorilla*), or silverback, is aggressive toward males intruding into his troop’s territory, a display of mate and resource guarding. However, when confronted with an unfamiliar female, the silverback should display more tolerance as to gain new mating opportunities. One cognitive process that is an essential skill for social life in most gregarious species is social recognition, or the ability to distinguish familiar conspecifics from strangers and to remember previous encounters. Without this skill, an animal could not distinguish between lower- or higher-ranking group members or mates from intruders. Indeed, humans have brain regions adept to recognizing faces and facial emotion. Functional neuroimaging and lesion studies have implicated the fusiform area in the inferior temporal lobe and amygdala as two regions in the human brain that are important for face recognition and determining facial expressions (Adolphs, 2003). In addition, non-human primates also have select brain regions that respond to various aspects of faces, such as expression and gaze direction (Perrett et al., 1992). Similar to humans, regions of the temporal lobe such as the superior temporal sulcus are activated when non-human primates look at conspecific faces. Furthermore, facial information from these temporal regions appears to integrate activity of the amygdala. In other mammalian species that rely more on olfactory cues to obtain social information, such as rodents, there are olfactory and vomeronasal neural systems dedicated to processing olfactory and pheromonal signals that provide relevant information about reproductive and social status.

Genetic studies conducted within the last decade have yielded several new insights about the neuroendocrine regulation of social recognition. Social recognition deficits have been observed in individual lines of genetic knockout mice for norepinephrine, oxytocin, and vasopressin and their receptors. Several studies have demonstrated that targeted injections of

these neurochemicals into the brain of knockout mice can restore social memory and recognition. Many brain regions have been implicated as sites of action for these neurochemicals in rat social recognition, including the olfactory bulb (OB), amygdala, hippocampus, lateral septum (LS), and medial pre-optic area (mPOA). For example, the socially relevant olfactory cues in rodents from the main and accessory olfactory systems converge in the medial subnucleus of the amygdala (MeA). In a series of experiments from Dluguz and colleagues, it was observed that the influence of this pathway on social recognition is mediated by an oxytocin-norepinephrine interaction (reviewed recently in Hammock and Young, 2007). Administration of oxytocin receptor antagonists or antisense DNA into the MeA impaired social recognition in wild-type mice. Similarly, oxytocin-knockout and complete oxytocin receptor-knockout mice have impaired social recognition, but infusion of oxytocin into the MeA of oxytocin-knockout mice reinstates social recognition. Oxytocin infused into the OB minutes before behavioral testing prolongs the social recognition response in rats. Still, oxytocin seems to only enhance regulation of social recognition via norepinephrine action. Blocking oxytocin receptors alone via administration of a selective receptor antagonist does not impede social recognition in rats, but chemical lesions of norepinephrine cells in the OB eliminates the oxytocin-induced enhancements to social recognition in rats. In addition, oxytocin treatments can increase the release of norepinephrine in the OB. Currently, it is suggested that oxytocin promotes norepinephrine action via activation of alpha-2 noradrenergic receptors in the OB, which subsequently suppress local inhibitory granule cells—cells that inhibit output from the OB that is germane to social recognition. This norepinephrine-induced disinhibition of output cells of the OB allows for enhanced signaling from the OB projections to various brain regions to promote social recognition memory. In addition, in a line of forebrain oxytocin receptor-knockout mice, oxytocin receptor expression is reduced in the LS, hippocampus, and ventral pallidum (VP) but remains normal in the MeA, OB, olfactory nucleus, and neocortex compared with wild-type mice. Interestingly, these forebrain oxytocin receptor-knockout mice display only limited social recognition deficits, suggesting a greater role for oxytocin action in non-forebrain structures, such as the OB and MeA, in social recognition.

From the field of social neuroscience (Decety and Cacioppo, 2011) and related fields, there has been evidence to suggest that the social brain has evolved to promote select adaptive social behaviors. These behaviors are associated with and, in a sense, are reinforced by the activation of reward centers in the brain by social cues, ensuring that close social interactions promote positive emotionality, and the negative impact of social stress and loss on mental health and well-being. There has been a major effort to better understand the neurobiological mechanisms governing these behaviors to further appreciate the basis of social bonding. Information gleaned from these studies also has the potential to identify underlying mechanisms of many human mental disorders—such as autism, social anxiety, and schizophrenia—as a major diagnostic component of these disorders includes the inability to properly form social bonds.

PARENT–OFFSPRING BONDING

Proper parenting and formation of parent–infant attachments are considered the cornerstone of an individual's well-being and adaptation throughout life. Discovering the neurobiological basis of the parent–infant bonding process may be invaluable for understanding the natural consequences of disruption to bonds and the etiology of associated pathologies. In accordance to Bowlby's (1958) attachment theory, parent–infant attachments must require neural circuitry that regulates social recognition, motivation and reward, and affiliation and emotional processing pathways. Research has been conducted to outline a number of neural substrates that regulate infant–parent, mother–infant, and, when appropriate and to a lesser extent, father–infant attachment spanning over a number of mammalian species. This section reviews such literature.

INFANT–PARENT ATTACHMENT

Infants form an attachment, or affectional bond or tie, with their caregivers, and this attachment is the main source of safety and security for the child. The bond associated with infant attachment is defined by selective preference, approach, and interaction with their caregivers as well as distress during periods of separation from these individuals. Infant attachments may serve to ensure infant–caregiver proximity and elicit infant care from parents, ultimately increasing the probability of survival until maturity and reproduction in offspring. The characterization of imprinting in birds (Bateson, 1966), early social olfactory learning in rabbits (Hudson, 1993) and rats (Raineke et al., 2010), social behavior development in infant non-human primates (Harlow and Suomi, 1971), and bonding in young children (Bowlby, 1958) have produced a foundation for understanding the inception of infant attachment. Bowlby characterized this attachment in four components: (1) infants rapidly form attachments to their caregivers, (2) infants seek close proximity to their caregivers, (3) caregivers reflect safety and security, and (4) infants will endure considerable abuse to remain with their caregivers. These components reflect a secure infant attachment—providing pleasure, safety, and security for the infant—and are germane for infant attachment observed in humans and throughout the animal kingdom.

Infant attachment to caregivers appears to form during a critical period. For infant–mother attachment, the critical period begins before birth when the infant is exposed to and learns different mother-associated cues (e.g., the mother's voice and odor). After birth, the infant learns the mother's face and continues to form an attachment to the mother when the infant pairs the mother's voice and odor learned in the intrauterine environment to the postnatal environment. Infants can also begin forming attachments in early life to other caregivers, such as the father, in the same manner. These caregiver-associated cues induce innate infant behavior (e.g., proximity-seeking and orienting, caregiver–infant skin-to-skin contact, and nipple attachment and milk suckling). From a neurobiological perspective, more knowledge has been gleaned from separation than attachment, but there are three neurochemical systems that have sufficient evidence to be included into a neural circuit of infant attachment (Fig. 86.1A).

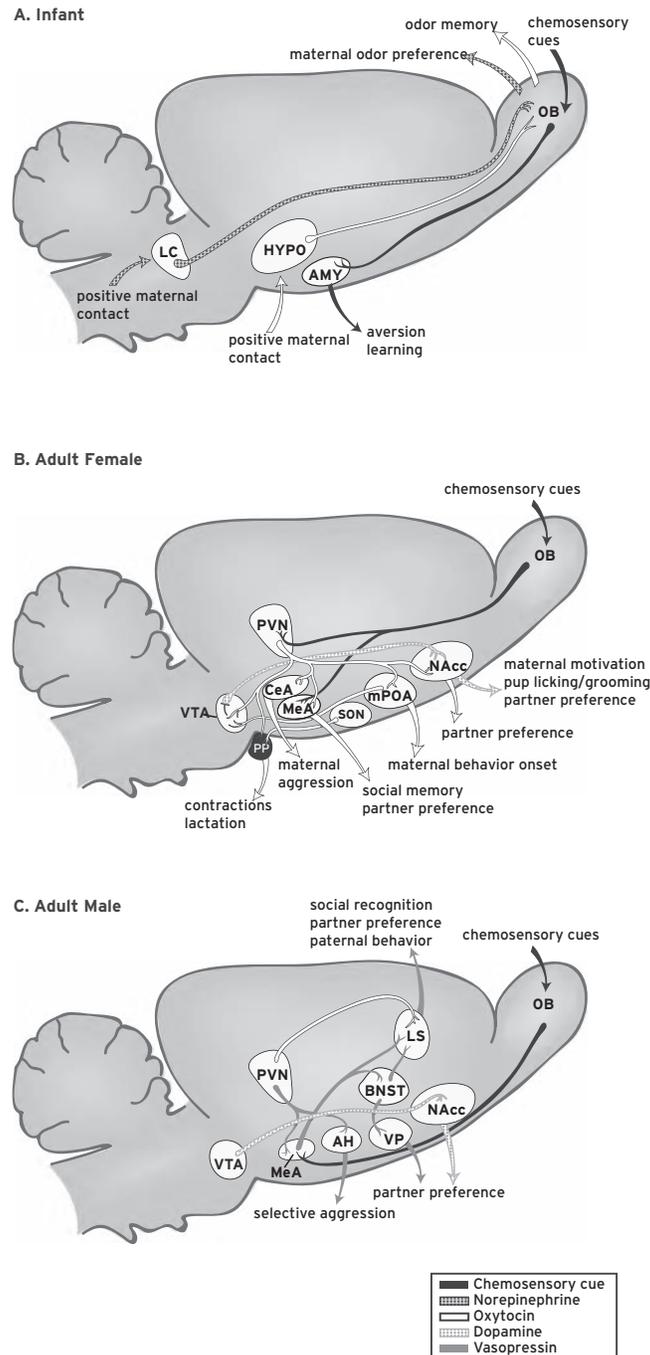

Figure 86.1 Schematic representations of the neurocircuitry required for social bonding in infants, adult females, and adult males. (A) In the infant bonding model, neonatal learning of caregiver-associated odor and odor preference occurs during a sensitive period through olfactory bulb activation, facilitated by norepinephrine from the locus coeruleus (LC) and oxytocin from the hypothalamus (HYPO). Odor aversion learning occurs via amygdala (AMY) signaling, but this pathway is inhibited during the sensitive period that leads to infant attachment. (B) In the adult female bonding model, olfactory signals from the mate or infant are transmitted via the OB to the medial subnucleus of the amygdala (MeA) or paraventricular nucleus of the hypothalamus (PVN). Oxytocin from the PVN or supraoptic nucleus of the hypothalamus (SON) acts in the central subnucleus of the amygdala (CeA), MeA, medial preoptic area (mPOA), nucleus accumbens (NAcc), or posterior lobe of the pituitary gland (PP) to facilitate social memory, childbirth, lactation, and various bond-dependent behaviors, including partner preference and maternal behavior onset and aggression. In addition, oxytocin acts in the ventral tegmental area (VTA) to stimulate dopamine release in the NAcc to promote maternal motivation, infant-directed behaviors, and partner preference formation. (C) In the male bonding model, olfactory signals from the mate or infant transmitted to the MeA from the OB. Vasopressin from the PVN is released in the anterior hypothalamus (AH) to induce selective aggression. In addition, vasopressin from the PVN, MeA, and bed nucleus of the stria terminalis (BNST) acts in the MeA, lateral septum (LS), and ventral pallidum (VP) to promote social recognition, partner preference, and paternal behavior. Oxytocin from the PVN and dopamine from the VTA act in the LS and NAcc, respectively, to facilitate partner preference formation.

NEUROANATOMY AND CHEMICAL SUBSTRATES

In general, altricial species rely, to some degree, on learning about their caregivers to form attachments. This is embodied in the avian imprinting model, occurring at sensitive periods which are limited and restricted to early life (Bateson, 1966). Mammalian infants also display attachment toward their caregivers. For example, the sound and site of their mothers can be strong cues to promote social recognition and attachment for infants, as demonstrated in human infants (DeCasper and Spence, 1986). Mother-associated olfactory cues are also particularly critical for many mammalian species to recognize and preferentially affiliate with the mother, including humans (e.g., Porter and Winberg, 1999). Considering the requisite for infants to display a maternal preference for survival (i.e., orientation, nipple attachment, and huddling), it is advantageous for infants to rapidly form a maternal odor preference and hinder learning that would be aversive to an infant–mother attachment. Olfactory imprinting is particularly important for altricial mammals, like rabbits and rats, as offspring need to remain in the nest while the mother is gone foraging and to orient toward the mother in her presence to procure milk, warmth, and protection. Therefore, infant survival may depend upon the capacity for offspring to learn to approach and remain in close proximity to the mother or other primary caregivers. Sullivan and colleagues have conducted a series of studies noting that during a sensitive period, olfactory discrimination tests show rat pups prefer the odor of the mother (for a recent review, see Raineki et al., 2010). In addition, norepinephrine neurons deriving from the locus coeruleus (LC) regulate function in the OB to promote this maternal odor preference, whereas OB neurons projecting to the amygdala modulate aversion learning. Thus, blocking norepinephrine action in the OB by chemically lesioning the LC or administering a norepinephrine receptor inhibitor hinders learning the mother's odor, or maternal-associated odors, in rat pups. Moreover, odor preferences can be promoted by infusing norepinephrine into the OB, either by exogenous administration or stimulating the LC.

Furthermore, the oxytocin system may promote infant recognition by promoting maternal-associated odor preferences and infant affection by inducing feelings of calmness and stress reduction associated with the mother. Oxytocin facilitates learning of social cues in rat pups, a process inhibited by administration of an oxytocin receptor antagonist (Nelson and Panksepp, 1998). During suckling, the nipple area is a natural source of attraction for the infant, providing significant mother-associated odor and an obvious source of sustenance, and it is during this behavior that oxytocin seems to function in enhancing odor learning. Specifically, this neuropeptide is released in the infant brain during suckling and can act on the OB. In the OB, oxytocin can promote odor memory by augmenting long-term potentiation of neural activation associated with memory (Fang et al., 2008). This provides a significant mechanism in which oxytocin action regulates infant recognition, and ultimately attachment, for the mother. The natural occurrence of skin-to-skin contact between the mother and infant during sucking can also lead to enhanced filial huddling preference in rat pups. Interestingly, release of

oxytocin in the hypothalamus is associated with skin-to-skin contact with the mother (Kojima et al., 2012), and oxytocin administration can promote filial huddling preference in rat pups (Kojima and Alberts, 2011). These data coincide with the volume of research indicating that prosocial mother–infant contact induces release of oxytocin, evaluated in the mother during parturition and nursing. Furthermore, it suggests that hypothalamic oxytocin may be released during maternal contact, a source of cutaneous warmth and tactile stimulation, and subsequently regulates the formation of filial huddling preferences and preference for maternal odor.

Infant–mother interactions also require social approach and motivation circuits. There are a few studies to implicate oxytocinergic and dopaminergic pathways in the formation of maternal-associated olfactory cues. However, more research in humans, non-human primates, sheep, and rats have been conducted to indicate that the endogenous opioid systems can attenuate aversion learning induced by stress from maternal separation and are involved in the motivation of an infant to seek maternal contact, perhaps through natural reward neural circuits. First, maternal separation leads to distress vocalizations in infants, but opioid agonists diminish this behavioral response in a number of mammalian species, including rhesus monkeys, dogs, pigs, sheep, and rats (Nelson and Panksepp, 1998). Interestingly, maternal contact can also lead to diminished distress vocalizations in infants, but this maternal buffering effect is ablated by opioid antagonist administration. In addition, endogenous opioids are involved in the attribution of positive value to maternal contact. Maternal contact and milk transferring are natural sources of endogenous opioid release in infants (Weller and Feldman, 2003). Thus, these mother-associated cues may signal the rewarding effects of maternal contact and motivate infants to maintain proximity and establish an affiliative bond with the mother.

CLINICAL CORRELATES: AUTISM

Children with autism often fail to develop, or display limited, recognition of and attachment to their primary caregivers. Thus, much effort has recently been committed to correlate the neurobiology of normally developed infant attachment to those disrupted by autism to better understand this neuropsychological disorder. The positive relationship between oxytocin transmission in the brain and normal infant–mother bonding has led many to speculate on the function of abnormalities in the oxytocin system in the etiology of autism (for a recent review, see Green and Hollander, 2010). Certainly, several studies indicate that variation in the DNA sequences, known as single nucleotide polymorphisms, which encode for the oxytocin and oxytocin receptor genes, are associated with the propensity of autism in children. Furthermore, infusion of oxytocin in adults with autism and other related disorders, such as Asperger disorder, can alter the display of symptoms such as increasing comprehension and memory of word affect as well as reducing repetitive behaviors (e.g., repeating, self-injuring, and touching). In addition, many studies report a number of prosocial effects from intranasal application of oxytocin, including increased trust, generosity, emotional empathy, and salience of social information as well as socially reinforced learning

(Striepens et al., 2011). Despite these correlative data, abnormal function of the brain oxytocin system of children with autism remains to be demonstrated. Furthermore, the neurotransmitter system serotonin has also been associated with autism; nearly 30% of children with autism have increased blood serotonin levels (Cook and Leventhal, 1996). Serotonin acts as a developmental signal in the brain—promoting neural organization and differentiation, neurite outgrowth, synaptogenesis, dendritic branching, and neurogenesis—before assuming its role as a neurotransmitter (Whitaker-Azmitia, 2001). The serotonin system autoregulates its own development via a negative feedback loop and regulates development of other systems such as the oxytocin system (Martin et al., 2012). Therefore, serotonin may also modulate the effects that other neurochemical systems have on the etiology of autism.

MOTHER-INFANT ATTACHMENT

From birth, mammalian infants rely heavily on the care and protection provided by the mother to reassure survival and proper development. Because the mother is the primary, or sole, caregiver for most mammalian species, the onus of maternal investment is great and tethered to infant survival. It seems that mother–infant interactions (e.g., childbirth, infant-related sensory cues, maternal care, and nursing) and the mother’s own physiology are skewed to foster maternal attachment and a desire to give warmth, comfort, food, and protection. Mother–infant attachment also manifests via increased intrinsically rewarding properties of contact with offspring, increased protective behavior (i.e., maternal defense or aggression), and reduced stress via mother–infant interaction (i.e., infant buffering). Furthermore, some evidence suggests associations among these effects (e.g., maternal aggression and stress: Bosch and Neumann, 2012; Gammie et al., 2008). Development and maturation of a mother–infant attachment are regulated by a variety of neurochemical systems including, but not limited to, the oxytocin, dopamine, and corticotrophin-releasing hormone (CRH) systems, as well as the interaction between these neural systems (see Fig. 86.1B).

NEUROANATOMY AND CHEMICAL SUBSTRATES

In the peripartum period, the mother’s physiology and infant behavior seem to facilitate mother–infant attachments, and oxytocin, a reproductive neuropeptide, may explain these effects. Oxytocin is mainly synthesized in the hypothalamic paraventricular (PVN) and supraoptic (SON) nuclei and is released peripherally via the posterior pituitary in response to distension of the cervix and uterus during labor, leading to contractions of the uterine smooth muscles and succoring birth. After birth, skin-to-skin contact with the newborn, infant pre-feeding behavior (e.g., touching and licking mother’s nipples), and breastfeeding also stimulate increased pulsatile release of oxytocin to promote milk ejection (Matthiesen et al., 2001; Nissen et al., 1995). The fact that oxytocin is pivotal in these behaviors and reproductive functions in which maternal bonding occurs initially led to the suggestion that oxytocin may be involved in the bonding process as well (Nelson and

Panksepp, 1998). In fact, the hypothalamic cells that synthesize oxytocin project to various brain regions throughout cortical areas, the olfactory system, the basal ganglia, the limbic system, the thalamus, the hypothalamus, the brainstem, and the spinal cord that express oxytocin receptors, and many of these brain areas are sensitive to social cues and regulate social affiliation (Gimpl and Fahrenholz, 2001). Furthermore, stimulation of neurons in the PVN can lead to release of oxytocin in the brain, acting on neurons expressing oxytocin receptors. Thus, in addition to female reproductive tissue, the central nervous system is sensitive to oxytocin action.

The release of oxytocin in response to childbirth, lactation, and innate infant behavior act on the maternal brain, changing oxytocinergic neuronal morphology and affecting other neural systems that promote maternal behaviors (Insel, 1992). For instance, oxytocin levels during pregnancy and the peripartum period are related to establishing contact with or checking on the infant, attachment-related thoughts, and infant-directed gazing, vocalizations, touching, and positive affect in women (Feldman et al., 2007), maternal olfactory-based recognition in sheep (Kendrick et al., 1997), and grooming and contact of mother rhesus monkeys with their young (Maestripieri et al., 2009). Thus, the hormonal milieu associated with childbirth, breastfeeding, and innate infant behavior (e.g., mother–infant skin contact and milk suckling) leads to oxytocin release, which reinforces maternal behavior. Ultimately, maternal oxytocin levels have also been associated with higher maternal–infant attachment in women (Galbally et al., 2011).

The laboratory rat has been extensively utilized for studying the effect of oxytocin on maternal care as, unlike most mammalian species, female rats show little interest in infants of their own species, even aversions, until just before parturition when they begin to display maternal care (Fig. 86.2A). This shift in behavior is associated with changes to oxytocinergic neuronal morphology during pregnancy and peripartum that promotes onset of maternal care behaviors, including increased oxytocin gene expression and oxytocin receptor binding in the mPOA (Fig. 86.2A,B). Furthermore, in estrogen-primed nulliparous female rats, central administration of oxytocin facilitates the onset of maternal behavior. These effects were first observed when Pedersen and Prange (1979) noted that intracerebroventricular (ICV) administration of oxytocin will induce full maternal response (i.e., nest-building and grouping, licking, crouching, and retrieval of pups) in estrogen-primed nulliparous female rats. Moreover, blockade of oxytocin action in the brain—chemically via oxytocin receptor antagonist or antiserum or by lesioning oxytocinergic neurons in the hypothalamus—significantly impairs onset of rat maternal behavior. These behavioral effects have also been observed when oxytocin action was manipulation in the mPOA or ventral tegmental area (VTA) in rats and the nucleus accumbens (NAcc) in prairie voles (*Microtus ochrogaster*), indicating selective brain regions for oxytocin-induced maternal care (Pedersen, 2004). For instance, oxytocin injections into the mPOA induce a maternal response in most virgin female rats in which chemical blockade of oxytocin receptors in this brain area prevent the onset of maternal behaviors in lactating rats (Fig. 86.2C,D). Interestingly, postpartum rats displaying

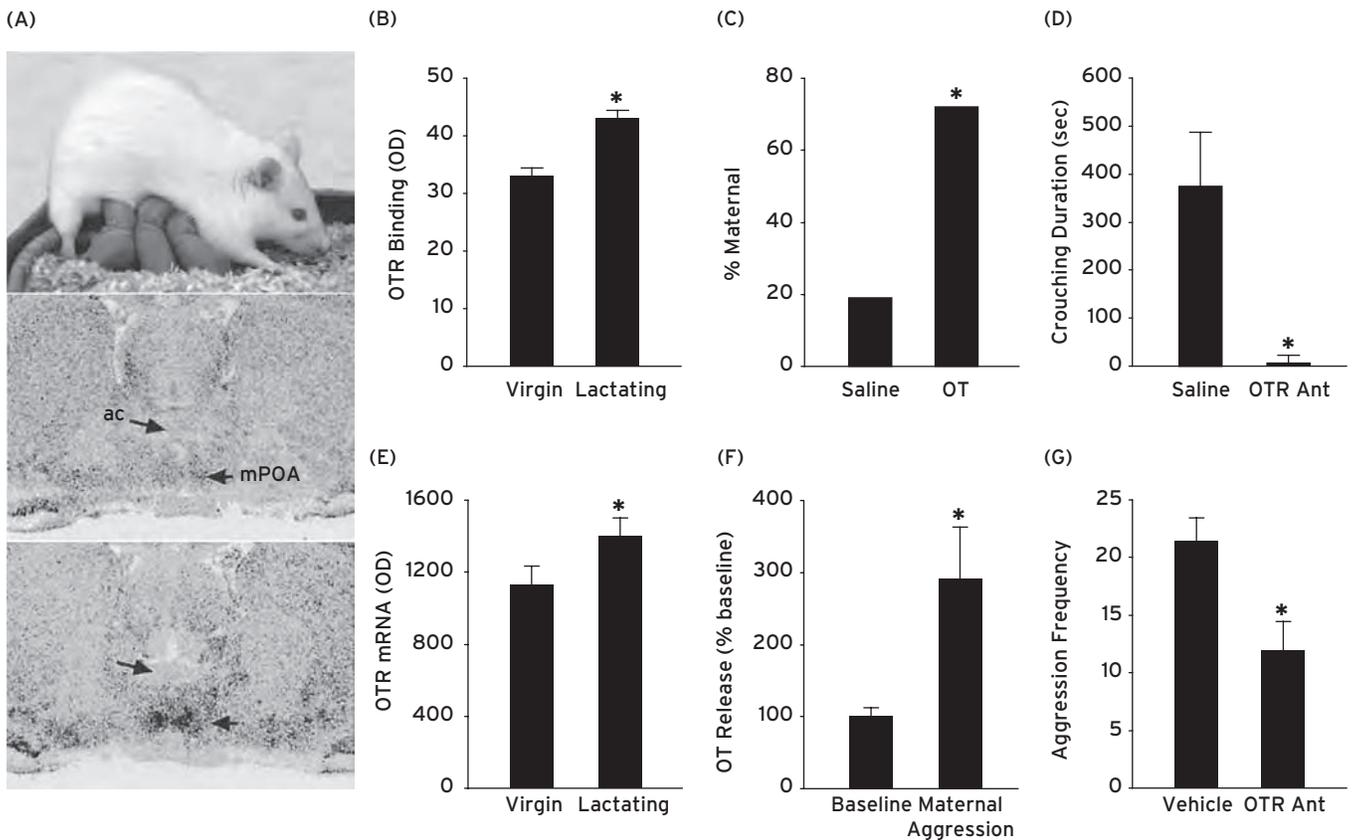

Figure 86.2 Oxytocin (OT) acts in the medial preoptic area (mPOA) to facilitate the onset of maternal behavior and central subnucleus of the amygdala (CeA) to promote maternal aggression in rats. (A) Photo depicts maternal behavior (i.e., arched-back nursing) in female rats (top) as well as differences in oxytocin receptor (OTR) mRNA expression in the mPOA between virgin (middle) and lactating (bottom) female rats. (B) Lactating rats have higher optical densities (OD) of OTR binding in the mPOA than virgin female rats. (C) OT injected in the mPOA induces a higher percentage of virgin female rats to display a full maternal response during a pup interaction test than saline injections. (D) The onset of maternal behavior (e.g., crouching over pups) is inhibited in lactating rats receiving an injection of an OTR antagonist in the mPOA. (E) OTR mRNA expression in the CeA is higher in lactating rats than virgin female rats. (F) OT release in the CeA increases during aggressive interactions with an intruding conspecific during a maternal defense test compared to a period immediately before the onset of the test in which the female rats are undisturbed. (G) Maternal aggression can be reduced via an injection of an OTR antagonist in the CeA. Bars indicate means \pm standard error of the mean. * $p < 0.05$. (Adapted from Bosch et al. (2005); Bosch et al. (2010); Neumann (2008); Pedersen et al. (1982, 1994); Young et al. (1997).)

maternal care are not affected by blocking the central oxytocin system signaling. This suggests that oxytocin is required for the onset of rat maternal behavior but is not involved in the maintenance of these behaviors.

In the brain, oxytocin seems to provide an incentive for the mother to appraise infants as rewarding attachment objects, motivating maternal care and attention. In fact, mothers consider their infants to be intensely rewarding, particularly in the early postpartum months (Swain, 2011). There is also good evidence that the mesocorticolimbic dopamine system promotes the onset of maternal behavior and that hypothalamic oxytocin, particularly from the mPOA, regulates this pathway. For example, intense mother-offspring interactions during suckling result in activation of the dopamine reward system in mothers (Febo et al., 2005). Blockade of local dopamine signaling in the NAcc via lesioning of the VTA, a brain region projecting dopaminergic fibers that innervate the NAcc, reduces maternal behavior as well as the salience of the rewarding properties of pups (for a recent review, see Numan and Stolzenberg, 2009). The oxytocin system seems to innervate dopamine regulation of maternal care in the VTA. Specifically, oxytocin receptors

are expressed in the VTA in rats, and in tract-tracing studies, oxytocin-positive cells and neurons responsive to maternal care in the mPOA have been observed to project to the VTA (Numan and Stolzenberg, 2009; Shahrokh et al., 2010), modulating subsequent VTA-mediated dopamine release in the NAcc. Recent data have also shown that oxytocin action in the VTA can regulate dopamine release in the NAcc associated with pup licking/grooming in female rats. In rats, high licking/grooming mothers have more oxytocinergic neurons in the mPOA and PVN that project into the VTA compared with low licking/grooming mothers. Furthermore, inhibition of oxytocin action in the VTA can impair pup licking/grooming and the amount of dopamine release in the NAcc induced by these behaviors (Shahrokh et al., 2010). Thus, hypothalamic oxytocin seems to interact with the mesocorticolimbic dopamine system in motivating the initial maternal responsiveness toward infants. After a critical period of interaction, it is proposed that the mPOA is reorganized in such a way that pup stimuli alone are sufficient to induce the motivation of maternal behavior and rewarding properties of the infant without the needed regulation of the oxytocin system.

In addition to inducing direct maternal care, oxytocin reduces aggression directed toward neonates and aversion associated with infant cues (Kendrick et al., 1997; Pedersen, 2004). This may be enhanced by the role that oxytocin has in producing the calming and antistress effect associated with infant contact and breastfeeding. In lactating females, oxytocin release during nipple stimulation and breastfeeding reduces basal and stress-induced rises in stress hormones and suppresses heart rates, blood pressure, and stress-related behaviors (Carter and Altemus, 1997). Thus, infant contact during breastfeeding and subsequent oxytocin release could buffer a mother's stress response. This could provide a mechanism through which mother–infant contact ameliorates stress associated with the infant and limits anxiety-induced aggression. Also, there are some data suggesting that maternal stress is associated with maternal defense, and oxytocin mediates this relationship. First, maternal care is associated with increased aggression toward potential threats near the infant. Bosch and Neumann (2012) recently reviewed an emerging body of literature indicating oxytocin may promote intruder-directed maternal aggression. Several brain regions have been identified as sites for oxytocin-mediated maternal aggression, including the central subnucleus of the amygdala (CeA) and PVN and to a lesser extent the bed nucleus of the stria terminalis (BNST) and LS. In the CeA, oxytocin gene expression is increased in this brain area during the peripartum period in rats (Fig. 86.2E). Furthermore, in lactating rats, oxytocin is released in the CeA and PVN during displays of maternal defense, but not during interactions with an unfamiliar conspecific with little or no aggression (Fig. 86.2F). The amount of maternal aggressive behavior displayed by lactating rats during these encounters correlates with the amount of oxytocin released in these brain areas. Administration of oxytocin in the CeA and PVN can also promote maternal aggression. In addition, retrodialysis of an oxytocin receptor antagonist into the CeA or PVN can hinder maternal aggression in lactating rats during a maternal defense test (Fig. 86.2G). Second, maternal stress physiology—such as the release of CRH, a stress hormone regulating one of the major biological stress pathways known as the hypothalamic–pituitary–adrenal (HPA) axis—is negatively associated with the display of maternal aggression. It has been noted that stress and CRH injections can reduce maternal aggression in lactating mice and rats (Gammie et al., 2008). For that reason, inhibition of CRHergic neurons may be a prerequisite for the expression of maternal defensive behavior. The inhibitory action of oxytocin on CRHergic activity, particularly in the PVN, may achieve this requirement (reviewed by Gammie et al., 2008; Smith and Wang, 2012). Therefore, infant-induced activation of central oxytocin—which can be promoted by childbirth, lactation, and innate infant behavior—may minimize negative associations toward infant cues, reducing maternal anxiety and promoting infant proximity and contact, while increasing perceived threats from unfamiliar conspecifics and subsequent maternal protective behaviors. This mechanism could explain the reduced aversion toward infants and enhanced selective aggression toward intruders in mothers.

CLINICAL CORRELATES: MATERNAL NEGLECT

For parental bonding, similar neurochemistry has been observed between humans and other mammalian species, with a focus on oxytocin, dopamine, and vasopressin. However, neural circuitry has primarily been studied in rodent species that only display maternal behavior. Because humans display bi-parental care and have a more complex cortical systems, in comparison with rodents, it will be beneficial to understand how these factors influence the neurobiological regulation of parental bonding in both mothers and fathers. Still, comparing normal variation in the patterns of parental care has led to insights into how different parental brain responses may contribute to aberrant parental bonding, as observed in maternal neglect. Strathearn (2011) noted that insecure attachment—allied with emotional neglect—is associated with the same neural substrates that govern rodent maternal behavior, specifically the oxytocin and mesocorticolimbic dopamine reward systems. Mothers displaying such a dismissive nature have reduced activation of the limbic system as well as decreased peripheral oxytocin response to infant contact. Because oxytocin is released during childbirth and lactation peripherally as well as centrally, as observed in animal literature, one hypothetical mechanism for maternal neglect could include a deficit in brain oxytocin transmission. Women with such a deficit would still be able to have successful deliveries and nurse; however, they would not experience the same reinforcements associated with infant contact or display the same type of responsiveness to infant distress.

FATHER–INFANT ATTACHMENT

A widely accepted benefit of pair bonding in humans, as in other species, is the physical and psychological well-being of children, an effect likely caused by the co-occurrence of pair bonding with the bi-parental care of young. Indeed, paternal involvement in child care has become increasingly recognized as equally important as maternal influences on successful child development in humans, and even more so in some monogamous, bi-parental non-human primate species (for examples, see Solomon and French, 1997). After conception, direct paternal investment in mammals does not manifest until childbirth because males do not gestate. However, during early infancy, the care that fathers provide to their offspring can be equal to that provided by mothers, with the exception of lactation, in many bi-parental species—including humans, prairie voles, degus (*Octodon degus*) California mice (*Peromyscus californicus*), marmoset and tamarin monkeys (family Callitrichidae), and titi monkeys (*Callicebus moloch*). Specifically, fathers from bi-parental mammalian species display a broad range of paternal behaviors, some direct (e.g., carrying, grooming, playing, and eventually feeding) and others indirect (e.g., nest building, paternal defense, and support of the female during pregnancy). Yet, the display of infant care is not always apparent in males that are not pair-bonded or breeding with a female partner. In fact, virgin male California mice are infanticidal rather than paternal, a behavior that persists after mating and through the gestation of their female partner and does not subside until their female partner gives birth. Thus, father–infant attachment

may manifest in part by suppressing negative associations to infant stimuli (e.g., progeny of a successful rival male and thus a threat to one's own reproductive success) and promoting care and protective behaviors that are reinforced by stimulating the brain reward centers. In fact, fathers consider their newborns as intensely rewarding (Swain, 2011). However, we know little about the neurobiology of paternal attachment.

NEUROANATOMY AND CHEMICAL SUBSTRATES

One mechanism that has provided some data is the vasopressin system (Fig. 86.1C). Only a few studies have evaluated the effects of pharmacological manipulations of vasopressin signaling on paternal behavior. These studies have been conducted in two closely related *Microtus* rodents, the bi-parental prairie vole (*M. ochrogaster*) and the non-paternal meadow vole (*Microtus pennsylvanicus*). Blockade of vasopressin receptors reduced paternal behavior and increased occurrence of pup attacks in male prairie voles, but this required concurrent inhibition of oxytocin receptors (Bales et al., 2004). In naturally non-paternal meadow voles, vasopressin injections promoted parental behaviors and reduced pup-directed aggression, an effect reversed by a vasopressin receptor antagonist (Parker and Lee, 2001). Thus, *Microtus* paternal behavior seems to be enhanced by the vasopressin system. In addition, Wang et al. (1998) noted that vasopressin injections directly into the LS increased the amount of time male prairie voles engaged in paternal behavior (e.g., contacting and crouching over the pup), whereas pretreatment with a vasopressin 1-alpha receptor (V1aR) antagonist abolished these effects. It is worth mentioning that male prairie voles display high levels of spontaneous paternal behavior, including pup huddling, licking/grooming, and retrieving, which can be augmented further by social experiences, including parental experience and adult male–female bonding. Wang and colleagues noted that parental experience also alters the vasopressin neural system in male prairie voles. Specifically, after parturition of their female partner and parental experience, male prairie voles have less vasopressin-immunoreactive fibers in the LS, which is accompanied by significantly more vasopressin gene expression in the BNST—a brain region that projects to the LS. This reduction in vasopressin immunoreactivity may reflect increased septal vasopressin release because of paternal experience that is not immediately restored. Still, in prairie voles, like many bi-parental species, male infant care is spontaneous. Thus, it may not need hormonal regulation to elicit onset. However, it seems that social experience associated with childbirth and infant contact can enhance neural circuitry that augments the display of male parental behavior while reducing infant-directed aggression. Therefore, father–infant attachment may be associated with altering the perception of an infant from an unfamiliar conspecific or progeny of a rival male, and thus a threat, to an affiliative object that requires care and protection.

ADULT BONDING

Mammalian societies are often complex and can contain adult relationships fostered by reproduction or kinship (i.e., breeding

mates and extended families) or facilitated by environmental pressures such as territorial or predatory defense as well as resource allocation (i.e., group mates, allies, and friendships). In many species, adult relationships include same-sex dyads or coalitions that are required for survival and longevity and sustained by kinship, social tolerance, and even social affiliation. About 3% to 5% of mammalian species, primarily rodents and New World primates, display monogamy as the dominant mating system (Solomon and French, 1997). The dominant relationship in these social groups is defined between the breeding male–female partner, which often includes a stable and enduring social attachment (i.e., pair bond). The formation and maintenance of these bonds are integral to the fabric of human social behavior and implicated in an individual's mental and physical health and well-being. Yet little is known about the underlying neurobiology, potentially because of its inherent complexity and relative rarity in mammals.

Nevertheless, research evaluating the neurobiological basis of pair bonding has provided insight into the regulatory mechanisms of behavioral cornerstones of this bond, including selective social preference and affiliation behavior, mate guarding, bi-parental care, and separation distress. Further, much of this research has focused on *Microtus* rodents or voles because this genus includes closely related species that are either monogamous (e.g., the prairie vole) or non-monogamous (e.g., the meadow vole), and includes similar neurochemical systems involved in parent–infant bonding; namely, oxytocin, vasopressin, and dopamine. From these comparative studies, the differences in social behavior and distribution patterns of central vasopressin and oxytocin systems observed between prairie and meadow voles have been suggested to be related to the divergent life strategies in these species (an example of these results are illustrated in Fig. 86.3A). Instead of delving further into these comparative studies, this section highlights vole research by focusing on the monogamous prairie vole to better understand the neurobiological mechanisms that govern the formation and maintenance of pair bonding in adulthood for females and males (see Fig. 86.1B,C).

PAIR BONDING

Prairie vole pair bonding behaviors have been documented in field research, using radiotelemetry combined with repeated trapping. Sexually naïve prairie voles are highly gregarious and socially tolerant, displaying nonselective affiliative behaviors and low levels of aggression toward conspecifics. However, following extensive mating or cohabitation with the opposite sex, male and female prairie voles remain in close proximity to their breeding partner reinforced by limiting roaming patterns to a defined nest and home range that is shared and protected by the breeding pair, and even traveling together. Bonded adult male and female prairie voles maintain this spatial and social proximity usually until one partner dies, and even then, the survivor rarely forms a new pair bond (Pizzuto and Getz, 1998). Furthermore, male–female breeding partners display behavioral hallmarks of a monogamous pairing such as selective social preferences for their familiar partner (Aragona and Wang, 2004), aggression toward

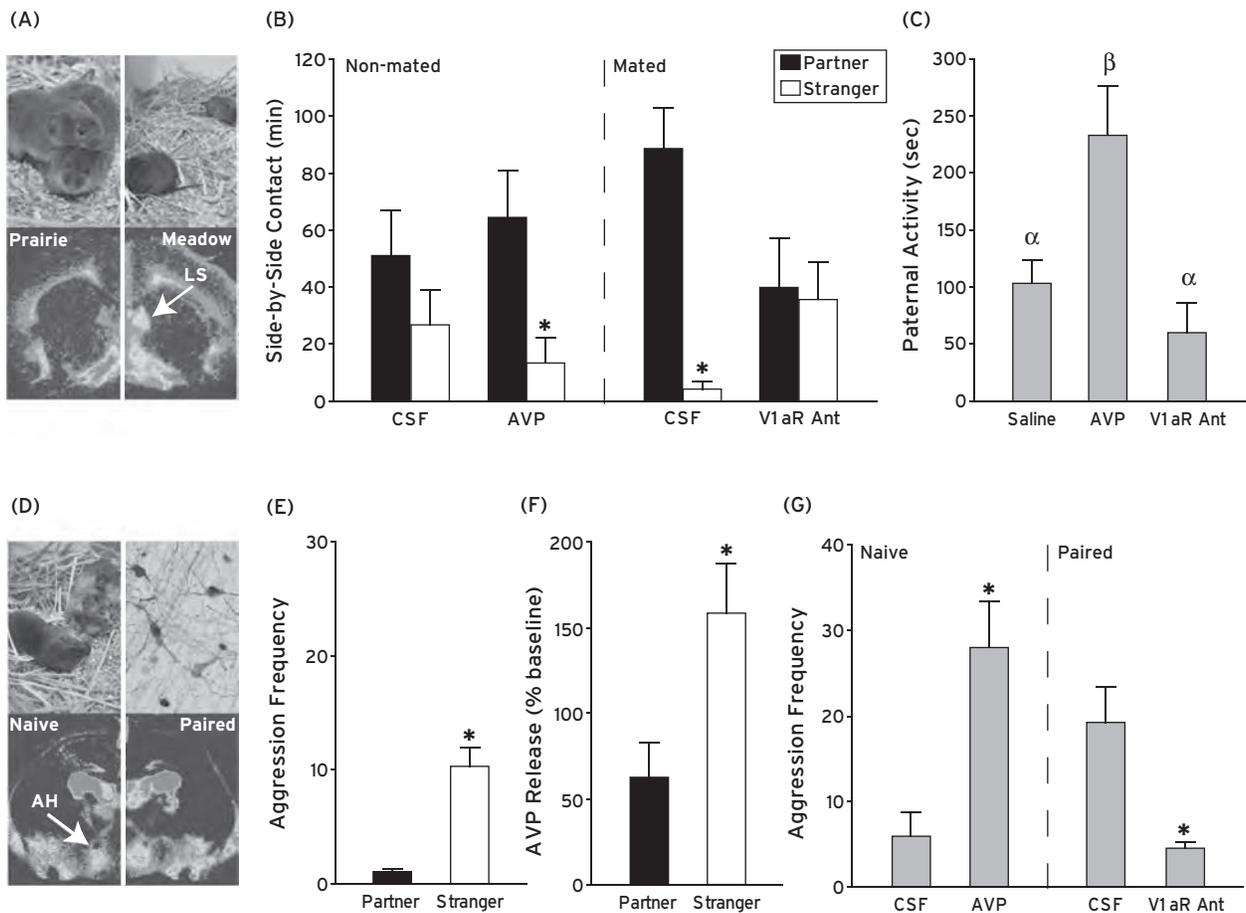

Figure 86.3 Vasopressin (AVP) regulates partner preference formation and paternal behavior via signaling in the lateral septum (LS) and selective aggression via action in the anterior hypothalamus (AH) in male prairie voles. (A) Photos and photo images illustrating species-specific differences in social affiliation (top) and density of vasopressin 1-alpha receptor (V1aR) binding in the LS (bottom) between the monogamous prairie vole (left) and polygamous, solitary meadow vole (right). (B) AVP injected in the LS facilitates partner preference formation in non-mated male prairie voles, whereas an intra-LS injection of a V1aR antagonist blocks such behavior. (C) An intra-LS injection of AVP, not a V1aR antagonist, can also promote paternal behavior in male prairie voles. (D) Photo and photomicrographs depict selective aggression (top left) and aggression-induced neuronal activity (Fos-immunoreactive cells with dark nuclear staining) in AVP-immunoreactive cells (Dark gray cytoplasmic staining) in the AH (top right) in paired male prairie voles as well as the differences in V1aR binding in the AH between sexually naive (bottom left) and paired (bottom right) male prairie voles. (E) Paired male prairie voles display significantly more aggression toward an intruding conspecific (stranger) compared with a familiar female partner. (F) AVP release in the AH increases during aggressive interactions, with an intruding conspecific during a resident intruder test compared with a period immediately before the onset of the test in which the male prairie vole is undisturbed. (G) AVP injected in the AH induces intruder-directed aggression in sexually naive males, whereas an intra-AH injection of a V1aR antagonist blunts such aggression in paired males. Bars indicate means \pm standard error of the mean. Bars with different Greek letters differ significantly from each other. * $p < 0.05$. (Adapted from Gobrogge et al. (2009); Liu et al. (2001); Wang et al. (1994).)

intruding conspecifics (Gobrogge and Wang, 2011), remaining together through gestation and displaying bi-parental care throughout lactation (Wang et al., 1998), and reducing the stress response and distress associated with social separation or bond loss via social contact and consolatory behaviors (Smith and Wang, 2012). Therefore, these aspects of prairie vole social behavior facilitate and aid in the retention of a pair-bond. Behavioral paradigms have been developed in the laboratory to quantify these behaviors and study the governing neurobiological systems (e.g., oxytocin, vasopressin, and dopamine).

NEUROANATOMY AND CHEMICAL SUBSTRATES

A selective social preference, or partner preference, reflects the extent to which prairie voles seek out social contact with

their partner over other conspecifics, and is a reliable laboratory index of the formation of a pair bond in prairie voles. This selective affiliation can be assessed using a partner preference test first developed in the laboratory of Dr. Sue Carter (Williams et al., 1992). The partner preference test is a three-hour test in which the subject is placed in a three-chamber choice apparatus and allowed to freely roam among the three chambers—an empty cage, which acts as a non-social control environment, and two adjoining cages that house either the subject's social partner or an unfamiliar, opposite-sex conspecific. After 24 hours of cohabitation and mating, male and female prairie voles consistently display a selective preference to spend the majority of time in their partner's cage and affiliating more with their partner compared with the opposite-sex conspecific, indicating a partner preference. The inaugural evidence that two closely related neuropeptidergic systems, namely, oxytocin and vasopressin,

regulated partner preference behavior came in the effects of bond-inducing social and sexual behaviors on these systems in the brain. Notably, mating, although not required, can facilitate pair bonding in prairie voles (Williams et al., 1992), and sexually naïve female prairie voles exposed to male chemosensory cues or housed with a male have altered oxytocin receptor density in the anterior olfactory nucleus and release oxytocin in the NAcc from oxytocin-immunoreactive cells originating in the PVN and SON (Ross et al., 2009; Witt et al., 1991). In addition, mating also induces dopamine release in the NAcc in prairie voles. Like maternal attachment, hypothalamic oxytocin can promote dopamine release in the NAcc and, subsequently, promote female pair bonding. In male prairie voles, mating during cohabitation decreases the number of vasopressin-immunoreactive fibers in the LS and increases vasopressin gene expression in the BNST—a brain region that projects to the LS (Wang et al., 1998). Like the paternal experience-induced effects in male prairie voles, these data suggest that sociosexual experience with a female may promote vasopressin release in the LS derived from vasopressinergic cells in the BNST, potentially promoting male pair bonding. Like females, mating induces dopamine release in the NAcc in male prairie voles, providing one behavioral mechanism for partner preference, and thus, motivation to maintain selective social proximity in prairie voles.

More direct evidence for the involvement of oxytocin and vasopressin in prairie vole pair bonding has manifested by use of ICV and site-specific injections of oxytocin, vasopressin, selective antagonists, and viral vectors (reviewed in Aragona and Wang, 2004). Intracerebroventricular administration of oxytocin can facilitate partner preference formation in female prairie voles, and males to a certain degree, diminishing the period of cohabitation required for this behavioral preference to manifest. A selective oxytocin receptor antagonist administered centrally can inhibit the effects of oxytocin release in the brain on partner preference, induced endogenously via mating or cohabitation or administered exogenously. Furthermore, ICV injections of vasopressin can facilitate, whereas a concurrent injection of a selective vasopressin receptor antagonist can inhibit, the display of a partner preference in male prairie voles. In fact, oxytocin and vasopressin both can facilitate partner preference formation in males and females; however, site-specific manipulates indicate sex-specific circuitry. In females, the NAcc and prelimbic cortex (PLC) have been implicated in the oxytocin regulation of partner preferences. Oxytocin injected directly into the NAcc induces partner preferences, whereas an oxytocin receptor antagonist injected into either the NAcc or PLC can inhibit mating-induced female partner preferences. By contrast, oxytocin receptor antagonist administration into the LS can inhibit a partner preference in male prairie voles. Furthermore, vasopressin administration directly into the LS induces male partner preferences in the absence of mating (Fig. 86.3B). Blockade of vasopressin action in the LS by a V1aR antagonist can abolish mating-induced effects on male partner preferences. Vasopressin-immunoreactive fibers are found in dense networks in the LS and extend ventrally into the VP in male prairie vole. Interestingly, overexpression of the V1aR via an adeno-associated viral vector in the VP also facilitates a partner preference in males. As mentioned, an injection

of vasopressin in the LS can also promote paternal behavior in male prairie voles (Fig. 86.3C). Thus, vasopressinergic signaling in the LS seems to promote social bonding in male prairie voles, both as a pair-bonded partner and a father.

Data from a series of experiments have indicated that mesolimbic dopamine activity, particularly in the NAcc, can also promote partner preferences in voles in a receptor-specific manner (Aragona and Wang, 2009; Fig. 86.4A–D). The vole VTA synthesizes dopamine that projects axon fibers that terminate in the NAcc where two families of dopamine receptors are expressed, D1-like (D1R) and D2-like (D2R) receptors (see Fig. 86.4A). They each have opposite intracellular signaling and behavioral effects. Specifically, partner preference formation and expression is stimulated by an injection of a D2R agonist, but blocked by an injection of a D1R agonist, into the NAcc in male prairie voles (see Fig. 86.4B). D1R and D2R have the opposite effects over cyclic adenosine monophosphate (cAMP) signaling (see Fig. 86.4C). D1R signaling activates stimulatory G-proteins that increase conversion of adenosine triphosphate (ATP) to cAMP via adenylyl cyclase activation. This increases cAMP production activates protein kinase A (PKA), leading to activation of transcription factors and gene expression. In contrast, activation of D2R activates inhibitory G-proteins that prevent adenylyl cyclase from converting ATP to cAMP, leaving PKA in an inactive state. Given that when dopamine receptor signaling promotes partner preference formation in prairie voles cAMP signaling-induced PKA activity in the NAcc is decreased, it was hypothesized that blockade of this intracellular signaling pathway was required for partner preference formation. Consistent with the effects of D2R signaling, when PKA activity in the NAcc was pharmacologically depressed in male prairie voles during a short-term cohabitation with a female conspecific, males formed partner preferences, whereas untreated males did not display such preferences (see Fig. 86.4D). Like D1R activation, when PKA activity in the NAcc was chemically increased during a long-term cohabitation, males did not form partner preferences. Thus, dopamine mediates partner preference formation in a receptor-specific manner through intracellular cAMP signaling and PKA activity in the NAcc. In addition, pair-bonded males also have increased D1R expression levels in the NAcc compared to sexually naïve male prairie voles. Because D1R activity inhibits partner preference formation, this may be a neural mechanism that prevents the formation of new pair bonds by attenuating the salience of the rewarding effects of interacting with other conspecifics. Together, these data highlight the functional role and site-specificity of oxytocin, vasopressin, and dopamine in the regulation of partner preference formation in females and males. Nevertheless, although partner preferences persist throughout the adult relationship, even potentially enduring well beyond as prairie voles seldom establish a new pairing after their partner dies, no data have been collected to document the effects of these neurochemicals on the maintenance of this bond-related behavior.

Although selective preference for a partner may facilitate bonding, selective aggression in the form of intruder-directed aggression is one behavior that aids in the maintenance of such a bond. Mating-induced aggression is common in many species. However, this usually takes form as temporary mate guarding,

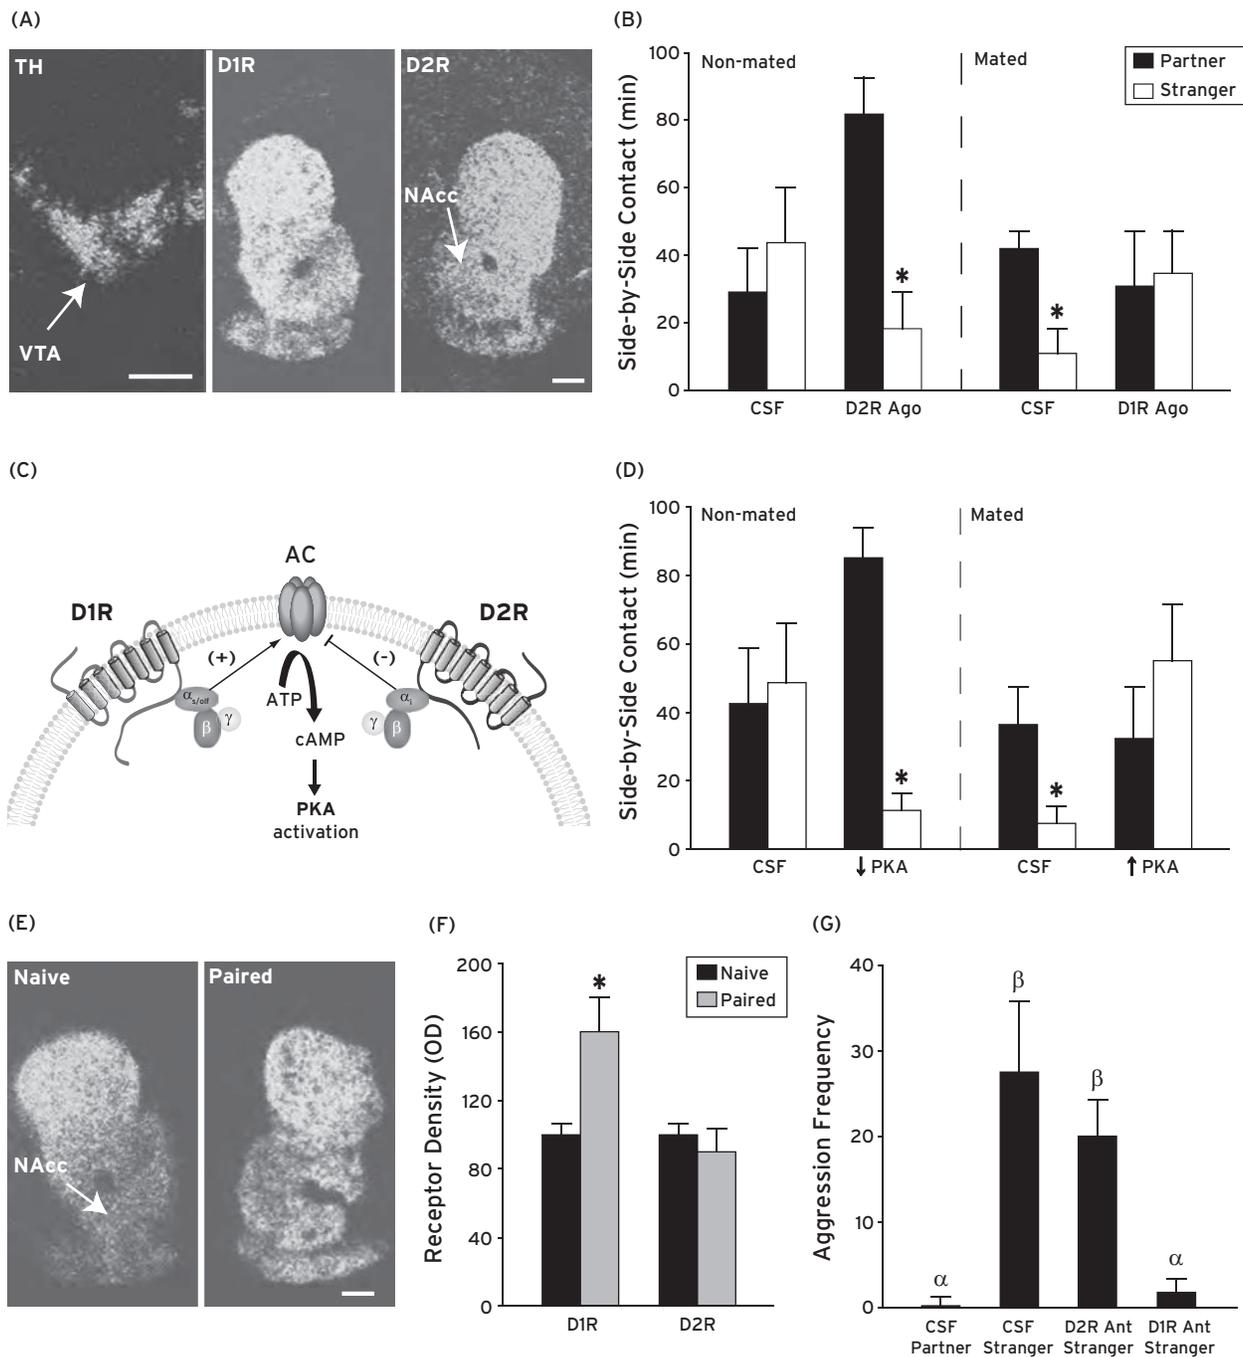

Figure 86.4 Nucleus accumbens (NAcc) dopamine involvement in partner preference formation, selective aggression, and intracellular signaling pathways in a receptor-specific manner in male prairie voles. (A) Photomicrographs showing immunoreactive staining for tyrosine hydroxylase (TH) mRNA in the ventral tegmental area (left) and receptor binding for D1R (middle) and D2R (right) in the NAcc. (B) D2R agonist (D2R ago) injected in the NAcc induces a partner preference in non-mated males, whereas a D1R agonist (D1R ago) injection blocks partner preference formation in mated males. (C) Illustration representing receptor-specific effects of D1R and D2R on cAMP intracellular signaling. D1R signaling excites stimulatory G-proteins, which promotes ATP conversion to cAMP via adenyl cyclase (AC) and cAMP-induced PKA activation. In contrast, D2R signaling excites inhibitory G-proteins blocking AC-induced cAMP production and PKA activation via cAMP. (D) Partner preference formation is facilitated in non-mated males via pharmacological inactivation of PKA in the NAcc and blocked in mated males via pharmacological activation of PKA in the NAcc. (E) Photo images portray differences in D1R binding density between sexually naive and paired male prairie voles. (F) D1R production is increased in paired males compared with sexually naive males, but D2R production is not. (G) Selective aggression toward strangers can be eliminated by an intra-NAcc injection of a D1R antagonist, but no effect is observed with a D2R antagonist injection. Bars indicate means \pm standard error of the mean. Bars with different Greek letters differ significantly from each other. * $p < 0.05$. (Adapted from Aragona et al., 2006; Aragona and Wang, 2007; Aragona, B.J., Liu, Y., Yu, Y.J., 2006. Nucleus accumbens dopamine differentially mediates the formation and maintenance of monogamous pair bonds. *Nat. Neurosci.* 9:133–139; Aragona, B.J., Wang, Z. 2007. to improve reproductive success via paternal certainty, leading to intrasexual aggression toward conspecifics. In monogamous species such as prairie voles, mating-induced aggression often facilitates both intra- and intersexual aggression toward unfamiliar conspecifics (see Fig. 86.3D,E), thus thwarting competitors and forgoing potential extra-pair mating opportunities. This is one behavioral mechanism of pair bond maintenance. Interestingly, although vasopressin is involved with promoting selective partner-directed affiliation, there are data to outline its regulatory role in mating-induced intruder-directed aggression in male prairie voles (for a recent review, see Gobrogge and Wang, 2011). Initial experiments indicate that V1aR binding in the anterior hypothalamus (AH) increases after male prairie voles are paired with a female, and neuronal activity, particularly in vasopressin-expressing neurons, increases in the AH and MeA following aggressive interactions with an unfamiliar conspecific compared with non-aggressive interactions or contact with a familiar partner (see Fig. 86.3 D). In addition, aggressive interactions with an unfamiliar conspecific induce increased vasopressin release in the AH (see Fig. 86.3 F). Furthermore, vasopressin injections directly into the AH can promote intruder-directed aggression in male prairie voles, an effect mediated by V1aR as a concurrent injection of a V1aR antagonist can abolish intruder aggression (see Fig. 86.3G). Thus, AH vasopressin is both necessary and sufficient to regulate mating-induced selective aggression in male prairie voles. Given that D1R expression and binding are increased in the NAcc after pairing with a female (see Fig. 86.4E,F), which induces male prairie voles to display selective aggression toward intruders, efforts have been made to also explore the effects of dopamine on this behavior (Aragona and Wang, 2009). Sure enough, when D1R activation was inhibited in the NAcc via an injection of a D1R-specific antagonist, pair-bonded male prairie voles were affiliative, not aggressive, toward intruding, unfamiliar females. However, pair-bonded males receiving a vehicle treatment or a selective D2R antagonist were highly aggressive and displayed little affiliative behavior toward the female intruders (see Fig. 86.4G). Therefore, the plasticity of the vasopressin and mesolimbic dopamine systems underlie the behavioral mechanism of pair bonding that leads to aggressively rejecting new potential mates, ensuring the maintenance of the existing pair bond.

In addition to selective aggression, bi-parental care and separation distress seem to be contributing social factors that promote bond maintenance. First, considerable evidence suggests that the neural processes necessary for parental behavior and pair bonding may be shared in prairie voles. Recent evidence even indicates that prior parental experience can promote activity of the oxytocin and vasopressin systems in the brain and facilitate partner preference in male prairie voles (Kenkel et al., 2012). However, female prairie vole mate choice is dictated by the amount of partner-directed affiliative behavior, not paternal care, that a male displays, and male prairie vole partner-directed affiliation and parental care are not correlated (Ophir et al., 2008). Bi-parental care provides advantages to parental reproductive fitness and the offspring in terms of supporting development and improving mental and physical health and well-being. Nevertheless, although neurobiological substrates have been identified to

promote parent–infant bonding in prairie voles and other monogamous species, more research is needed to determine if parental behavior is required to retain a monogamous bond. Second, in a recent review, Smith and Wang (2012) noted that the HPA axis and oxytocin activity may mediate the aversive effects of partner separation, and thus regulate the preservation and maintenance of existing pair bonds. Social separation from a pair-bonded partner during periods of psychological distress can intensify the HPA axis and stress-related behavioral response in prairie voles. However, the response to social separation from familiar conspecifics may depend upon the intensity of existing affiliative bonds because separation from a same-sex conspecific—an adult relationship that is not associated with social bonding in prairie voles—does not affect stress physiology. Social contact with a pair-bonded partner can disrupt the behavioral and physiological stress response in female prairie voles; this is known as social buffering. Interestingly, contact with a pair-bonded partner following a stressful event can induce the release of oxytocin in the PVN in female prairie voles. This release may have functional effects because oxytocin injected into the PVN can also reduce the stress response. Further, the stress-reducing effect of a bonded-partner on the HPA axis response and stress-related behavior in females is marginalized when a selective oxytocin receptor antagonist is injected into the PVN before social contact. Thus, social buffering in prairie voles seems to be regulated by oxytocin action in the PVN that limits the HPA response to stress. Furthermore, disruption of CRH action, and thus HPA axis function, by induction of a CRH receptor antagonist can eliminate behavioral distress associated with social loss in prairie voles (i.e., permanent separation from a pair-bonded partner). Thus, pair bonding maintenance may be enhanced by the benefits of social contact, via oxytocin, and consequences of pair bond disruption, via CRH and the HPA axis. The function of a pair bond on the regulation of the biobehavioral stress response may be one reason why individuals attempt to maintain established bonds, and oxytocin and CRH may be governing neuropeptide systems.

CLINICAL CORRELATE: HUMAN BONDING

Humans develop long-lasting and selective social bonds in adulthood, but the neurobiology of human pair bonding remains unresolved. Certainly, human love and pair bonding in non-human primates are regulated by higher-level cortical structures to a greater degree than social attachments in rodents. But it could be conceived that the same neural substrates that regulate rodent pair bonding such as in prairie voles; namely, oxytocin, vasopressin, and dopamine systems, may also be involved in humans. This would require similarities in the neuroanatomy between prairie voles and humans. The pattern of receptor expression in oxytocin and vasopressin has been examined in humans, and although there is some overlap between human and prairie vole receptor expression, there are brain regions in the human brain analogous to the prairie vole brain that lack these receptors (Gimpl and Fahrenholz, 2001). This may suggest that human pair bonding is mediated by different mechanisms or that these neural systems affect bonding behavior by alternative neural circuitry. Still, there is evidence

that human pair bonding is governed, at least in part, by these same neurochemical systems. For example, intranasal application of oxytocin has been reported in a number of studies to promote prosocial effects that would facilitate human bonding, including increased trust, generosity, emotional empathy, conflict resolution, and salience of social information as well as socially reinforced learning (Striepens et al., 2011). In addition, vasopressin is associated with human aggression; the life history of aggression in men and women are positively correlated with the concentration of vasopressin in cerebrospinal fluid (reviewed in Gobrogge and Wang, 2011). Sex could also influence the formation of human pair bonds as it does in monogamous rodents. Although sex is not required for human pair bonding, features of human sexuality such as sexual arousal and orgasm, even nipple stimulation, may induce the release of oxytocin and vasopressin (Carmichael et al., 1987; Murphy et al., 1987). Furthermore, mesocorticolimbic dopamine activity may propagate romantic love. People had significantly more activity in this pathway while viewing pictures of their romantic partner compared with images of non-romantic friends in a neuroimaging study (Bartels and Zeki, 2000).

CONCLUSIONS

NEUROBIOLOGY OF PARENT-INFANT BONDING

The neurobiological data on the three forms of parent-infant bonding (i.e., infant-parent, mother-infant, and father-infant) focus on neural substrates that regulate social recognition, motivation and reward, and affiliation and emotional processing pathways (see Fig. 86.1). Infant-parent attachment, specifically infant-mother attachment, has centered on the critical capacity for infants to recognize the mother—highlighting olfactory learning—and be motivated to establish close proximity to the mother. From this literature, it seems that norepinephrine projections from the LC and oxytocin from the PVN terminating in the OB are mediating recognition of the mother's odor, beginning from amniotic fluid *in utero* to odors associated with the nipples and milk. In addition, motivation to seek contact with a caregiver is promoted by the endogenous opioid system, although specific opioid centers in the brain have not been clearly identified. Nevertheless, some prognostication may be learned from the neuroanatomical substrates of the infant distress response during maternal separation. Neurophysiological recording and functional brain imaging studies point to the anterior cingulate cortex as a hub for the generation of separation calls and infant crying that can be influenced by decreasing opioid action in this brain region (Newman, 2007). Because maternal buffering of separation distress is promoted by increased opioid activity in the infant brain, the anterior cingulate cortex may be a brain region involved in this regulation. For mother-infant attachment, the onset of maternal behavior is associated with increased neuronal activity, particularly of the oxytocin system, in the mPOA—a brain region that receives projections from the amygdala and BNST. In addition, oxytocinergic fibers from the mPOA innervating the VTA can mediate the activity of the mesocorticolimbic dopamine system, particularly release of NAcc DA, subsequently affecting

the regulation of maternal incentive to establish contact with her infant. Maternal aggression and stress are influenced by the social environment and are regulated by oxytocin action in the CeA and PVN, CRH action in the PVN associated with regulation of the HPA axis, and oxytocin-CRH interaction in these brain areas. Finally, father-infant attachment has not been as comprehensively studied. However, there are data to suggest that the vasopressinergic fibers from the BNST project to the LS, and stimulation of the LS can enhance paternal behavior while reducing infant-directed aggression.

NEUROBIOLOGY OF PAIR BONDING

The neurobiological basis of pair bonding focuses on neural substrates that regulate partner preference, selective aggression, bi-parental care, and separation distress (see Fig. 86.1). Partner preference behavior is reinforced by several neurochemical systems—oxytocin, vasopressin, and dopamine. For female prairie voles, male chemosensory cues or cohabitation is required to induce estrus as well as altering oxytocin receptor density in the anterior olfactory nucleus and release oxytocin in the NAcc from oxytocin-immunoreactive cells originating from the PVN and SON (Ross et al., 2009; Witt et al., 1991). Like in mothers, hypothalamic oxytocin may regulate NAcc dopamine release in pair-bonded females, which can itself facilitate the formation and expression of female partner preferences. For male prairie voles, partner preference behavior is enhanced by mating, which can increase BNST vasopressin gene expression and decrease vasopressin fiber density in the LS—a brain region in addition to the VP that vasopressin-expressing neurons from the BNST send axonal projections to. Specific activation of V1aR in the LS and VP can subsequently enhance male partner preferences. Together, vasopressinergic neurons located in the BNST regulate partner preference formation through the release of vasopressin in the LS and VP, promoting vasopressin signaling through V1aR activation. In addition, dopamine release in the NAcc can modulate male partner preference behavior in a receptor-specific manner (i.e., increased via D2R signaling and decreased via D1R signaling). Beyond partner preference formation, the vasopressin system seems to also regulate pair bonding long-term by enhancing selective aggression toward unfamiliar conspecifics. However, it seems that vasopressin action occurs in the MeA and AH to promote intruder aggression rather than the LS and VP as in partner preference formation. Finally, social reinforcement or retention of the pair bond is enhanced via distress associated with bond loss and stress buffering effects associated with social contact and consolatory behaviors. During social loss, the CRH action in the PVN, and subsequent HPA axis function, seems to lead to distress behavior, whereas oxytocin also in the PVN can reduce these stress effects and is necessary for the beneficial effects of social buffering.

EXPLORING A “BONDING BRAIN” AND FUTURE DIRECTIONS

Across all relationships reviewed, the bonding process seems similar: (1) initiate contact with potential attachment object (e.g., infant, parent, or partner); (2) process socially salient

information and learn specific identity of this individual; (3) invest to maintain relationship and develop motivational association to attachment object; and (4) reject other conspecifics. These steps may be achieved by different behaviors, but there seems to be some conservation in the neural processes involved (see Fig. 86.1). Some exceptions include the lack of involvement in different brain regions (e.g., amygdala) in infant attachment, but this may be explained by immature neural circuitry. Also, many of the monoamines and neuropeptides involved in infant, mother, and father attachments as well as adult pair bonding are preserved. Such socially aroused neurochemicals include oxytocin, vasopressin, and dopamine. For example, oxytocin release in the brain of peripartum female rats during pup contact or sexually naïve female prairie voles during contact with a male conspecific can facilitate activation of the mesocorticolimbic dopamine systems, inducing a neural incentive to maintain social proximity. Further, pair bonding and paternal behavior in male prairie voles are associated with increased vasopressin action in the LS, which is innervated by the BNST. Therefore, oxytocin, vasopressin, and dopamine neural circuits may propagate female and male social behavior selectively to promote and protect a social bond. These neural substrates seem generally excitable by social stimuli until a bond manifests and then activation is discriminate to stimulation from a bonded individual. For example, in male prairie voles, NAcc dopamine signaling via D2R activation promotes partner preference formation, whereas D1R activity prevents such behavior. Once males are pair-bonded, D1R expression increases in the NAcc, potentially as a neural mechanism to prevent new bonds from forming. Thus, the rewarding aspects of social interaction with an attachment object may selectively propagate that bond while preventing new bonds from forming.

In the field of social neuroscience, the focus will, in part, be to continue to understand how the oxytocin and vasopressin systems regulate bond-related social behaviors and modulate the mesocorticolimbic dopamine reward center to regulate motivation for social attachments. Nevertheless, in bonded individuals, social behavior is reinforced by stimulation of the brain reward centers by bond-salient stimuli, ensuring attachment objects elicit positive emotionality and consequences to mental health and well-being associated with social stress and loss. From this perspective, the incentive to form new bonds should be similar to the reluctance to break social bonds, providing a need to better understand the neurobiology of bond retention. In addition, research examining sociability in humans is on the rise with new pharmacology, genetic, and neuroimaging techniques. These tools should be implemented in studying human bonding to allow for more substantial comparisons to animal models. Moreover, information derived from studying the neurobiology of social attachment in animal models and humans has the potential to provide insight into the underlying mechanism of many human mental disorders—such as autism, social anxiety, and schizophrenia—as a major diagnostic component of these disorders includes the inability to properly form social bonds.

ACKNOWLEDGMENTS

We would like to thank Y. Liu for her assistance in capturing photo images for several figures. We gratefully acknowledge C. Badland for his photographic contributions for vole images and assistance with the figures. Special thanks to O. Bosch and D. Bayerl also for their photographic contributions for the rat image and to O. Bosch for providing additional data that appear in the figures.

GIULIO TONONI AND CHIARA CIRELLI

Sleep is a state of reduced responsiveness to environmental stimuli, usually associated with immobility and stereotyped postures. This reduced responsiveness is rapidly reversible—distinguishing sleep from coma—but is still potentially dangerous. Considering that such a state of reduced responsiveness occupies one third of our life, that it is universal, being present in every animal species studied, and that it is tightly regulated, it is likely to serve some essential function. However, what that function is remains uncertain to this day. What is certain is that if we stay awake much longer than the usual 16 hours a day, we are soon overcome by sleepiness, and we become cognitively impaired. The brain is spontaneously active during sleep, so changes in sleep rhythms can be a sensitive indicator of changes in brain function in neuropsychiatric disorders.

This chapter first examines how sleep is traditionally subdivided into different stages that alternate in the course of the night. We then consider the brain centers that determine whether we are asleep or awake and examine the negative consequences of sleep deprivation. We then discuss how brain activity changes between sleep and wakefulness and consider how this leads to the characteristic modifications of consciousness experienced during dreaming and dreamless sleep. Finally, we turn to the paramount but still mysterious question of sleep function.

SLEEP STAGES AND CYCLES

The scientific study of sleep and wakefulness came of age in 1928 when Hans Berger developed an amplifier that could record the electrical activity generated by the brain and discovered that the electroencephalogram (EEG) changes dramatically between wakefulness and sleep, mostly because of the appearance of sleep slow waves and spindles (Jung and Berger, 1979). Another key development occurred in 1953, when Aserinsky and Kleitman discovered a stage of sleep during which the EEG was similar to that of wakefulness (Aserinsky and Kleitman, 1953). Because this stage was associated with bursts of eye movements, it was called rapid eye movement (REM) sleep. By contrast, all other sleep has come to be called non-rapid eye movement (NREM) sleep.

Nowadays, sleep is studied for clinical and research purposes by combining behavioral observations with electrophysiological recordings. The EEG records synchronous synaptic activity from millions of neurons underlying electrodes applied to the scalp (Fig. 87.1). The electrooculogram (EOG), which is

recorded from electrodes attached to the skin near the eyes, detects small electrical fields generated by eye movements. The electromyogram (EMG), which is generally recorded from electrodes attached to the chin, is used to detect sustained (tonic) and episodic (phasic) changes in muscle activity that correlate with changes in behavioral state. In the course of the night, the EEG, EOG, and EMG patterns undergo coordinated changes that are used to distinguish among different sleep stages.

WAKEFULNESS

During wakefulness, the EEG is characterized by waves of low amplitude and high frequency. This kind of EEG pattern is known as low-voltage fast-activity or activated. When eyes close in preparation for sleep, EEG alpha activity (8–13 Hz) becomes prominent, particularly in occipital regions. Such alpha activity is thought to correspond to an “idling” rhythm in visual areas. The waking EOG reveals frequent voluntary eye movements and eye blinks. The EMG reveals tonic muscle activity with additional phasic activity related to voluntary movements.

NREM SLEEP STAGE 1

Falling asleep is a gradual phenomenon of progressive disconnection from the environment. Sleep is usually entered through a transitional state, stage 1 (N1), characterized by loss of alpha activity and the appearance of a low-voltage mixed-frequency EEG pattern with prominent theta activity (3–7 Hz). Eye movements become slow and rolling, and muscle tone relaxes. Although there is decreased awareness of sensory stimuli, a subject in stage 1 may deny that he was asleep. Motor activity may persist for a number of seconds during stage 1. Occasionally participants experience sudden muscle contractions (hypnic jerks), sometimes accompanied by a sense of falling and dreamlike imagery. Participants deprived of sleep often have “microsleep” episodes that consist of brief (5–10 seconds) bouts of stage 1 sleep; these episodes can have serious consequences in situations that demand constant attention, such as driving a car.

NREM SLEEP STAGE 2

After a few minutes in stage 1, people usually progress to stage 2 sleep (N2). This stage is heralded in the EEG by the appearance of K-complexes and sleep spindles, which are especially evident over central regions. K-complexes are made up of a high-amplitude negative sharp wave followed by a positive slow

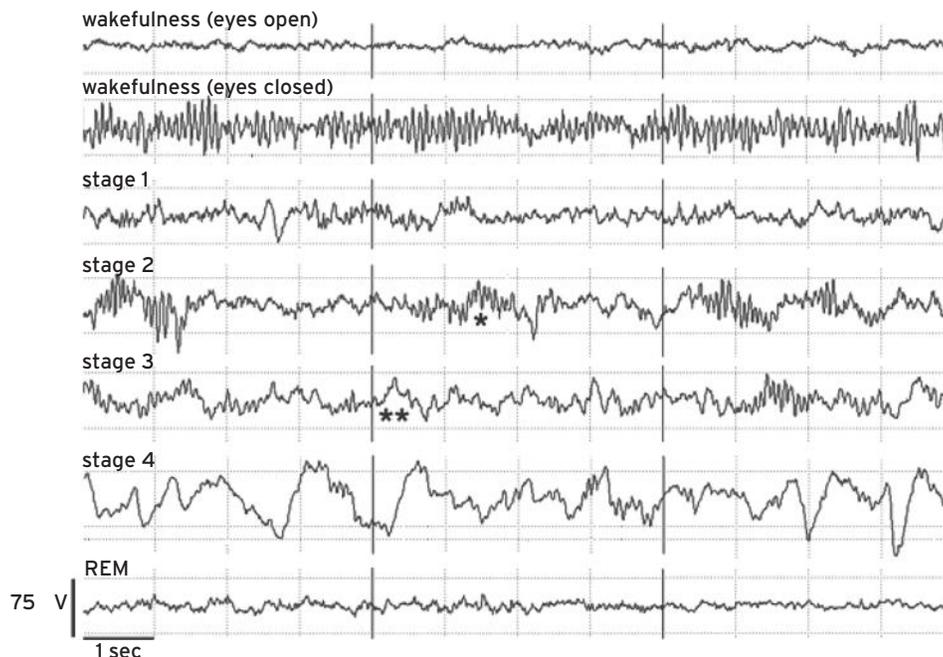

Figure 87.1 The human electroencephalogram (EEG) during wakefulness and the different stages of sleep (*, sleep spindles; **, slow wave).

wave and are often triggered by external stimuli. Sleep spindles are waxing and waning oscillations at around 12–15 Hz that last about 1 second and occur 5–10 times a minute. Eye movements and muscle tone are much reduced. Stage 2 qualifies fully as sleep because people are partially disconnected from the environment, meaning that they do not respond to the events around them—their arousal threshold is increased. If stimuli are strong enough to wake them up, people in stage 2 will confirm that they were asleep.

NREM SLEEP STAGES 3 AND 4

Particularly at the beginning of the night, stage 2 is generally followed by N3, a period when 20% or more of each sleep epoch consists of slow waves (i.e., waves of 0.5–2 Hz frequencies with peak-to-peak amplitude of $>75 \mu\text{V}$). N3 is also defined as slow wave sleep, delta sleep, or deep sleep, because arousal threshold increases incrementally from stage N1 to N3. Until recently, slow wave sleep was subdivided according to the proportion of slow waves in the epoch (stage 3, 20–50%; stage 4, $>50\%$), but the validity and biological significance of this subdivision has been called into question and stages 3 and 4 are now together called stage N3 (Silber et al., 2007). Eye movements cease during stages N2 and N3, and EMG activity decreases further. The process of awakening from slow wave sleep is drawn out, and participants often remain confused for some time.

REM SLEEP

After deepening through stage N3, NREM sleep lightens and returns to stage N2, after which the sleeper enters REM sleep. As was mentioned, REM sleep derives its name from the frequent bursts of rapid eye movements (Aserinsky and Kleitman,

1953; Dement and Kleitman, 1957). Rapid-eye-movement (REM) sleep is also referred to as paradoxical sleep (Jouvet, 1962, 1965, 1998) because the EEG during REM sleep is similar to the activated EEG of waking or of stage N1. Indeed, the EEG of REM sleep is characterized by low-voltage fast-activity, often with increased power in the theta band (three–seven Hz). REM sleep is not subdivided into stages but is rather described in terms of tonic and phasic components. Tonic aspects of REM sleep include the activated EEG and a generalized loss of muscle tone, except for the extraocular muscles that drive the REMs, and the diaphragm that keeps us breathing. REM sleep is also accompanied by penile erections (their significance is unknown, but their occurrence can rule out neurological causes of impotence). Phasic features of REM sleep include irregular bursts of REMs and muscle twitches. Behaviorally, REM sleep is deep sleep, with an arousal threshold that is as high as in slow wave sleep.

SLEEP DURING THE LIFE SPAN

Sleep patterns change markedly across the life span (Baker and Colrain, 2011; Carskadon, 2011; Carskadon, 2014; Jenni et al., 2004a, 2004b). Newborn infants spend 16–18 hours per day sleeping, with an early version of REM sleep, called active sleep, occupying about half of their sleep time. At approximately three–four months of age, when sleep starts to become consolidated during the night, the sleep EEG shows more mature waveforms characteristic of NREM and REM sleep. During early childhood, total sleep time decreases, and REM sleep proportion drops to adult levels. The proportion of NREM sleep spent in slow wave sleep increases during the first year of life, reaches a peak, declines during adolescence and adulthood and may disappear entirely by age 60.

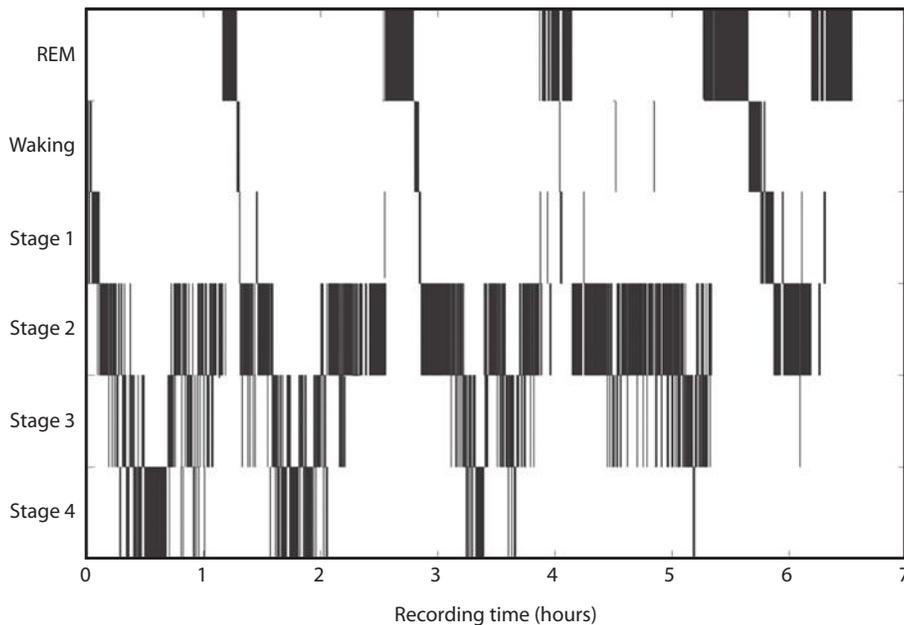

Figure 87.2 Hypnogram for an all-night recording in a young man. Note the occurrence of five sleep cycles, the predominance of slow wave sleep (stages 3 and 4) early in the night and the increasing length of REM sleep episodes later in the night.

THE SLEEP CYCLE

The succession of NREM sleep stages followed by an episode of REM sleep is called a *sleep cycle* and lasts approximately 90–110 minutes in humans. As shown in Figure 87.2, there are a total of four to five cycles every night. Slow wave sleep is prominent early in the night, especially during the first sleep cycle, and diminishes as the night progresses. As slow wave sleep wanes, periods of REM sleep lengthen and show greater phasic activity. The proportion of time spent in each stage and the pattern of stages across the night is fairly consistent in normal adults. A healthy young adult will typically spend about 5% of the sleep period in stage N1 sleep, about 50% in stage N2 sleep, 20–25% in slow wave sleep (N3), and 20–25% in REM sleep.

BRAIN CENTERS REGULATING WAKEFULNESS AND SLEEP

Two antagonistic sets of brain structures are responsible for orchestrating the regular alternation between wakefulness and sleep. The neuronal groups that promote wakefulness are located in the basal forebrain, posterior hypothalamus, and in the upper brain stem, whereas those promoting NREM sleep are located in the anterior hypothalamus and basal forebrain (Jones, 2003, 2005; Lin et al., 2011; McGinty, 2008 Saper et al., 2005a; Szymusiak and). Other cellular groups in the dorsal part of the pons and in the medulla constitute the so-called REM sleep generator (Fig. 87.3) (Jouvet, 1962, 1965, 1994; Luppi et al., 2012; McCarley, 2011; Siegel, 2005). The circadian clock, centered on the suprachiasmatic nucleus of the hypothalamus (SCN), exerts an overall control on many of these brain areas, to ensure that sleep occurs at the appropriate time of the 24-hour light–dark cycle (Aston-Jones, 2005; Mistlberger, 2005; Saper et al., 2005b; Zee and Manthana, 2007).

Maintenance of wakefulness is dependent on several heterogeneous cell groups extending from the upper pons and midbrain (the so-called reticular activating system, RAS; Lindsley et al., 1949; Moruzzi and Magoun, 1949) to the posterior hypothalamus and basal forebrain. These cell groups are strategically placed so that they can release, over wide regions of the brain, neuromodulators and neurotransmitters that produce EEG activation, such as acetylcholine, hypocretin, histamine, norepinephrine, and glutamate. The main mechanism by which these neuromodulators and neurotransmitters produce cortical activation is by closing leakage potassium channels on the cell membrane of cortical and thalamic neurons, thus keeping cells depolarized and ready to fire.

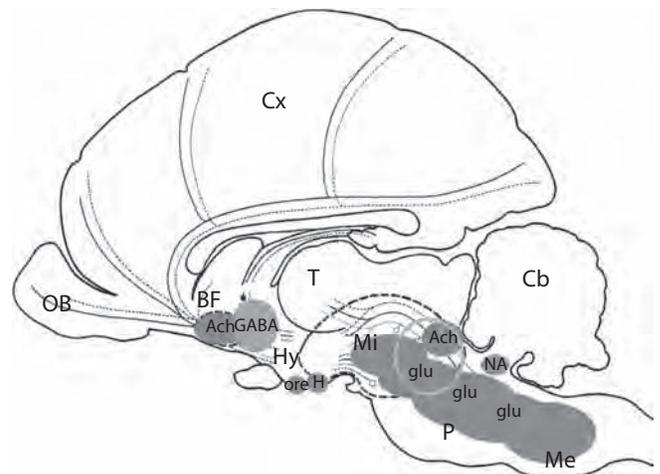

Figure 87.3 The major brain areas involved in initiating and maintaining wakefulness (glu, glutamate; Ach, acetylcholine; NA, noradrenaline; H, histamine; ore, orexin), NREM sleep (GABA), and REM sleep (Ach).

ACETYLCHOLINE

Cholinergic cells are located in the basal forebrain and in two small nuclei in the pons: the pedunculopontine tegmental and lateral dorsal tegmental nuclei (PPT/LDT). Basal forebrain and pontine cholinergic cells fire at high rates in wakefulness and REM sleep and decrease or stop firing during NREM sleep (el Mansari et al., 1989; Lee et al., 2005b). Pontine cholinergic cells project to the thalamus, where they help depolarize specific and intralaminar thalamic nuclei. The latter, which are dispersed throughout the thalamus and project diffusely to the cortex, fire at very high frequencies during wakefulness and REM sleep and help to synchronize cortical firing in the gamma (>28 Hz) range (Jones, 2005; McCormick, 1989; Steriade, 2004). They also project to other cholinergic and non-cholinergic (many of them glutamatergic) cells in the basal forebrain, which in turn provide an excitatory input to the entire cortex (Jones, 2003, 2005). Indeed, drugs with anticholinergic activity, including tricyclic antidepressants and atropine, can cause sedation and produce slow waves in the EEG (Domino et al., 1968; Itil and Fink, 1968). On the other hand, cholinergic agonists (e.g., nicotine) usually enhance arousal (Gillin et al., 2005; Metherate et al., 1992). In patients with Alzheimer's disease, loss of cholinergic cells is associated with slowing of the cortical EEG (Dierks et al., 1995; Montplaisir et al., 1998; Prinz et al., 1982; Soininen et al., 1992).

HISTAMINE

Cholinergic neurons in the pons also project to the posterior hypothalamus, where histaminergic neurons are located in the tuberomammillary nucleus (Brown et al., 2001). Histaminergic neurons, which project throughout the cortex, fire at the highest rates during wakefulness and are inhibited during NREM and REM sleep (Takahashi et al., 2006). They have an important wakefulness-promoting function, as shown by the increased sleep and drowsiness when they are experimentally inactivated (Lin et al., 1989, 1996, 2011). Indeed, over-the-counter antihistaminergic drugs are used all over the world to facilitate the induction of sleep (Barbier and Bradbury, 2007).

GLUTAMATE

Probably the largest contingent of the wakefulness-promoting system is made up by cells dispersed throughout the brainstem reticular formation and the basal forebrain that do not release conventional neuromodulators but rather the ubiquitous neurotransmitter glutamate. By binding to metabotropic receptors, glutamate can act as a neuromodulator and influence the excitability of target cells. Most glutamatergic neurons in the basal forebrain discharge at their fastest rates during wakefulness (a subgroup also during REM sleep), although some are most active during slow wave sleep (Hassani et al., 2009). Extracellular glutamate levels in the cortex increase progressively during wakefulness and REM sleep (Dash et al., 2009). The wake-promoting effect of glutamate may also be indirect, via activation of hypothalamic neurons containing hypocretin and histamine (John et al., 2008; Li et al., 2002).

NOREPINEPHRINE

Noradrenergic cells are concentrated in the locus coeruleus in the upper pons, from where they project throughout the brain (Aston-Jones and Cohen, 2005; Berridge and Waterhouse, 2003). They fire tonically during wakefulness and emit short, phasic bursts of activity during behavioral choices or salient events (Aston-Jones and Bloom, 1981a, 1981b; Aston-Jones and Cohen, 2005; Berridge and Abercrombie, 1999; Foote et al., 1980). The release of norepinephrine increases the response of cortical neurons to incoming stimuli, but it is not necessary for EEG activation (noradrenergic lesions induce mild sedation) (Berridge and Espana, 2000; Berridge and Foote, 1991; Cape and Jones, 1998; McCormick, 1989). However, the release of norepinephrine during wakefulness is essential for the induction of genes such as *P-CREB*, *Arc*, and *BDNF*, which are involved in synaptic potentiation and thereby in learning (Cirelli and Tononi, 2000; Cirelli et al., 1996). By contrast, locus coeruleus neurons decrease their firing during NREM sleep and cease firing altogether during REM sleep: in this way, neural activity during sleep does not translate into long-term synaptic potentiation, so we do not end up learning the wrong things and confuse dreams for reality.

SEROTONIN

Serotonergic cells from the dorsal raphe nucleus also project widely throughout the brain. Serotonergic neurons, like noradrenergic neurons, fire at higher levels in waking, lower levels in NREM sleep, and fall silent during REM sleep. However, in contrast to noradrenergic neurons, serotonergic neurons are inactivated when animals make behavioral choices or orient to salient stimuli and are activated instead during repetitive motor activity such as locomoting, grooming, or feeding (Jacobs et al., 2002; McGinty and Harper, 1976). The inactivity of serotonin cells during sleep may contribute to the sensory disconnection from the environment that occurs during sleep. Overall, serotonin has been shown to have a complex, biphasic effect on sleep, first enhancing wakefulness and then facilitating the onset of NREM sleep (Landolt and Wehrle, 2009; Ursin, 2002), at least in part by inhibiting the cholinergic system (Cape and Jones, 1998; Jones, 2005; Jouvett, 1999; Monti and Jantos, 2008).

DOPAMINE

Another aminergic neuromodulator is dopamine (DA). Dopamine-containing neurons located in the substantia nigra and ventral tegmental area innervate the frontal cortex, basal forebrain, and limbic structures (Monti and Monti, 2007). Unlike other aminergic cells, dopaminergic neurons do not appear to change their overall firing rate depending on behavioral state. However, their bursting activity, which is known to induce large synaptic DA release, increases during the consumption of palatable food and during REM sleep relative to NREM sleep (Dahan et al., 2007). Moreover, lesions of areas containing dopaminergic cell bodies in the ventral midbrain or their ascending pathways can lead to loss of behavioral arousal while maintaining cortical activation. Finally, psychostimulants

such as amphetamines and cocaine that block reuptake of monoamines including norepinephrine, DA, and serotonin, promote prolonged wakefulness and increase cortical activation and behavioral arousal (Monti and Jantos, 2008). Thus, the evidence for a role of dopamine as a wake-promoting neurotransmitter is substantial.

HYPOCRETIN

The peptide hypocretin (also known as orexin) is produced by cells in the dorsolateral hypothalamus that provide excitatory input to all components of the waking system (Kilduff and Peyron, 2000; Sakurai, 2007). These cells, too, are most active during waking, especially in relation to motor activity and exploratory behavior, and almost stop firing during NREM and REM sleep (Lee et al., 2005a; Mileykovskiy et al., 2005). Specific activation of hypocretin cells, via optogenetic or pharmacogenetic stimulation, facilitates arousal and increases time spent awake (Adamantidis et al., 2007; Sasaki et al., 2011). Most patients with narcolepsy, a disorder characterized by excessive somnolence and cataplectic attacks, have low or undetectable levels of hypocretin in the cerebrospinal fluid (Dauvilliers et al., 2007).

HYPOTHALAMUS, BASAL FOREBRAIN, AND SLEEP

As we seek a quiet, dark, and silent place to fall asleep and close our eyes, the activity of the waking-promoting neuronal groups is decreased because of reduced sensory input. In addition, several of these brain areas are actively inhibited by antagonistic neuronal populations located in the hypothalamic and basal forebrain, and which become active at sleep onset. When the waking-promoting neuronal groups become nearly silent, the decreasing levels of acetylcholine and other waking-promoting neuromodulators and neurotransmitters lead to the opening of leak potassium channels in cortical and thalamic neurons, which become hyperpolarized and begin oscillating at low frequencies.

The importance of hypothalamic structures for sleep induction was recognized at the beginning of the twentieth century during an epidemic of a viral infection of the brain called encephalitis lethargica. Von Economo concluded that if the infection destroyed the posterior hypothalamus, patients became indeed lethargic, but if the anterior hypothalamus was lesioned, patients became severely insomniac (von Economo, 1931). Indeed, subsequent studies confirmed that cell groups within the anterior hypothalamus are involved in the initiation and maintenance of sleep. The ventrolateral preoptic area has been suggested as a possible sleep switch (Sherin et al., 1996; Szymusiak et al., 1998). However, many other neurons scattered through the anterior hypothalamus, for instance in the median preoptic nucleus (Suntsova et al., 2002), also play a major role in initiating and maintaining sleep. These neurons tend to fire during sleep and stop firing during wakefulness. When they are active, many of them release γ -aminobutyric acid (GABA) and the peptide galanin, and inhibit most waking-promoting areas, including cholinergic, noradrenergic, histaminergic,

hypocretinergic, and serotonergic cells. In turn, the latter inhibit several sleep-promoting neuronal groups (Jones, 2003, 2005; Lin et al., 2011; Saper et al., 2005a; Szymusiak and McGinty, 2008). Another group of GABAergic neurons is located in the basal forebrain and projects to the cerebral cortex. GABA levels in the cortex are higher during NREM sleep than during wakefulness or REM sleep (Vanini et al., 2012).

THE REM SLEEP GENERATOR

The REM sleep generator consists of pontine cholinergic cell groups (LDT and PPT) that we have already encountered as waking-promoting areas, and of nearby cell groups in the medial pontine reticular formation and in the medulla (Jouvet, 1962, 1965, 1994; Luppi et al., 2012; McCarley, 2011; Siegel, 2005). Lesions in these areas eliminate REM sleep without significantly disrupting NREM sleep. Rapid eye movement sleep can also be eliminated by certain antidepressants, especially monoamine oxidase inhibitors. As we have seen, pontine cholinergic neurons produce EEG activation by releasing acetylcholine to the thalamus and to cholinergic and glutamatergic basal forebrain neurons that in turn activate the limbic system and cortex. However, though during wakefulness other wak-promoting neuronal groups such as noradrenergic, histaminergic, hypocretinergic, and serotonergic neurons are also active, they are inhibited during REM sleep. Other REM active neurons in the dorsal pons are responsible for the tonic inhibition of muscle tone during REM sleep. Finally, neurons in the medial pontine reticular formation fire in bursts and produce phasic events of REM sleep, such as REMs and muscle twitches.

THE CIRCADIAN CLOCK

In mammals, the primary clock that keeps circadian time is the suprachiasmatic nucleus (SCN) of the hypothalamus. The SCN regulates a number of endocrine and behavioral parameters to coordinate the state of the organism with the 24-hour light-dark cycle, including wakefulness and sleep (Aston-Jones, 2005; Deboer et al., 2007; Mistlberger, 2005; Saper et al., 2005a; Zee and Manthana, 2007). In diurnal animals, the SCN activates waking-promoting areas and inhibits sleep-promoting areas during the day, maximally at the end of the day, whereas the converse is true at night. This makes it difficult to sleep in the early evening or to be awake in the early morning. In animals in which the SCN has been lesioned, sleep is no longer concentrated in one main episode but is dispersed across the entire 24-hour cycle (Bergmann et al., 1987; Mistlberger et al., 1983; Tobler et al., 1983). Each of the ~20,000 cells of the SCN contain a molecular clock that changes their excitability according to a near-24-hour rhythm, and which is reset by light. The SCN produces a coherent output because its cells synchronize among themselves (Mohawk and Takahashi, 2011).

HUMORAL FACTORS

For a long time, it was assumed that sleep was mediated by the accumulation of some humoral factor during wakefulness—a kind of hypnotoxin. Despite a long search, only a few humoral

factors have any well-defined role in sleep physiology. One of the best-studied substances is adenosine, not surprising given the well-known wake-promoting effect of the A1 antagonist caffeine (Basheer et al., 2004; Porkka-Heiskanen et al., 2002). Extracellular adenosine levels progressively increase in the basal forebrain during wakefulness, inhibiting cholinergic neurons and promoting sleep (Porkka-Heiskanen et al., 1997). During wakefulness adenosine levels also increase (although not progressively) in cortex and hippocampus, and astrocyte-derived adenosine plays a role in sleep homeostasis (Halassa et al., 2009; Porkka-Heiskanen et al., 2000; Schmitt et al., 2012). Prostaglandin D₂, another sleep promoting substance, acting on the prostaglandin D (PGD) receptor, indirectly activates adenosine A2A-dependent pathways in the basal forebrain (Huang et al., 2007). However, neither A1 nor PGD receptor knockout mice have abnormal baseline sleep. Similarly, a number of lymphokines, such as interleukin-1 (IL-1) and tumor necrosis factor (TNF) alpha, modulate sleep. These effects are often species specific and could be most relevant in the context of acute inflammation or infection. However, the TNF and IL-1 type I receptor knockouts have abnormal sleep, suggesting also a role in baseline sleep regulation (Krueger et al., 2001).

The pineal hormone melatonin is strongly regulated by the circadian clock and peaks at night in diurnal and nocturnal animals (it has been called the “darkness hormone”). Melatonin

receptors are highly expressed in the SCN, and melatonin can help reset circadian rhythms and thereby influence sleep (Zee and Manthena, 2007). Light and melatonin can be used to alleviate and correct circadian rhythm disorders and conditions such as jet lag and night shift work. Melatonin is also effective in regularizing the sleep–wake schedule of light-blind subjects whose sleep–wake periods tend to free-run, as well as in children and in the elderly with brain disorders, for example in the treatment of the “sundowning” often seen in dementia (Arendt, 2005; Richardson, 2005).

SLEEP REGULATION AND SLEEP DEPRIVATION

If we are not allowed to sleep and are forced to stay awake longer than usual, sleep pressure mounts and soon becomes overwhelming. Thus, sleep is homeostatically regulated: the more we stay awake, the longer and more intensely we sleep afterwards: arousal thresholds increase, there are fewer awakenings, and during NREM sleep the amplitude and prevalence of slow waves becomes much higher (Fig. 87.4) and there can be a rebound of REM sleep. Sleep pressure only diminishes if one is allowed to sleep, and the number and amplitude of sleep slow waves gradually diminishes.

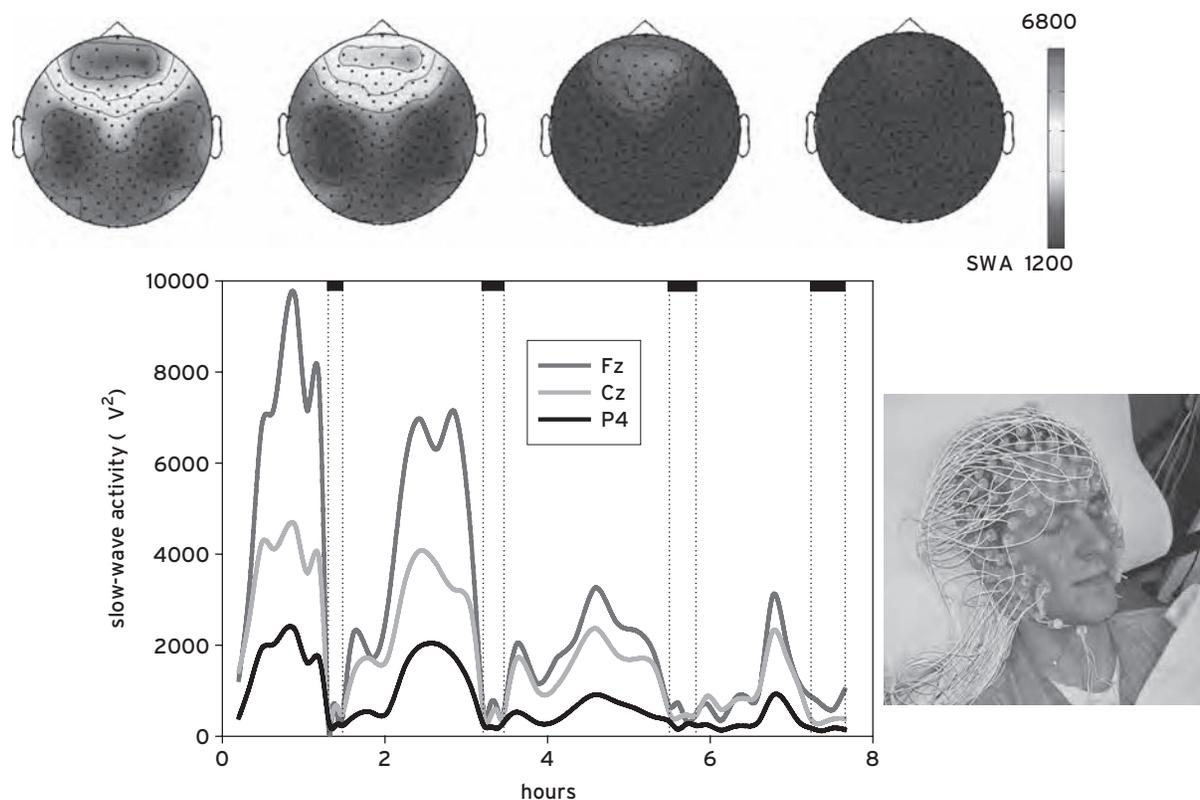

Figure 87.4 Sleep slow waves as a marker of sleep pressure. Bottom panel: During early sleep, at the end of a day of wakefulness, sleep pressure is maximal. This is reflected in frequent and large sleep slow waves, measured here as slow wave activity (power in the 0.5–4 Hz band, in red for a frontal electroencephalogram (EEG) channel, green for a central channel, and blue for an occipital channel). During sleep slow wave activity decreases exponentially, reflecting a reduction of sleep pressure. The transitory drops in slow-wave activity correspond to episodes of rapid-eye-movement (REM) sleep. Top panel: Topographic display of slow wave activity over the scalp for the four sleep cycles. Notice the frontal predominance and the progressive decline in the course of the night. (See color insert.)

In humans, the most prominent effect of total sleep deprivation, and even of sleep restriction (for several nights), is cognitive impairment, with striking practical consequences (Banks and Dinges, 2007; Killgore, 2010). A person who is sleep deprived tends to take longer to respond to stimuli, particularly when tasks are monotonous and low in cognitive demands. However, sleep deprivation produces more than just decreased alertness. Tasks emphasizing higher cognitive functions, such as logical reasoning, encoding, decoding, and parsing complex sentences; complex subtraction tasks; and tasks involving a flexible thinking style and the ability to focus on a large number of goals simultaneously, are all significantly affected even after one single night of sleep deprivation. Tasks requiring sustained attention, such as those including goal-directed activities, can be impaired by even a few hours of sleep loss. For example, medical interns make more frequent serious diagnostic errors when they worked frequent shifts of 24 hours or more than when they worked shorter shifts (Barger et al., 2006). Unfortunately, sleep deprived subjects underestimate the severity of their cognitive impairment, often with tragic consequences. Also, lack of sleep does not completely eliminate the capacity to perform but rather makes the performance inconsistent and unreliable (Doran et al., 2001). Thus, a sleepy driver will either respond normally to an emergency or not at all, due to rapid changes in vigilance state and the sudden intrusion of microsleeps during waking. Similarly, people may still be able to transiently perform at baseline levels in short tests even after three–four days of sleep deprivation. However, the same subjects will perform very poorly when engaged in tasks requiring sustained attention. An important issue that remains unresolved is whether the cognitive impairment seen after sleep deprivation and sleep restriction is exclusively caused by sleepiness—the increasing internal pressure to fall asleep presumably mediated by the sleep-promoting areas discussed before—or to progressive cellular dysfunctions in cortical and other circuits that have been awake too long, a veritable form of neuronal tiredness.

It should be mentioned that several well-controlled studies have discredited the once-popular notion that loss of REM sleep might lead to psychosis and suicide. Indeed, REM sleep deprivation, as well as total sleep deprivation or selective slow wave deprivation, improves mood in approximately 50% of people who are depressed (Hemmeter et al., 2010; Landsness et al., 2011).

NEURAL CORRELATES OF WAKEFULNESS AND SLEEP

Wakefulness and NREM and REM sleep are accompanied by distinctive molecular changes, changes in spontaneous neural activity and metabolism, and responsiveness to stimuli.

MOLECULAR CHANGES

It might seem unlikely that the mere change from wakefulness to sleep should lead to changes in the expression of genes in the brain, but this is actually what happens, and on a massive scale. Hundreds of gene transcripts (messenger ribonucleic acids

[RNAs]) are expressed at higher levels in the waking brain, and different sets of transcripts are expressed at higher levels in sleep (Cirelli, 2009; Cirelli et al., 2004). Many of these molecular changes are specific to the brain because they do not occur in other tissues such as liver and muscle. Transcripts upregulated during wakefulness code for proteins that help the brain to face high-energy demand, high synaptic excitatory transmission, high transcriptional activity, as well as the cellular stress that may derive from one or more of these processes. Moreover, wakefulness is associated with the increased expression of several genes that are involved in long-term potentiation of synaptic strength, such as *P-CREB*, *Arc*, *NGFI-A* and *BDNF* (Cirelli and Tononi, 2000; Cirelli et al., 1996) (Fig. 87.5). As we have seen, one reason these genes are expressed in wakefulness and not in sleep has to do with the release of norepinephrine, which is high during wakefulness, when animals make decisions and learn about the environment, but is low during sleep.

By contrast, the genes that increase their expression during sleep include several that may be involved in long-term depression of synaptic strength and possibly in synaptic consolidation (Cirelli et al., 2004; Cirelli, 2009). Other sleep-related genes appear to favor the rate of protein synthesis, which is

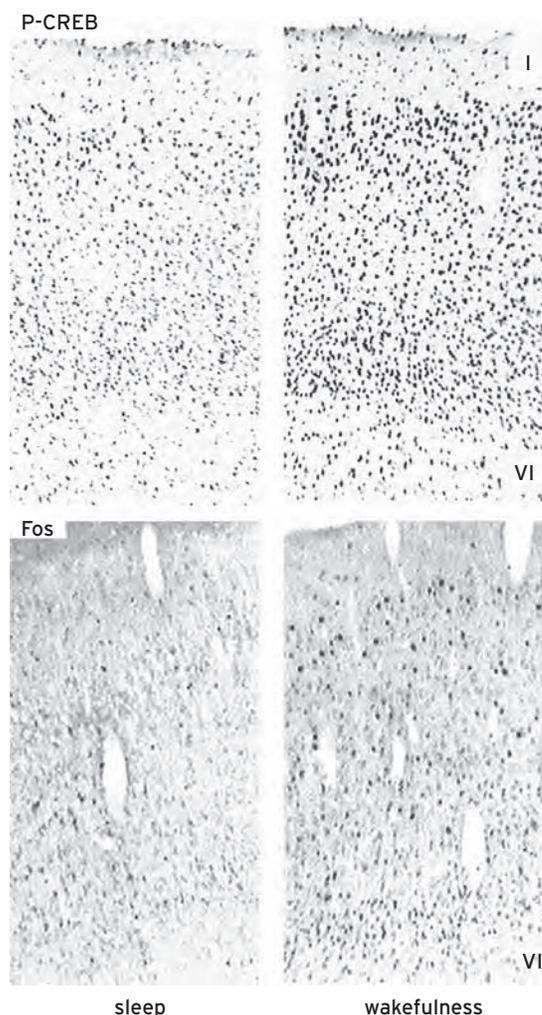

Figure 87.5 The expression of the transcription factors *P-CREB* and *Fos* is high in wakefulness and low in sleep (rat parietal cortex: I, VI, cortical layers I and VI).

also increased in sleep. Finally, many sleep-related genes play a significant role in membrane trafficking and maintenance. Thus, these findings suggest that although sleep is a state of behavioral inactivity, it is associated not only with intense neural activity, but also with the increased expression of many genes that may favor specific cellular functions.

SPONTANEOUS NEURAL ACTIVITY

WAKEFULNESS

The waking EEG, characterized by the presence of low-voltage fast-activity, is known as activated because most cortical neurons are steadily depolarized close to their firing threshold (Fig. 87.6A), and are thus ready to respond to the slightest change in their inputs. The steady depolarization is caused by the release of acetylcholine and other neurotransmitters and neuromodulators, which close leakage potassium channels on the membrane of cortical neurons. The readiness to respond of cortical and thalamic neurons enables fast and effective interactions among distributed regions of the thalamocortical system, resulting in a continuously changing sequence of specific firing patterns. Because these firing patterns are not globally synchronous across the cortex, the EEG displays rapid fluctuations of low amplitude rather than high-voltage, low-frequency waves. Nevertheless, superimposed on the low-voltage, fast-activity background of wakefulness one frequently observes rhythmic oscillatory episodes within the alpha (8–13 Hz), beta (14–28 Hz), and gamma (>28 Hz) range, which are usually localized to specific cortical areas. These waking rhythms are due to the activation of oscillatory mechanisms intrinsic to each cell as well as to the entrainment of oscillatory circuits among excitatory and inhibitory neurons.

NREM SLEEP

As we have seen, the EEG of NREM sleep is very different from that of wakefulness and is characterized by the occurrence of slow waves (<2 Hz in humans), K-complexes, and sleep spindles. At the beginning of sleep, the release of acetylcholine and other neuromodulators is much reduced, with the consequence that leakage potassium channels on the membrane of cortical and thalamic cells open, positively charged potassium ions leave the cells, and membrane potentials are drawn toward hyperpolarization. This and other neuromodulatory mediated changes trigger a series of membrane currents that lead to an oscillation in cellular membrane potential called the slow oscillation (see Fig. 87.6A) (Steriade et al., 2001). As shown by intracellular recordings, the slow oscillation is made up of a hyperpolarization phase or down-state, which lasts a few hundreds milliseconds, and a slightly longer depolarization phase or up state. The down state is associated with the virtual absence of synaptic activity within cortical networks (OFF periods). During the up state, by contrast, cortical cells fire at rates that are as high or even higher than those seen in waking and may even show periods of fast oscillatory activity in the gamma range.

The slow oscillation is found in virtually every cortical neuron and is synchronized across much of the cortical mantle by corticocortical connections, which is why the EEG records

high-voltage, low-frequency waves. Human EEG recordings using 256 channels have revealed that the slow oscillation behaves as a traveling wave that sweeps across a large portion of the cerebral cortex (Massimini et al., 2004). Most of the time, the sweep starts in the very front of the brain and propagates front to back. These sweeps occur very infrequently during stage N1, around 5 times a minute during stage N2, and more than 10–20 times a minute in stage N3. Thus, a wave of depolarization and intense synaptic activity, followed by a wave of hyperpolarization and synaptic silence, sweeps across the brain more and more frequently just as NREM sleep becomes deeper. These waves of activity and inactivity are reminiscent of those of contraction and relaxation that sweep through the cardiac tissue triggered by the electrical activity originating in the sinus pacemaker that travels along the conduction system. It is as if, during NREM sleep, the brain were to unveil its own spontaneous “brain beat.”

The various EEG waves that characterize NREM sleep are closely associated with the slow oscillation. Slow oscillations can occur every few seconds at a single cortical source, or can originate at short intervals at multiple cortical sites, in which case they superimpose or interfere, leading to EEG slow waves that are shorter and more fractured (delta waves, 1–2 Hz in humans). Waves in the delta range are also favored by certain intrinsic currents present in cortical and thalamic neurons. Topographically, slow waves are especially prominent over dorsolateral prefrontal cortex. K-complexes are probably nothing more than slow oscillations, usually triggered by external stimuli, which appear particularly prominent because they are not immediately preceded or followed by other slow waves.

Sleep spindles occur during the depolarized phase of the slow oscillation and are generated in thalamic circuits as a consequence of cortical firing. When the cortex enters an up state, strong cortical firing excites GABAergic neurons in the reticular nucleus of the thalamus. These in turn strongly inhibit thalamocortical neurons, triggering intrinsic currents that produce a rebound burst of action potentials. These bursts percolate within local thalamoreticular circuits and produce oscillatory firing at around 12–15 Hz. Thalamic spindle sequences reach back to the cortex and are globally synchronized by corticothalamic circuits, wherein they appear in the EEG as sleep spindles.

Recently, both rodent and human experiments have shown that sleep slow waves and spindles are global at the beginning of sleep, but become mostly local, occurring in some cortical areas and not in others, when sleep pressure has dissipated (Fig. 87.6B) (Nir et al., 2011; Vyazovskiy et al., 2011). Other studies have found that sleep slow waves can be regulated locally, their amplitude and number increasing after experience-dependent plasticity and synaptic potentiation and decreasing after synaptic depression (Faraguna et al., 2008; Hanlon et al., 2009; Huber et al., 2004, 2006, 2008; Hung et al., 2012). Moreover, it was recently found that, the longer a rat stays awake, the more cortical neurons show brief periods of silence in their firing that are essentially indistinguishable from the down states (OFF periods) observed during slow oscillations in a sleeping animal (Vyazovskiy et al., 2011). These OFF periods are local, in that they may

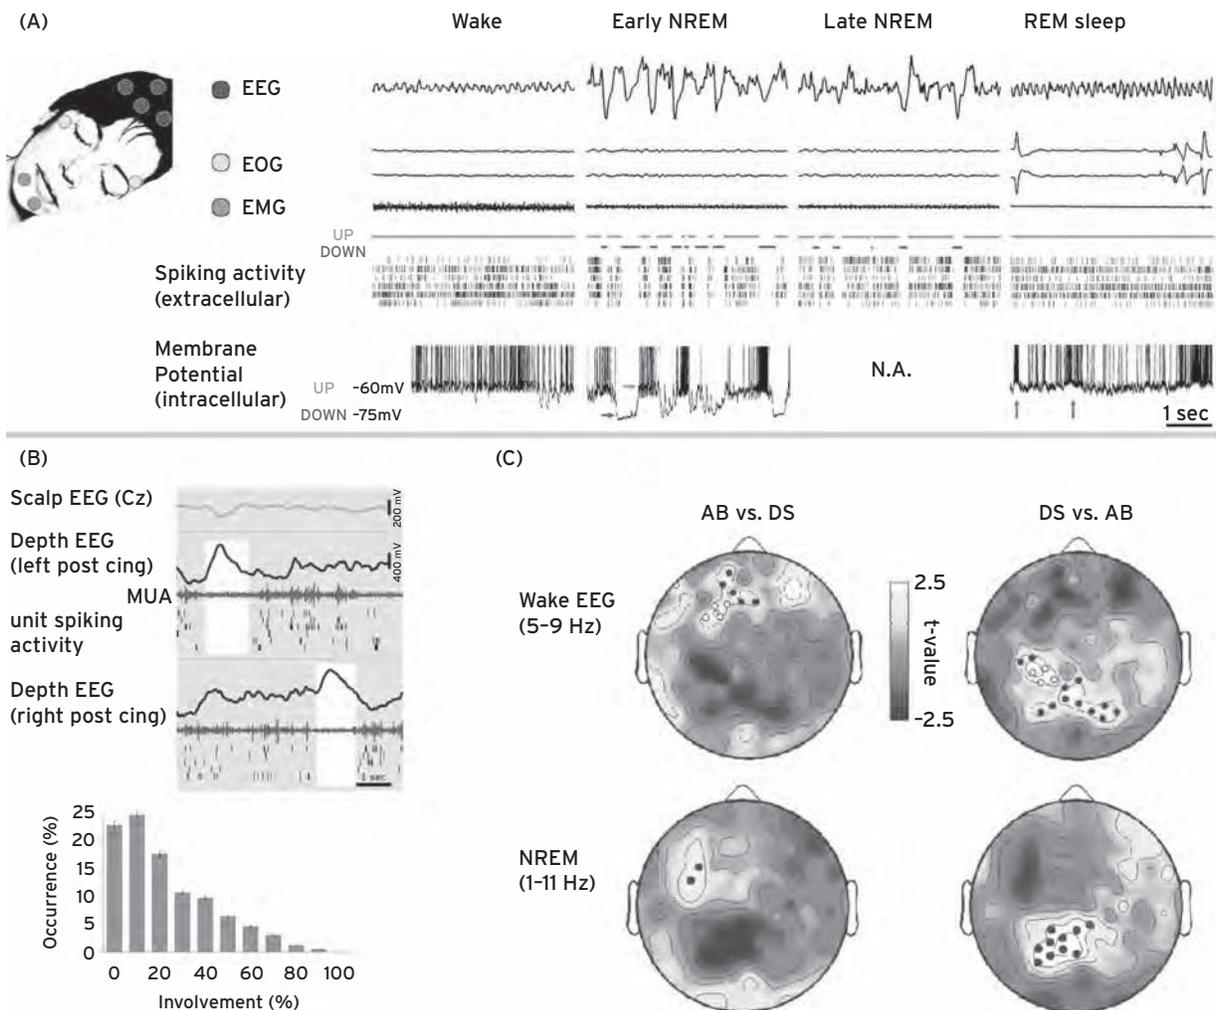

Figure 87.6 (A) Cortical activity in sleep and wake. Intracellular studies have shown that the membrane potential of cortical neurons in both wake and REM sleep is depolarized and fluctuates around -63 mV and -61 mV, respectively. In REM sleep, whenever phasic events such as rapid eye movements occur, neurons increase their firing rates to levels that surpass those found in wake. In early NREM sleep, neurons alternate between two distinct states, each lasting tens to hundreds of milliseconds: UP states (upper arrow) are associated with depolarization and increased firing, whereas in DOWN states (lower arrow) the membrane potential is hyperpolarized around -75 mV, and neuronal firing fades. Extracellular studies found that spiking of individual neurons in REM sleep reaches similar levels as in active wake. In both wake and REM sleep, neurons exhibit tonic irregular asynchronous activity. Sustained activity in wake and REM sleep can be viewed as a continuous UP state. In early NREM sleep, UP states are short and synchronous across neuronal populations, and are frequently interrupted by long DOWN states. In late NREM sleep, UP states are longer and less synchronized. Polysomnography. Waking is characterized by low-amplitude, high-frequency EEG activity, occasional saccadic eye movements, and elevated muscle tone. In early NREM sleep, high-amplitude slow waves (<4 Hz) dominate the EEG. Neuronal UP and DOWN states correspond to positive and negative peaks in the surface EEG, respectively. In late NREM sleep, slow waves are less frequent, whereas spindles (related to UP states and surface EEG positivity) become more common. Eye movements and muscle tone are largely similar to early NREM sleep. In REM sleep, theta activity ($4-7$ Hz) prevails, rapid eye movements occur and muscle tone is reduced. (B) Top: an example of local sleep slow waves occurring at different times in left and right posterior cingulate cortices. Rows (top to bottom) depict activity in scalp EEG (Cz), left posterior cingulate, and right posterior cingulate. Depth EEG multi-unit activity (MUA); black lines, single-unit spikes. White shadings mark local OFF periods. Bottom: Most slow waves are local. Distribution of slow wave involvement (percentage of monitored brain structures expressing each wave) is shown. (C) Subjects recorded with high-density EEG completed two experiments during which they stayed awake for ≥ 24 h practicing a language task (AB) or a visuomotor task (DS). Top: topographic distribution of relative power changes from baseline to the last wake session (after 24 h wake) between AB and DS in the theta frequency band ($5-9$ Hz). Black and white dots show channels with significant increase in spectral power. Bottom: topographic distribution of relative power changes in the low frequencies including slow waves ($1-11$ Hz) between AB and DS during the recovery night after 24 h wake. Channels showing significant increase in spectral power in AB relative to DS are indicated by black dots. ([A] Modified from Nir and Tononi, 2010; [B] From Nir et al. (2011); [C] Modified from Hung et al. 2012.)

occur at different times in different brain regions, and when they occur in the wrong region at the wrong time they can produce performance deficits. Experience-dependent plasticity extended beyond the normal wake duration also leads to a local slowing of the wake EEG in humans. This slowing is more prominent in the specific brain regions challenged by plasticity, and the subsequent sleep is more intense over

the same areas (Fig. 87.6C) (Hung et al., 2012). Thus, it is now clear that the intensity of sleep, as measured by sleep slow waves, can also be regulated at the local level and reflects experience-dependent plasticity occurring during prior wakefulness. Moreover, it appears that the need to sleep is strongly dependent on synaptic plasticity occurring during wake.

REM SLEEP

During REM sleep, the EEG returns to an activated, low-voltage fast-activity pattern that is similar to that of quiet wakefulness or stage 1. As in wakefulness, the tonic depolarization of cortical and thalamic neurons is caused by the closure of leakage potassium channels. In fact, during REM sleep acetylcholine and other neuromodulators are released again at high levels, just as in wakefulness, and neuronal firing rates in several brain areas tend to be even higher.

METABOLISM AND BLOOD FLOW

Recently, the data painstakingly obtained by recording the activity of individual neurons have been complemented by imaging studies that provide a simultaneous picture of synaptic activity over the entire brain, although at much lower resolution (Dang-Vu et al., 2010; Maquet, 2010).

NREM SLEEP

Positron emission tomography (PET) studies show that metabolic activity and blood flow are globally reduced in NREM sleep compared to resting wakefulness. During slow wave sleep, metabolic activity can be reduced by as much as 40%. Metabolic activity is mostly owing to the energetic requirements of synaptic transmission, and its reduction during NREM sleep is thus most likely owing to the hyperpolarized phase of the slow oscillation, during which synaptic activity is essentially abolished. At a regional level, activation is especially reduced in the thalamus, because of its profound hyperpolarization during NREM sleep. In the cerebral cortex, activation is reduced in the dorsolateral prefrontal, orbitofrontal, and anterior cingulate cortex. This deactivation is to be expected given that slow oscillations are especially prominent in these areas. The parietal, precuneus, and posterior cingulate cortex, as well as medial temporal cortex also show relative deactivations. By contrast, primary sensory cortices are not deactivated compared to resting wakefulness. Basal ganglia and cerebellum are also deactivated, probably because of the reduced inflow from cortical areas.

REM SLEEP

During REM sleep absolute levels of blood flow and metabolic activity are high, reaching levels similar to those seen during wakefulness, as would be expected based on the tonic depolarization and high firing rates of neurons. There are, however, interesting regional differences. Some brain areas are more active in REM sleep than in wakefulness. For example, there is a strong activation of limbic areas, including the amygdala and the parahippocampal cortex. Cerebral cortical areas that receive strong inputs from the amygdala, such as the anterior cingulate and the parietal lobule, are also activated, as are extrastriate areas. By contrast, the rest of the parietal cortex, precuneus, and posterior cingulate, and dorsolateral prefrontal cortex are relatively deactivated. As we will see, these regional activations and inactivations are consistent with the differences in mental state between sleep and wakefulness.

Upon awakening, blood flow is rapidly reestablished in brain stem and thalamus, as well as in the anterior cingulate cortex. However, it can take up to 20 minutes for blood flow to be fully

reestablished in other brain areas, notably dorsolateral prefrontal cortex. It is likely that this sluggish reactivation is responsible for the phenomenon of sleep inertia—a postawakening deficit in alertness and performance that can last for tens of minutes.

RESPONSIVENESS TO STIMULI

The most striking behavioral consequence of falling asleep is a progressive disconnection from the outside world. We stop responding to stimuli and, to the extent that we remain conscious, our experiences become largely independent of the current environment. This disconnection would appear to be important because we make several behavioral adjustments to bring it about: we seek a quiet environment, find a comfortable position, and close our eyes. However, people (especially small children) can fall asleep in a noisy environment and in uncomfortable positions—in the laboratory people can even sleep with their eyes taped open. Everything else being equal, the threshold for responding to peripheral stimuli gradually increases with the succession of NREM sleep stages 1 to 4 and remains high during REM sleep. Because cortical neurons continue to fire actively during sleep, how does this disconnection come about?

NREM SLEEP

As we have seen, during the transition from wakefulness to NREM sleep, the release of acetylcholine and other neuromodulators is reduced, leading to the progressive hyperpolarization of thalamocortical neurons. As a consequence, sensory stimuli that normally would be relayed to the cortex often fail to do so because they do not manage to fire thalamocortical cells. In addition, the rhythmic hyperpolarization during sleep spindles is especially effective in blocking incoming stimuli because it imposes an intrinsic oscillatory rhythm that effectively decouples inputs from outputs. Thus, the “thalamic gate” to the cerebral cortex is partially closed (Steriade and Timofeev, 2003). However, sensory stimuli in various modalities still elicit evoked potentials from the cerebral cortex, and neuroimaging studies show that primary cortical areas are still being activated (Portas et al., 2000). Studies using transcranial magnetic stimulation (TMS) and high-density EEG have employed direct cortical stimulation to bypass the thalamic gate (Massimini et al., 2005). The results show that during wakefulness TMS induces an initial local response followed for about 300 milliseconds by multiple, fast waves of activity associated with rapidly changing configurations of scalp potentials (Fig. 87.7). With the onset of NREM sleep, however, the brain response to TMS changes markedly. The initial response doubles in amplitude and lasts longer. After this large wave, however, no further TMS-locked activity can be detected, and all TMS-evoked activity ceases by 150 milliseconds. Moreover, this response, which lacks high-frequency components, remains localized and does not propagate to connected brain regions. Apparently, the ability of brain regions to interact causally with each other—their effective connectivity—breaks down during NREM sleep.

REM SLEEP

With the transition from NREM to REM sleep, neurons return to be steadily depolarized much as they are during quiet

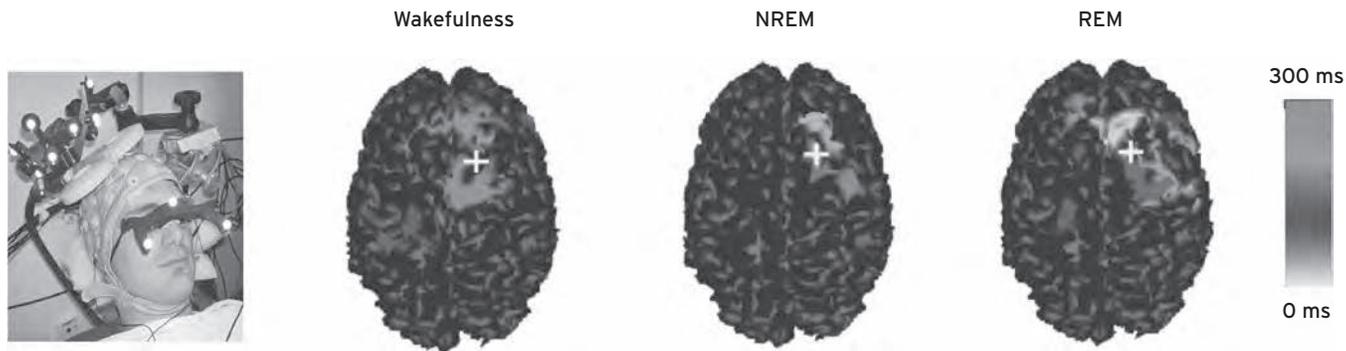

Figure 87.7 Spatiotemporal cortical current maps of transcranial magnetic stimulation (TMS)-induced activity during wakefulness, non-rapid eye movement (NREM), and REM sleep. On the left is the setup for TMS/EEG. From the electroencephalogram (EEG) data, maximum current sources corresponding to periods of significant activations were plotted and color-coded according to their latency of activation (light blue, 0 ms; red, 300 ms). The yellow cross marks the TMS target on the cortical surface. Note the rapidly changing patterns of activation during wakefulness, lasting up to 300 ms and involving several different areas; the brief activation that remains localized to the area of stimulation during NREM sleep; and an intermediate pattern of activation during REM sleep. (From Massimini M., Ferrarelli F., Huber R., et al., 2005. Breakdown of cortical effective connectivity during sleep. *Science* 309:2228–2232.) (See color insert.)

wakefulness, yet we still ignore sensory stimuli. It is as if we are preoccupied with the brain's intrinsic activity rather than with what goes on in the external world (Llinas and Pare, 1991), similar to what happens during states of intense absorption that can occur even when awake, say when one is engrossed in reading a captivating novel. The underlying mechanisms, however, are not clear. As we have seen, prefrontal and parietal cortical areas are deactivated in REM sleep compared to wakefulness. These regions include brain areas important for directing and sustaining attention to what is going on in sensory cortices. Sensory inputs reaching primary cortices would then find themselves to be systematically unattended. It is likely that the reduced activity in these cortical regions is a direct consequence of changes in the neuromodulatory milieu during REM sleep. The reduction of serotonin release during REM sleep may favor a dissociative hallucinogenic state, as seen with certain psychoactive compounds.

Nevertheless, in contrast to a person in a coma or a vegetative state, a sleeping person can always be awakened if stimuli are strong enough, or especially meaningful. For example, it is well known that the sound of one's name, or the wailing of a baby, is among the most effective signals for awakening.

CONSCIOUSNESS DURING SLEEP

Sleep brings about at once the most common and the most dramatic change in consciousness that we are likely to witness—from the near fading of all experience to the bizarre hallucinations of dreams. Indeed, studying mental activity during sleep offers a unique opportunity to find out how changes in brain activity are associated with changes in consciousness (Nir and Tononi, 2010). Typically, subjects are awoken at different times of night and asked to report whatever was going through their mind.

SLEEP ONSET

Reports from sleep onset, that is, stage 1, are very frequent (80–90% of the time), but they are also very short, usually hallucinatory experiences. These are called hypnagogic

hallucinations, from a Greek word meaning “leading into sleep.” In contrast to typical dreams, hypnagogic hallucinations are often static, similar to single snapshots or a short sequence of still frames.

NREM SLEEP

Awakenings from NREM sleep yield reports 60–80% of the time. Thus, there is a substantial number of awakenings from NREM sleep that yield no report whatsoever, especially early in the night when stages 3 and 4 are prevalent. The length of NREM reports is widely distributed. However, there are many very short reports early in the night, and much longer reports later in the night, considerably longer than those typically obtained at sleep onset or even during quiet wakefulness. Reports from NREM sleep, especially early in the night, can be thought-like and lack perceptual vividness. However, especially later in the night, they can be much more hallucinatory and, generally speaking, more dreamlike. Indeed, hallucinatory content increases steeply from waking to sleep onset, and then to NREM sleep and REM sleep, whereas thought-like content behaves in the opposite way.

REM SLEEP

Awakenings from REM sleep yield reports 80–90% of the time, a percentage similar to that obtained at sleep onset. Especially in the morning hours, the percentage is close to 100% (the report rate for wakefulness). Remarkably, the median word count of REM sleep reports is even higher than that of wakefulness reports, whether quiet or active. This finding seems to fit with the notion that dreams are single-minded, and thus less frequently interrupted by extraneous thoughts than waking consciousness. The average length of REM reports increases with the duration of the REM sleep episode. By contrast, there is no such relationship for NREM sleep reports.

These observations lead to several conclusions. Contrary to initial claims, some kind of conscious experience during sleep is the rule, rather than the exception. Especially late in the night, several NREM reports must be considered as bona fide dreams, no matter what criteria one uses, although they are on

average not as long, vivid, and bizarre as those obtained from REM sleep. Another general conclusion from recent studies is that the length, hallucinatory content, and overall dreamlike quality of reports increases from the beginning to the end of the night, irrespective of sleep stage. Thus, the relationship between sleep stages and dream features is probabilistic rather than absolute.

However, we must not forget that a number of NREM reports, especially from the early part of the night, show little evidence of conscious content. Considering that people awakened from stage 3 and 4 NREM sleep, even when they do report something, often take a long time to wake up and confabulate while still half asleep, it seems reasonable to assume that this may be the only time of our regular existence when we are close to losing consciousness altogether. So why does consciousness fade in NREM sleep early in the night, especially considering that spontaneous activity persists? One possibility is that the down state of the slow oscillation, which sweeps the cerebral cortex once a second and produces an intermittent, near-global deactivation, results in the effective disconnection of cortical regions. Indeed, as we have seen above, studies of TMS/EEG have shown a breakdown of cortical effective connectivity during early NREM sleep (Massimini et al., 2005). By contrast, at sleep onset, and in stage 2 NREM sleep toward the morning, there are relatively long periods of activation between slow oscillations that may explain why most participants report dreamlike experiences, although usually short ones. Finally, the long and vivid dreams of REM sleep can occur because brain activation is not interrupted at all by slow oscillations (see Fig. 87.7).

Finally, though the vivid dreams of REM sleep can at times be hard to distinguish from waking experience, usually they share some features that are remarkably consistent with the changes in brain activation revealed by neuroimaging studies. For example, a key feature of dreaming consciousness is the reduced responsiveness to external stimuli, accompanied by vivid hallucinations, especially visual ones. Accordingly, PET studies of REM sleep show reduced activity in primary visual cortex, accompanied by increased activity in higher visual areas. Another relevant difference between dreaming and waking consciousness concerns the ability to reflect on oneself and one's experience, especially the ability to judge the verisimilitude of dreams. As we have seen, dorsolateral prefrontal cortex, which is involved in volitional control and self-monitoring, is especially deactivated during REM sleep. Reduced activation of dorsolateral prefrontal cortex may also contribute to the disorientation, reduction of directed thinking, and working memory observed in dreams, and contributes to dreaming amnesia. Conversely, dreams are characterized by a high degree of emotional involvement, especially fear and anxiety. Correspondingly, imaging studies have revealed a marked activation of limbic and paralimbic structures such as the amygdala, the anterior cingulate cortex, the insula, and medial orbitofrontal cortex during REM sleep. Although we still do not know what is responsible for the changes in brain regional activation that occur during REM sleep, it is likely that neuromodulatory systems may be involved. For example, because monoaminergic systems are silent during REM sleep, acetylcholine is alone in maintaining brain activation. Consistent with imaging results, the cholinergic innervation is especially

strong in limbic and paralimbic areas and much weaker in dorsolateral prefrontal cortex.

THE FUNCTIONS OF SLEEP

Why should we periodically abandon daily activities, relinquish the search for food, forgo our reproductive duties, stop monitoring the environment for dangers or opportunities, and slumber for hours into an altered state of consciousness? An appealing idea is that sleep may have evolved from the circadian rest-activity cycle and may thus represent a default state of inactivity that keeps us out of trouble during the dark hours (or the light hours for nocturnal creature) when we have nothing better to do. However, it is likely that sleep serves some more fundamental function. First, why should animals engage in prolonged periods of quiescence during which they are dangerously out of touch? Second, sleep seems to be universal. All animal species carefully studied so far sleep, from invertebrates such as fruit flies and bees to birds and mammals (Cirelli and Tononi, 2008). Nor has evolution found an easy way of getting rid of sleep. Some animals who need continuous vigilance while swimming or flying, for example, certain dolphins and migrating birds, have developed alternating unihemispheric sleep rather than eliminating sleep altogether. Third, sleep need is carefully regulated. If sleep is eliminated or restricted for some time, there is a gradual increase in sleep pressure that rapidly becomes irresistible, and the subsequent sleep is longer and more intense. This suggests that ensuring a certain amount of sleep is as important as preserving appropriate levels of temperature, energy, or electrolytes. Many of the hypotheses that have been put forth over the years fall into two main categories: those that propose a role of sleep in memory, and those that envision a role in brain restitution.

SLEEP AND MEMORY

A connection between sleep and memory was noted a long time ago (Jenkins and Dallenback, 1924). After struggling to learn a new piece of music for much of the day, we often play it better after a night of sleep. Recently, the importance of sleep and even naps occurring after certain types of declarative and non-declarative learning has been documented in well-controlled experiments (Diekelmann and Born, 2010; Stickgold and Walker, 2007). Sleep could indeed offer a favorable context for certain aspects of learning and memory. The sensory disconnection associated with sleep reduces interference between ongoing activities and the consolidation of previously acquired memories. Moreover, sleep permits the repeated reactivation, in an off-line mode, of the neural circuits originally activated during the memorable experience. Studies using multielectrode recordings in animals and PET/functional magnetic resonance imaging (fMRI) in humans have shown that brain areas or cells activated during waking are preferentially reactivated during subsequent sleep (Buhry et al., 2011; Dang-Vu et al., 2010). A further advantage of sleep is that the relevant neural circuits can be reactivated in a spaced and interleaved fashion. This would favor the integration of

new with old memories and would avoid catastrophic interference. The intense, high-frequency bursts of spontaneous neural activity that occur during sleep may be particularly important for triggering molecular mechanisms of synaptic consolidation and to enlarge the network of associations.

Many unknowns remain, however. Whether sleep may favor the consolidation of newly established memories or the maintenance of older ones is not clear. Offline sequential activity also occurs during wakefulness, and in some cases the sequences activated offline correspond to trajectories never experienced by the animal, suggesting that this “reactivation” may be also involved in the maintenance of spatial representation and planning (Buhry et al., 2011). The molecular correlates of such processes are still unclear. Most molecular markers of memory acquisition are turned off during sleep, which may be advantageous given that the intense neural activity of sleep occurs while the animal is disconnected from the environment. Also, much of the early literature connecting sleep and memory was concerned with REM sleep. However, prolonged inhibition of REM sleep in humans through certain antidepressants does not seem to disrupt memory, nor does the complete disappearance of REM sleep after certain brainstem lesions (Siegel, 2001; Vertes, 2004).

SLEEP AND BRAIN RESTITUTION

When we have been awake too long we say we are tired, and after sleep we feel refreshed. Not surprisingly, the most intuitively compelling idea about the function of sleep is that sleep may restore some precious fuel or energy charge that was depleted during wakefulness. It is likely that sleep may indeed reduce energy waste by enforcing body rest in animals with high metabolic rates (this is certainly what hibernation does by drastically reducing body and brain metabolism, shutting off brain activity, and reducing temperature). However, in humans the metabolic savings of spending the night asleep rather than quietly awake are no more than a slice of bread (Horne, 1980). Moreover, we also say we are tired after muscle exertions, yet most bodily organs can recover through quiet wakefulness and do not need sleep. The notable exception is the brain: if we do not sleep, even though we may remain immobile, we rapidly suffer cognitive impairment. Therefore most researchers agree that sleep may be especially important for restoring the brain and provide something not afforded by quiet waking. However, there is great uncertainty when it comes to which chemical or molecular pathway in the brain may be wasted during waking and restored during sleep. For example, it has been suggested that sleep may favor the replenishment of glycogen in glial stores (Benington and Heller, 1995), although recent evidence shows that this may only be true in a few brain regions (Franken et al., 2003, 2006; Gip et al., 2002). The molecular changes that take place between wakefulness and sleep suggest other possibilities as well: sleep could counteract synaptic fatigue by favoring the replenishment of calcium in presynaptic stores, the replenishment of glutamate vesicles, the resting of mitochondria, the synthesis of proteins, or the trafficking and recycling of membranes (Cirelli et al., 2004; Mackiewicz et al., 2007; Mongrain et al., 2010). Unfortunately, most of these possibilities remain unexplored.

SLEEP AND SYNAPTIC HOMEOSTASIS

Memory consolidation and brain restitution are important perspectives on the function of sleep that are not mutually exclusive. A recently hypothesis reconciles these two perspectives by proposing that the main function of sleep is to control the strength of synapses impinging on neurons in the cortex and elsewhere (Tononi and Cirelli, 2003, 2006, 2012). This hypothesis effectively proposes a role for sleep in brain restitution—synaptic strength would increase during wakefulness and return to baseline during sleep. At the same time, the hypothesis claims that sleep is the price we pay because our brains are plastic and is thus related in an important manner to memory.

The hypothesis focuses mostly on NREM sleep, but REM sleep may fulfill a similar role with different mechanisms. The hypothesis says, first, that wakefulness is associated with synaptic potentiation in several cortical circuits (as we have seen, genes involved in synaptic potentiation are indeed unregulated during wakefulness). Although this remarkable plasticity is a good thing, reflecting our ability to learn and adapt, it comes at a cost. Synaptic activity is where the brain spends most of its energy, and increased synaptic strength means increased energy consumption just to keep the brain running (even if we merely sit and do nothing). Increased synaptic strength also means increased housekeeping and space needs. Neural cells have enormous dendritic trees literally covered with synapses, whose maintenance must burden membrane trafficking mechanisms. Moreover, there is very little room inside the brain for adding new synapses or making them bigger. In short, the brain is prone to synaptic overload, and it should have some homeostatic mechanism to save on energy, space, supplies, and to prevent the saturation of its plastic abilities. Therefore, synaptic strength must be regulated and returned to a sustainable level, restoring synaptic homeostasis. In this way, the costs in terms of energy, space, supplies, signal-to-noise ratios, and learning capacity are restored to baseline. The core claim of the hypothesis is that an essential function of sleep is the restoration of synaptic homeostasis, which is best achieved during sleep when there is no demand for learning and neurons can sample most of their inputs in an unbiased manner through off-line spontaneous activity. By contrast, during wake neurons preferentially sample the particular subsets of inputs determined by interactions with the environment, and they are required to learn on-line. Over the last several years much effort has been devoted to evaluating structural, molecular, and physiological indices of synaptic efficacy before and after sleep. So far, evidence obtained using a variety of experimental approaches has been supportive in flies, rodents, and humans: synaptic strength increases during wakefulness and decreases during sleep (Bushey et al., 2011; Donlea et al., 2009, 2011; Gilestro et al., 2009; Huber et al., 2012; Lante et al., 2011; Liu et al., 2010; Maret et al., 2011; Vyazovskiy et al., 2008; Yang and Gan, 2011).

SLEEP AND BRAIN DEVELOPMENT

The ideas and the findings discussed in the preceding usually pertain to adult sleep. However, we have seen that sleep is especially abundant early in development, before birth and during

the first year or two. This is a time of intense synaptogenesis as well as remodeling of connections—synaptic density in the cerebral cortex grows exuberantly during the first year of life and then decreases, most prominently during adolescence and then more slowly throughout life (Rakic et al., 1994). The increase in the number of synapses during early development is explosive, and it is bound to pose even greater challenges to neurons (and glia) than the increase in synaptic strength that occurs during wake in adult mammals. It is difficult to imagine how this massive formation of new synapses could be perfectly regulated, with precise titration of the total amount of synaptic weight impinging on each neuron. Instead, most likely during synaptogenesis neurons may undergo a substantial synaptic overload, and for the reasons discussed earlier synaptic rebalancing is best achieved off-line, when a neuron can sample most of its inputs in an unbiased manner. Two recent studies in mice have investigated the occurrence of sleep-dependent synaptic homeostasis during neurodevelopment, and found evidence that during adolescence sleep is associated with a net decrease in the number of synapses (Maret et al., 2011; Yang and Gan, 2011), thus possibly helping to maintain synaptic homeostasis in the face of ongoing synaptogenesis. Many questions remain, however, related to the role of sleep in earlier developmental stages, the role played by different kinds of sleep, and the consequences of sleep deprivation at such critical periods.

CONCLUSIONS

Sleep is characterized behaviorally by immobility and a reduced responsiveness to environmental stimuli that is rapidly reversible. The EEG, EMG, and EOG reveal distinct stages: a transitional stage N1; stage N2 (EEG spindles); stage N3 of NREM sleep (slow waves); and REM sleep (rapid eye movements with wake-like, activated EEG). There are four to five NREM–REM cycles every night. The transitions from wakefulness to sleep and between sleep stages are coordinated by a set of subcortical centers that are neurochemically heterogeneous. Broadly speaking, the reticular activating system in the posterior hypothalamus and upper brain-stem sustains brain activation through the release of neuromodulators such as acetylcholine, glutamate, histamine, and hypocretin; the anterior hypothalamus and basal forebrain coordinate sleep; the upper pons triggers REM sleep; and the suprachiasmatic nucleus is responsible for the circadian modulation of sleep propensity.

Various aspects of brain activity change during sleep, as shown by molecular, unit recordings, and imaging studies, but the brain by no means shuts off. For example, average firing rates in the cerebral cortex are similar to those of quiet wakefulness. However, during NREM sleep cortical cells undergo a characteristic slow oscillation: up to once a second, their membrane potential becomes hyperpolarized and all synaptic activity ceases for a few hundreds of milliseconds. When depolarization returns, it is often accompanied by sleep spindles—faster oscillations generated by interactions between the reticular thalamic nucleus and the thalamus proper. During NREM sleep metabolism in prefrontal and associative areas is reduced, and the brain is relatively disconnected from the environment, due in part to

a breakdown of effective connectivity among cortical regions. During REM sleep prefrontal areas are still deactivated, but there is a strong activation of limbic circuits. The interruption of serotonin release during REM sleep may contribute to the persisting disconnection from the environment.

Sleep represents a striking modification of consciousness, which fades early in the night and returns to be vivid later on in the form of dreams. A number of NREM awakenings, especially early in the night, yield little conscious recall. However, more often than not NREM awakenings result in meaningful reports, and in the later part of the night subjects may report full-fledged dreams. Awakenings from REM sleep almost always produce long and vivid dreams. Dreams are usually highly visual, in full color, but do not lack sound, touch, smell and taste, pleasure and pain. Just as in wakefulness, we experience objects, animals, people, faces, places, and so on. We can also have all sorts of thoughts and emotions, especially fear and anxiety. Thus, the dreaming brain is disconnected from the external world, yet it can generate a virtual, imagined world that is fairly similar to the real one. There are, however, some telltale signs of dreaming, including the fading of voluntary control, attention and reflective thought, and an impairment of working memory and episodic memory. By contrast, dreams rely on a network of associations that is less constrained than in waking life.

The periodic and obligatory alteration of consciousness that is forced upon us by sleep is likely to serve an essential function, but what this function might be remains an open issue. Sleep is potentially dangerous, yet it occupies a large fraction of our lives, it is universal in the animal kingdom, and lack of sleep is followed by increasing sleep pressure and cognitive impairment. Various ideas have been put forth, including a role in memory consolidation, in brain restitution, and in brain development. Finally, an intriguing hypothesis is that sleep may be the price we pay for synaptic plasticity during wakefulness.

ADRIANA FEDER, MARGARET HAGLUND, GANG WU,
STEVEN M. SOUTHWICK, AND DENNIS S. CHARNEY

Resilience is the ability to adapt successfully to severe or chronic stress (Charney, 2004; Rutter, 2006). Resilient individuals are those who are able to demonstrate healthy psychological and physiological stress responses in the face of extreme stress or trauma exposure, thus maintaining “psychobiological allostasis” (Feder et al., 2009; Karatsoreos and McEwen, 2011). Historically, most research on the effects of severe stress focused on its deleterious effects on well-being. The study of resilience began in the 1970s with the study of children exposed to significant adversity during development (Masten, 2001), later extending to the study of trauma-exposed adults (Alim et al., 2008; Bonanno, 2004). More recent epidemiological studies are beginning to look at longitudinal trajectories of posttraumatic stress disorder (PTSD) symptoms and resilience over time, and have begun to distinguish a resistance trajectory, characterized by the absence of symptoms, from a resilience trajectory, characterized by some initial symptom development, followed by prompt recovery (Bonanno et al., 2011; Hobfoll et al., 2009).

In the last decade, there has been a great deal of interest in delineating the neurobiological and psychological profile of resilient individuals. Supplementing studies in humans, animal studies are greatly advancing our understanding of neural and molecular mechanisms underlying resilience to stress (Russo et al., 2012). Identifying the factors that set resilient individuals apart from those who are vulnerable to the effects of stress has clinical significance: understanding the neurobiology and psychology of resilience enables researchers and clinicians to develop new therapies for the prevention and treatment of stress-induced psychopathology in non-resilient individuals. Furthermore, motivated individuals can draw from our increasing understanding of the features of resilience to achieve greater personal resilience to stress (Southwick and Charney, 2012a).

This chapter outlines the current understanding of resilience, from genetic, epigenetic, developmental, psychological, and neurobiological perspectives, and presents promising new therapies for the promotion of resilience to stress.

PREVALENCE OF RESILIENCE

The majority of individuals are exposed to trauma during their lifetime: in the United States, lifetime risk of at least one significant traumatic event, such as sudden unexpected death of a loved one, injury in a motor vehicle accident, or experiencing

assault, is estimated at 80–90% (Breslau et al., 1998; Bruce et al., 2001). The prevalence of resilience depends on the particular definition and measure(s) used, on the population studied, and importantly on the severity and chronicity of stress or trauma exposure. In the words of Rutter (2012), “resilience is an inference based on evidence that some individuals have a better outcome than others who have experienced a comparable level of adversity.”

Population studies in the United States have estimated the lifetime prevalence of PTSD at 8%, and the conditional probability of PTSD after exposure to trauma at 9% (Breslau et al., 1998; Kessler et al., 1995). Certain types of trauma, however, are significantly more likely to cause PTSD, particularly rape (65%) and combat exposure (38.8%) for men, and rape (45.9%) and physical abuse (48.5%) for women (Kessler et al., 1995). In general, traumatic events that are severe and unpredictable, intentionally caused by other human beings (such as assaultive trauma), and result in loss (of a loved one, property, or physical integrity) are most likely to lead to PTSD (Jordan et al., 1991; Yehuda, 2004). In a study of a high-risk primary care sample, the resilient group had a significantly lower lifetime prevalence of assaultive trauma (46.8% vs. 75.6%), as well as a significantly lower mean number of lifetime experienced trauma types (3.4% vs. 5.1%) than the group with current psychiatric disorders (Alim et al., 2008). Further, studies have shown that the degree of control that an individual has over a stressor or trauma is a key factor in modulating the impact of a stressor (Fleshner et al., 2011).

Recent longitudinal trajectories studies have employed latent growth mixture modeling, a statistical approach that identifies clusters of individuals following distinct courses of longitudinal symptom development without assuming a-priori trajectory types (Nagin and Odgers, 2010; Norris et al., 2009). In these studies, the prevalence of resilience has ranged widely depending on the population studied. For example, the resilience trajectory represented over 80% of the sample in a study of deployed US military service members (Bonanno et al., 2012), whereas it was 35.6% (resistance and resilience trajectories combined) in a sample under ongoing threat of terrorism and rocket attacks (Hobfoll et al., 2009). Of note, the second study used PTSD and depressive symptom measures to define resilience, whereas the first one only measured PTSD symptoms. Despite differences in prevalence across studies, research has shown that a significant percentage of individuals are resilient to the effects of extreme stress.

GENETICS OF RESILIENCE

Studies of gene-by-environment interactions have begun to identify how complex interactions between genetic contributions and an individual's particular history of exposure to environmental stressors yield a unique profile of adaptability of an individual's neurochemical stress responses and neural circuitry function upon exposure to new stressors. Further, as discussed in the following, epigenetic modifications are now understood to modulate stress reactivity by regulating gene expression at the molecular level.

It has long been known that stress-related disorders are at least partially heritable. For example, studies of combat-exposed men enrolled in the Vietnam Twin Registry have found that PTSD, panic disorder, and general anxiety disorder, frequently comorbid conditions, all have significant genetic contributions. It is estimated that up to 40% of the variance in occurrence of these disorders is accounted for by genetic factors, rather than by situation or trauma-related factors (Chantarujikapong et al., 2001; Scherrer et al., 2000; True et al., 1993). Genetic factors are not only important in determining an individual's response to a stressful event, but also influence the likelihood of exposure to that event (Kremen et al., 2012).

A series of studies have identified a range of specific genetic polymorphisms affecting stress reactivity, and thus likely affecting differential vulnerability to stress exposure, of which some examples follow. Regulation of the hypothalamic-pituitary-adrenal (HPA) axis, a key hormonal system involved in adaptation to stress, is affected by genetic factors. Two separate studies have shown that the presence of certain alleles and haplotypes of the gene coding for the corticotropin-releasing hormone (CRH) type 1 receptor moderates the severity of depressive symptoms in adults with a history of childhood abuse (Bradley et al., 2008). Functional polymorphisms of the glucocorticoid receptor (GR) have also been identified: for example, the N363S variant of the GR gene increases cortisol responses to the Trier Social Stress Test, a public speaking and mental arithmetic task (Derijk and de Kloet, 2008). Genetic variation in FKBP5, a gene coding for a protein responsible for regulating GR sensitivity, has been found to affect the efficiency of recovery of HPA axis activation after exposure to the Trier Social Stress Test in healthy individuals (Ising et al., 2008), and to interact with severity of childhood abuse in predicting PTSD symptom severity in adults (Binder et al., 2008). More efficient recovery of HPA axis activation after exposure to environmental stressors is thought to be a key characteristic of resilient individuals. Of note, by combining genetic with gene expression and hormone studies, it is now possible to identify subtypes of PTSD differing, for example, in the nature of HPA axis abnormality (Mehta et al., 2011).

Genetic variations in the serotonergic system have also been found to affect susceptibility to stress-induced psychopathology. The short (S) allele of the serotonin (5-HT) transporter promoter gene (*5HTTLPR*), which compared with the long (L) allele results in decreased transporter availability and lower uptake of 5-HT from synaptic clefts, has been implicated in a number of studies in a maladaptive response to stress. Although individuals who are carriers for the S allele of *5HTTLPR* show

elevated risk for depression upon stress exposure in some but not all studies (Caspi et al., 2003; Kendler et al., 2005; Uher and McGuffin, 2010), this finding has been confirmed in a recent large metaanalysis (Karg et al., 2011). S allele carriers also show heightened activation of the amygdala (Hariri et al., 2005) and decreased coupling between the amygdala and the regulatory perigenual cingulate region while viewing fearful or aversive stimuli (Pezawas et al., 2005). Differential neural activation to threat stimuli might represent a biological marker of differential susceptibility to stress. In a recent fMRI study in healthy women, neural systems involved in fear responses and attention to threat showed higher activation during anticipation of a mild shock to the wrist in participants with the SS allele compared with L carriers (Drabant et al., 2012). Further, differential neural activation in medial prefrontal cortex (mPFC) and insula was associated with differential self-reports of anxiety and success at anxiety regulation. Interestingly, recent studies have found that youth homozygous for the short allele of *5HTTLPR* were not only more vulnerable to negative parenting, but also more responsive to supportive parenting, showing higher levels of positive affect if parenting was supportive (Hankin et al., 2011). Thus some genetic variations might increase an individual's responsiveness to environmental influence, whether good or bad, potentially boosting or decreasing resilience depending on the quality of the environment during development (Homberg and Lesch, 2011). A recent prospective study in female college students found increased acute stress disorder symptoms after a college shooting in students with particular combinations of polymorphisms in the 5-HT transporter gene (Mercer et al., 2012). Variations in other genes affecting serotonin signaling are also being identified. For example, a common functional variation in the gene coding for the serotonin 1A autoreceptor was associated with differential amygdala reactivity to angry and fearful facial expressions in healthy adults, and indirectly with differential trait anxiety (Fakra et al., 2009).

Genetic polymorphisms affecting resilience to stress have been identified in the noradrenergic system as well as in the serotonergic system. Functional polymorphisms in the gene that produces catechol-O-methyltransferase (*COMT*), an enzyme that degrades dopamine (DA) and norepinephrine (NE), have been identified and found to affect response to stress. Individuals with the low functioning *met* allele for the enzyme, and hence higher circulating levels of DA and NE, tend to exhibit more anxious behaviors and lower resilience against negative moods (Heinz and Smolka, 2006). They also tend to avoid novelty-seeking behaviors, and while viewing aversive images, show heightened activity in the visuospatial attention system as well as increased reactivity and connectivity in corticolimbic circuits (Drabant et al., 2006), suggesting that they have a heightened awareness for potential threats (Smolka et al., 2005). Another group studying the *COMT* gene found that carriers of the low functioning *met* allele exhibited greater plasma endocrine and subjective stress responses in response to psychologically stressful tasks than did carriers of the high-functioning allele (Jabbi et al., 2007).

Polymorphisms in DA receptors and in the DA transporter gene have also been associated with vulnerability to depression and PTSD (Dunlop and Nemeroff, 2007). In a study of combat

veterans, for instance, the A1+ allele of the D₂ receptor was associated with more severe PTSD and higher levels of anxiety and depression (Lawford et al., 2006). Polymorphisms in other relevant systems have been identified. A polymorphism (Val66Met) in the gene for brain derived neurotrophic factor (BDNF), a widely expressed protein that stimulates neurogenesis and promotes learning and memory, has been linked with an increased likelihood of suffering stress-induced depression (Kim et al., 2007), and with increased amygdala reactivity in response to emotional stimuli in healthy females (Montag et al., 2008). A single nucleotide polymorphism (rs1617) located in the promoter region of the gene coding for neuropeptide Y (NPY), a peptide released during stress that appears to mitigate the negative effects of the stress response, alters NPY expression and was found to differentially affect stress responses and neural activation to emotional probes (Zhou et al., 2008).

A recent study identified associations between single nucleotide polymorphisms in the genes coding for the pituitary adenylate cyclase-activating polypeptide (PACAP) (involved in regulating the cellular stress response) and its PACAP-PAC1 receptor, and PTSD in females (Ressler et al., 2011). Additional genetic polymorphisms, gene-by-environment, and gene-by-gene-by-environment interactions involved in resilience to stress are currently being identified, the latter exemplified by a study of interactions between a history of childhood trauma and genetic polymorphisms in the CRH type 1 receptor and serotonin transporter genes on depressive symptoms in adults (Ressler et al., 2010). Thus our understanding of the genetics of resilience is likely to increase rapidly in coming years. As more of the genetic factors underlying resilience are uncovered, it may become possible for scientists to design gene or drug therapies specific for individuals with low-resilience genetic profiles.

THE DEVELOPMENT OF RESILIENCE: ROLE OF EARLY LIFE ENVIRONMENT

In addition to genetic makeup, another key contributor to resilience is developmental environment. The study of resilience from a developmental perspective dates back to the early 1970s (Masten and Obradovic, 2006). An important discovery to emerge from this research is that resilience is common, even in children who suffered severe adversity in early life. Studies of adolescents whose development was stunted in childhood due to traumatic experiences such as being orphaned have found that the majority of children rapidly demonstrate “developmental catch-up” when placed in safe and nurturing environments (Masten, 2001). It seems that, under the right circumstances, neural circuits involved in resilience are modifiable for many years after birth, possibly even into adulthood.

Nevertheless, severely traumatic experiences in early life can negatively affect the development of stress response systems, in some cases doing long-lasting damage. Studies of rodents and non-human primates indicate that animals abused by their mothers during the first few weeks after birth have delayed independence and a decreased ability to manage stress later in life, demonstrated by high levels of behavioral anxiety,

a hyperactive HPA axis, and increased basal levels of the anxiogenic CRH in the cerebrospinal fluid (Claes, 2004; McCormack et al., 2006; Strome et al., 2002). Furthermore, non-human primates who suffered damage to their stress response systems as a result of abuse in infancy seem more likely to mistreat their own infants, perpetuating the effects of abuse across generations (Maestripieri et al., 2007).

Studies of human survivors of early life stress and abuse have also found long-lasting alterations in central nervous system circuits and structures involved in psychological well-being. Severe prenatal stress and early childhood abuse have been linked to increased HPA axis activity later in life, putting survivors at risk for the adverse effects of chronic hypercortisolemia (Heim et al., 2000; Janssen et al., 2007 Seckl and Meaney, 2006; Vythilingam et al., 2002). Developmental environment also influences the adult functioning of the locus coeruleus–norepinephrine (LC–NE) system, with severe stress in early life leading to its hyperfunctioning. For instance, one study found that police recruits with a history of childhood trauma had significantly higher levels of a salivary metabolite of NE in response to viewing aversive videos than did healthy controls (Otte et al., 2005). Other research has found that physical or sexual abuse in childhood can lead to smaller-than-average hippocampal volumes; decreased hippocampal volume is commonly seen in individuals with depression or chronic stress disorders (Janssen et al., 2007). Thus, it appears that early abuse can cause long-standing changes in brain structures and circuits associated with resilience.

Although early exposure to unpredictable and uncontrollable stress or trauma commonly leads to later psychopathology, exposure to moderately stressful events that can be mastered to an extent (e.g. family relocation, illness of a parent, or loss of a friendship) seems to enable children to effectively regulate their stress response systems. Children who have experience successfully coping with difficult situations reap benefits when faced with stressors later in life, experiencing less physiological and psychological distress (Boyce and Chesterman, 1990; Khoshaba and Maddi, 1999). It seems that the experience of mastering stress provides a form of immunity against later challenges. This phenomenon is known as stress inoculation, based on the analogy to vaccine-induced inoculation against disease (Rutter, 1993). Just as exposure to a low dose of a pathogen enables the body to mount a long-lasting immune response, exposure to moderate amounts of stress enables organisms to conquer and fight off future stressors.

Research in rodents and primates supports the stress inoculation hypothesis and provides insight into its neurobiological mechanisms. Young monkeys presented with a manageable stressor in the form of periodic short maternal separations from postnatal weeks 17 to 27 experience acute distress during the separation periods, manifested by behavioral agitation and temporarily increased cortisol levels. Later in life, however, the same monkeys demonstrate lower anxiety (e.g. increased exploratory behavior in novel environments) and lower basal stress hormone levels at nine months of age than monkeys who never underwent periods of maternal separation (Parker et al., 2004). Furthermore, these stress-inoculated monkeys demonstrate higher cognitive control assessed at 1.5 years, higher curiosity

in a stress-free situation at 2.5 years, and larger ventromedial prefrontal cortex (PFC) volume assessed with neuroimaging at age 3.3 years compared with their non-stress-inoculated peers (Lyons et al., 2009; Parker et al., 2005). Poor control of prefrontal cognition has been associated with depression in humans (Harvey et al., 2005; Murphy et al., 2001). Of note, the size of the ventromedial PFC in humans predicts lower impulsivity, lower harm avoidance, and greater retention of learned fear extinction (Lyons et al., 2009).

Just as in humans, the degree of control that an animal has over a stressor plays a key role in determining whether the event will lead to subsequent vulnerability or resilience to stress. Animals administered unavoidable and unpredictable shocks tend to develop exaggerated fear responses, heightened anxiety states, and deficits in active coping when faced with subsequent stressors: this condition is known as learned helplessness (Overmier and Seligman, 1967). The phenomenon of learned helplessness is a well-known animal model for depression and is thought to lead to dysregulation of the serotonergic neurons in the dorsal raphe nuclei (Greenwood et al., 2003) as well as to reduce hippocampal cell proliferation. Because 5-HT has far-reaching effects in the limbic system, the dysregulations created by learned helplessness likely have serious negative effects on cognition and mood.

In contrast, animals that are administered shocks and given the ability to avoid them by modifying their behavior do not develop learned helplessness. Furthermore, animals that have at one time experienced behavioral control over predictable tail shocks are less likely than naïve animals to develop learned helplessness if they are subsequently exposed to unpredictable and inescapable shocks (Seligman and Maier, 1967). Similarly, human beings that have been “stress inoculated” to one type of stressor by successfully managing the stressor appear to acquire resilience to a broad range of other subsequent stressors (Masten and Obradovic, 2006). As noted by Rutter (2012), limited evidence from human studies suggests that steeling might occur via the acquisition of self-efficacy and mastery.

It is important to note that even among animals administered unpredictable and unavoidable shocks, not all develop learned helplessness. Similarly, in humans exposed to severe, unpredictable, and uncontrollable traumas, not all go on to develop PTSD or other anxiety or panic disorders. Clearly, genetic factors interact with environmental exposures to affect resilience. In some cases, a resilient genetic profile may be enough to overcome even the most adverse developmental circumstances.

EPIGENETICS

Prenatal and early postnatal environments regulate developmental processes at the molecular level via epigenetic mechanisms, affecting gene expression without involving changes in DNA sequence (Dudley et al., 2011). Initial studies in rodents showed that high maternal care early in development can lead to a “permanent increase” in GR expression in the hippocampus, resulting from lower GR promoter DNA methylation, and thereby lowering sensitivity to circulating glucocorticoids (Liu et al., 1997; Weaver et al., 2004). Further epigenetic changes

can occur in response to experiences including drug use, social interactions, and exposure to stress during critical development periods (Dudley et al., 2011).

Stress reactivity in adult animals is partially a result of epigenetic changes stemming from differential early life experience, such as methylation levels of promoter regions in genes of central importance to stress responses (e.g., GR, brain-derived neurotrophic factor), and located in key regions of the brain (e.g., hippocampus, prefrontal cortex) (Roth et al., 2009; Weaver et al., 2004). Similarly, prenatal stress can also result in epigenetic changes, which in turn impact stress reactivity; on the other hand, early evidence suggests that some of these changes are potentially reversible by optimal postnatal experience (Dudley et al., 2011). Studies in humans have begun to identify the role of epigenetic changes, as exemplified by a report of differential methylation of the GR gene in newborn babies of mothers with prenatal depression (Oberlander et al., 2008). There has been a recent surge of animal and human studies investigating the role of epigenetic mechanisms in differential stress reactivity (Mifsud et al., 2011; Radley et al., 2011; Yehuda et al., 2011).

Having reviewed the role of early life environment and recent findings on epigenetic changes, in the following sections we outline what current research holds to be some of the most important factors, psychological and neurobiological, characterizing resilience to extreme stress in the adult.

PSYCHOBIOLOGICAL FEATURES OF RESILIENCE

TRAITS AND BEHAVIORS

POSITIVE EMOTIONS

Positive emotions play an integral role in the capacity to tolerate stress. The broaden-and-build theory holds that positive emotions enable broader psychological and behavioral responses, ultimately building enduring resources (Fredrickson, 2001). Positive affect is associated with health-protecting factors including greater social connectedness and adaptive coping mechanisms (Steptoe et al., 2005). Positive emotions also appear to decrease autonomic arousal (Isen et al., 1987; Folkman and Moskowitz, 2000) and facilitate cardiovascular recovery after negative arousal in response to a stressor (Tugade and Fredrickson, 2004), leading to better physical health. Positive affect has been associated with reduced use of medical services; fewer stress-related illnesses; and decreased neuroendocrine, cardiovascular, and inflammatory reactivity (Carver et al., 1993; Danner et al., 2001; Steptoe et al., 2005; Scheier et al., 1989; Zeidner and Hammer, 1992).

Similarly, optimism has been repeatedly correlated with increased psychological well-being and health (Affleck and Tennen, 1996; Goldman et al., 1996) and with greater life satisfaction (Klohn, 1996). An optimistic disposition is thought to be in large part inherited; however, motivated individuals can increase their optimism with practice. Optimists maintain positive emotions even in the face of adversity because they tend to view problems as temporary and limited in scope. Pessimists, on the other hand, tend to think of their problems as permanent and pervasive and consequently are more prone

to depression (Table 88.1). Optimism has even been correlated with longevity: for example, a study of 180 nuns found that nuns whose diaries from youth reflected optimism lived significantly longer than nuns with more negative diaries (Danner et al., 2001). Optimists are thought to have robust brain reward circuits, which is discussed in further detail later in the chapter.

Dispositional gratitude, another positive emotion related to a generally appreciative outlook toward life, was shown in longitudinal studies to foster social support and protect individuals from stress and depression (Wood et al., 2008).

POSITIVE COGNITIVE REAPPRAISAL

Cognitive reappraisal, or the ability to find the silver lining in every cloud, is closely related to optimism and strongly associated with resilience (Gross, 2002; Southwick et al., 2005; Tugade

and Fredrickson, 2004). The technique, also known as cognitive flexibility or cognitive reframing, refers to the purposeful, conscious transformation of emotional experience. Cognitive reframing is the reinterpretation of traumatic events to find their positive meaning, value, or the new opportunity that they provide. It stands in contrast to suppression, which signifies conscious attempts to forget traumatic events. Individuals who use cognitive reappraisal when dealing with trauma have less anger and physiologic arousal than those who use suppression techniques (Gross, 2002). It is thought that cognitive reappraisal works in part by attenuating biological stress responses (Davidson and McEwen, 2012; Disner et al., 2011).

The ability to find personal meaning in tragedy is extraordinarily helpful in successfully overcoming trauma. Viktor Frankl, psychiatrist and Holocaust survivor, attributes his

TABLE 88.1. Selected psychological resilience factors: attitudes and behaviors that can help maintain well-being during stress

<p>1. Positive emotions and positive attitude Optimism is strongly related to resilience. Optimism is in part inherited but can be learned through therapy. Putative neurobiological mechanisms: strengthens reward circuits, decreases autonomic activity</p> <p>2. Cognitive flexibility and reappraisal Finding meaning or value in adversity Traumatic experiences can be reevaluated through a more positive lens. Trauma can lead to growth: learn to reappraise or reframe adversity, finding its benefits; assimilate the event into personal history; accept its occurrence; and recover. Recognize that failure is an essential ingredient for growth. Putative neurobiological mechanisms: alters memory reconsolidation, strengthens cognitive control over emotions</p> <p>3. Moral compass: embrace a set of core beliefs that few things can shatter Live by a set of guiding principles. For many, moral compass means religious or spiritual faith. Altruism strongly associated with resilience: selfless acts increase our own well being. Putative neurobiological mechanisms: spirituality/religiosity associated with strong serotonergic systems. Morality has neural basis, likely evolved because adaptive</p> <p>4. Finding a resilient role model/mentor Role models and mentors can help teach resilience: imitation is powerful mode of learning. Putative neurobiological mechanisms: oxytocin mediates initial bonding/attachment. "Mirror"/Von Economo neurons involved in neuronal imprinting of human values</p> <p>5. Facing fears: learning to move through fear Fear is normal and can be used as a guide for action. Facing and overcoming fears can increase self-esteem and sense of self-efficacy. Practice undertaking and completing challenging or anxiety-inducing tasks. Putative neurobiological mechanisms: promotes fear extinction, stress inoculation</p> <p>6. Active coping: seeking solutions, managing emotions Resilient individuals use active rather than passive coping skills (dealing with problem and with emotions versus withdrawal, resignation, numbing). Can be learned: work on minimizing appraisal of threat, creating positive statements about oneself, focusing on aspects that can be changed Putative neurobiological mechanisms: prevents fear conditioning and learned helplessness, promotes fear extinction</p> <p>7. Establishing and nurturing a supportive social network Establish and nurture a supportive social network. Very few can "go it alone"; resilient individuals derive strength from close relationships. Social support is safety net during stress. Putative neurobiological mechanisms: oxytocin mediates bonding/attachment, neural networks subserve automatic emotional responses and voluntary emotion regulation during social interactions</p> <p>8. Physical exercise and attending to physical well-being Physical exercise has positive effects on physical and psychological hardiness. Effective at increasing mood and self-esteem Putative neurobiological mechanisms: promotes neurogenesis, improves cognition, attenuates HPA activity, aids in regulation of emotion, boosts immune system</p> <p>9. Other resilience factors Training regularly (emotionally and physically), discipline Recognizing one's own strengths and fostering them</p>

survival of concentration camps largely to this process of “meaning making”; in fact, meaning making became the basis for the school of psychotherapy that he founded, known as logotherapy. On a long enforced march, weak from hunger and cold, he wrote, “I forced my thoughts to turn to another subject. Suddenly I saw myself standing on the platform of a well-lit, warm and pleasant lecture room. . . . I was giving a lecture on the psychology of the concentration camp!” (Frankl, 1959/2006: p. 73). The conscious construction of this narrative and of the meaning he would derive from his experiences provided Dr. Frankl with the psychological endurance to survive his days in concentration camps.

The importance of synthesizing traumatic events into one’s personal life narrative was described over a century ago by Pierre Janet, the French neurologist. Janet noted that his patients with posttraumatic pathology had failed to integrate their traumatic memories into a cohesive story. Janet stressed the necessity of cognitive reappraisal in preventing or overcoming posttraumatic stress; traumatic memories “needed to be modified and transformed, that is, placed in their proper context and reconstructed into neutral or meaningful narratives.” (van der Kolk and van der Hart, 1989).

PURPOSE IN LIFE

A closely related concept to that of finding meaning is having a sense of purpose in life. Studies are beginning to document an association between higher self-reported purpose in life and resilience or recovery from psychiatric illness in traumatized populations (Alim et al., 2008). Purpose in life was significantly associated with psychological well-being in a study of veterans living with spinal cord injury (deRoos-Cassini et al., 2009). Another study reported greater perceptions of purpose and control in resilient OEF-OIF (Operation Enduring Freedom-Operation Iraqi Freedom) veterans compared with those with PTSD (Pietrzak and Southwick, 2011).

ACTIVE COPING STYLES

Active coping means deploying productive strategies for solving problems, managing stress, and regulating negative emotions that may arise in the aftermath of adverse events. Active coping behaviors include acknowledging and trying to solve problems, accepting that which cannot be changed, facing fears, using humor and physical exercise to alleviate stress, and seeking out social support and role models. Active coping has repeatedly been associated with hardiness and psychological resilience in various populations (Moos and Schaefer, 1993). In contrast, passive coping, including the blunting of emotions through substance use, denial, disengagement, or resignation, is associated with depression and lower levels of hardiness (Maddi, 1999). Several studies have shown an association between avoidance coping and psychopathology (Pietrzak et al., 2011; Thompson et al., 2011).

ACCEPTANCE

Acceptance is an adaptive coping strategy commonly found among people who are able to tolerate extreme and uncontrollable stress (Manne et al., 2003; Siebert, 1996). Acceptance

involves recognizing the uncontrollable aspects of certain stressors, changing expectations about outcome based on reality, and focusing on controllable aspects of the stressor. Acceptance is not to be confused with resignation, which is giving up or coping passively. Acceptance has been linked with better physical and psychological health, lower levels of distress, and greater psychological adjustment after trauma exposure (Thompson et al., 2011; Wade et al., 2001). Recent evidence includes the finding that individuals who had an accepting coping style had fewer PTSD symptoms following the terrorist attacks of September 11, 2001 (Silver et al., 2002).

FACING FEARS

Facing fears is a key component of the active coping paradigm. Fear conditioning, which is discussed in greater detail later in the chapter, plays a major role in the development and maintenance of posttraumatic psychopathology. Individuals with PTSD avoid a wide variety of life’s opportunities (people, places, events, etc.) that may serve as reminders of the trauma; thus, conditioned fear is maintained rather than extinguished. In contrast, resilient individuals are more adept at managing fear, using it as a guide to critically appraise threat and to select appropriate action.

Active coping at the time of trauma or when exposed to traumatic reminders appears to attenuate fear conditioning, likely by redirecting activity in the lateral and central nuclei of the amygdala away from the brainstem and toward the motor circuits in the ventral striatum. This has the effect of reducing brainstem-mediated responses to fear, such as freezing behavior and autonomic and endocrine responses, and enabling productive action (LeDoux and Gorman, 2002). Resilient individuals have learned to face fears and to actively cope with them; by moving through fear, they avoid fear conditioning and are less likely to develop psychopathology and functional impairments in the aftermath of trauma.

HUMOR

Humor, frequently used by resilient individuals, has been identified as an adaptive coping style and mature defense mechanism (Vaillant, 1977). It appears that humor decreases the probability of developing stress-induced depression (Deaner and McConatha, 1993; Thorson and Powell, 1994). The use of humor has been studied in resilient Vietnam veterans (Haas and Hendin, 1984), surgical patients (Carver et al., 1993), cancer patients (Culver et al., 2002), and at-risk children (Werner and Smith, 1992; Wolin and Wolin, 1993) and has been shown to be protective against distress. Humor is thought to diminish the threatening nature and negative emotional impact of stressful situations (Folkman, 1997), fostering a more positive perspective on challenging circumstances. The use of humor also relieves tension and discomfort (Vaillant, 1992) and attracts social support. Humor is thought to activate a network of subcortical regions that are critically involved in the dopaminergic reward system (Mobbs et al., 2003).

PHYSICAL EXERCISE

Physical exercise has consistently been shown to have positive effects on physical hardiness, mood, and self-esteem. Individuals who exercise regularly report lower depression

scores than those who do not exercise (Brosse et al., 2002; Camacho et al., 1991). Physical exercise has effects on a number of neurobiological factors that affect resilience. It attenuates the HPA axis response to stress, increases release of endorphins, and increases levels of plasma monoamines and the 5-HT precursor tryptophan. It is also thought to induce the expression of several genes related to neuroplasticity and neurogenesis, such as hippocampal BDNF (Cotman and Berchtold, 2002). Studies in animals have shown that exercise helps contain the stress response via central sympathetic, serotonergic, and dopaminergic reward pathways, resulting in protection from stress-induced immunosuppression, cytokine elevation, and affective dysregulation (Fleshner et al., 2011). A study of high-impact running in humans suggested that the activity has a beneficial impact on cognitive functioning: high-impact running was associated with improved vocabulary learning and retention as well as a lower likelihood of age-related cognitive diminution (Winter et al., 2006).

SOCIAL SUPPORT

The last active coping strategy we discuss is the seeking out of social support. Higher levels of social support have been associated with better mental and physical health outcomes following a wide variety of stressors (Resick, 2001). Conversely, lower levels of social support have been linked to PTSD and other psychiatric disorders (Tsai et al., 2012). In a study of OEF-OIF veterans, resilience was associated with self-reports of greater family support and understanding (Pietrzak and Southwick, 2011). Social support is thought to decrease appraisals of threat (Fontana et al., 1989), counteract feelings of loneliness (Bisschop et al., 2004), increase sense of self-efficacy, reduce functional impairment (Travis et al., 2004), and increase treatment compliance. Role models and mentors form a valuable part of a strong social support network.

Social isolation and lack of social support are associated with higher rates of mood and anxiety disorders, higher levels of stress, and increased morbidity and mortality from medical illness. Individuals who seek and nurture a supportive social network during times of stress tend to fare better during stress or adversity than individuals who are socially isolated.

MORAL COMPASS: A SET OF GUIDING ETHICAL PRINCIPLES

Moral compass, or an internal framework of belief about right and wrong, is another feature common to resilient individuals (Southwick et al., 2005). This construct may, but does not have to, include adherence to a religious or spiritual system.

Religion and spirituality seem to have a protective effect on physical and psychological well-being. A metaanalysis of 126,000 individuals from 42 independent samples found religious practice or involvement to be associated with lower risk of mortality from all causes (McCullough et al., 2000). In addition, higher levels of religious belief have been correlated with lower incidence of depression and higher rates of remission from depression in a number of populations (Braam et al., 1997, 2002; Kasen et al., 2012; Koenig et al., 1998). Interestingly, one's particular religious affiliation is not implicated in the overall

relationship between religiousness and improved psychological and physical health.

There is some evidence suggesting that spiritual or self-transcendent experiences are associated with increased density of 5-HT_{1A} receptors in the dorsal raphe nuclei, hippocampus, and neocortex (reviewed by Hasler et al., 2004). Chronic stress appears to lead to a down-regulation of 5HT_{1A} receptors; spirituality and religiosity may enhance the functioning of the 5-HT system, fostering resilience and protecting against the development of posttraumatic mental illness.

Religious faith or spirituality is not an essential ingredient in a strong moral compass. In fact, morality appears to have a neural basis and is likely intrinsic to human nature. The idea that morality is inherent to human beings is ancient. Epictetus, a Greek philosopher living in Rome in the first century A.D. wrote: "Every one of us has come into this world with innate conceptions as to good and bad, noble and shameful... fitting and inappropriate" (Stockdale, 1991). Moral sense likely developed early in human evolution as our ancestors organized into societies: the successful functioning of society requires cooperation and trust between members. Many studies support the notion that principles of cooperation and reciprocity are ingrained within human nature. Games designed to test participants' morality repeatedly find that human beings act according to the rule that fairness to others should supersede self-interest. For example, in games in which participants are given money to divide between themselves and strangers, most participants choose to divide the money equally among players. Furthermore, participants who play fairly in such games tend to show heightened activation of their dopaminergic reward systems on imaging studies (Fehr and Fischbacher, 2003). These findings provide support for the hypothesis that people know what is right and derive fulfillment from acting accordingly.

ALTRUISM

Altruism, or putting one's moral compass into action, is a powerful contributor to resilience. For example, research on the behavior of citizens after bombing attacks during World War II showed that those who demonstrated altruism by caring for others suffered fewer trauma-related mood and anxiety symptoms than would be expected. Furthermore, individuals who had been symptomatic preattack experienced a meaningful decrease in psychological distress (Rachman, 1979). It appears that, similar to acting fairly, performing acts of altruism activates brain reward circuits. One study found that participants who gave money to charity, whether voluntarily or through taxation, showed heightened activation of the ventral striatum, an important part in reward pathways (Harbaugh et al., 2007).

Some individuals are able to find meaning in personal tragedy by embracing a survivor mission to help others. Rape survivors who go public with their experience to raise social awareness through events such as Take Back the Night, and the mothers who founded Mothers Against Drunk Driving after their children were injured or killed in drunk driving accidents, are examples of this phenomenon.

We now discuss some of the most important neurobiological factors associated with resilience. Individuals with the psychological features of resilience we have discussed likely have a neurobiological profile characterized by optimal levels of these factors.

NEUROBIOLOGICAL PROFILE OF RESILIENCE

A number of neurotransmitters, neuropeptides, and hormones have been implicated in acute and long-term adaptation to stress. A comprehensive review of the many functions and effects of these factors is beyond the scope of this chapter; we focus specifically on the factors' role in mediating the stress response (Table 88.2, Fig. 88.1; see also Color Fig 88.1 in separate insert).

CORTICOTROPIN-RELEASING HORMONE

The hypothalamus releases corticotropin-releasing hormone (CRH) in conditions of stress, activating the pituitary-adrenal axis and triggering the release of cortisol and dehydroepiandrosterone (DHEA). Corticotropin-releasing hormone also has important direct effects in the central nervous system; CRH containing neurons and CRH receptors are distributed widely throughout the brain and gut (Steckler and Holsboer, 1999). Activation of CRH neurons in the amygdala triggers fear-related behaviors, whereas activation of cortical CRH neurons reduces expectation of rewards. It seems that excessive stress in early life can result in abnormally elevated CRH activity in the adult brain (Strome et al., 2002).

Corticotropin-releasing hormone acts via two G-coupled receptors, CRH-1 and CRH-2. These receptors appear to have opposite effects in the response to stress (Bale et al., 2002; Grammatopoulos and Chrousos, 2002); the CRH-1 receptor primarily activates the behavioral, endocrine, and visceral responses to stress. Elevated hippocampal CRH-CRH-1 interaction may contribute to the structural and cognitive impairments associated with early-life stress (Ivy et al., 2010). CRH-1 receptor gene single nucleotide polymorphism rs110402 was found to moderate neural responses to emotional stimuli, thereby potentially increasing vulnerability for the development of psychiatric disorders (Hsu et al., 2012). The CRH-2 receptor generally serves to dampen these effects (Tache and Bonaz, 2007). However, activation of the CRH-2 receptor does produce some anxiogenic effects, for example, enhancing CRH-1 mediated suppression of feeding behavior (Bakshi et al., 2002). A more recent study shows that chronic activation of CRH-2 receptor by overexpressing its specific ligand (urocortin 3) promotes an anxiety-like state, yet with attenuated behavioral and HPA axis response to stress (Neufeld-Cohen et al., 2012). More research is necessary to determine the precise role of both receptors.

Abnormally high CRH levels in the cerebrospinal fluid have been linked to major depression and PTSD (Baker et al., 1999; Bremner et al., 1997; Nemeroff, 2002). Resilient individuals likely have the capacity to effectively regulate CRH levels and/or the relative activity of both receptor subtypes. Gender

differences in corticotropin response to CRH challenge may explain differential gender susceptibility to psychopathology following early-life trauma (DeSantis et al., 2011). Although initial studies showed promise for the use of CRH-1 receptor antagonists as potential new pharmacotherapies for anxiety and mood disorders as well as for stress-related gastrointestinal disorders such as irritable bowel syndrome (Tache and Bonaz, 2007; Zoumakis et al., 2006), subsequent clinical trials failed to show a beneficial effect of these compounds in patients with major depression (Binneman et al., 2008) or generalized anxiety disorder (Coric et al., 2010). A randomized controlled trial of a CRH-1 receptor antagonist in patients with PTSD is currently under way.

CORTISOL

Many forms of psychological stress increase the synthesis and release of cortisol, which leads to increased arousal, vigilance, inhibition of growth and reproduction, and containment of the immune response. In resilient individuals, the stress-induced increase in cortisol is effectively constrained via an elaborate negative feedback system involving GR and mineralocorticoid receptors (MR) (de Kloet et al., 2007). Excessive and sustained cortisol secretion can have serious adverse effects, including osteoporosis, immunosuppression, hypertension, metabolic syndrome, depression, and anxiety (Carroll et al., 2007; Whitworth et al., 2005).

Cortisol has important regulatory effects on the hippocampus, amygdala, and PFC. It plays a role in the formation, processing, and retrieval of memories, particularly fearful memories. Cortisol levels appear to be dysregulated in depression and PTSD. Patients with major depressive disorder tend to have higher than normal levels of cortisol and a blunted suppression of cortisol secretion in response to the dexamethasone suppression test (Yehuda, 2001). In contrast, basal circulating cortisol levels are generally lower in individuals with PTSD than in healthy individuals (Bierer et al., 2006; Gill et al., 2008; Griffin et al., 2005; Yang or Brand et al., 2006; Yehuda, 2006). Correspondingly, individuals with PTSD tend to show higher-than-average cortisol suppression during the dexamethasone suppression test, implying that their HPA-axis GRs are hypersensitive. Altered HPA-axis function is associated with impaired fear inhibition in subjects with PTSD (Jovanovic et al., 2010). Women with PTSD having lower basal salivary cortisol levels than men with PTSD may contribute to the gender difference in PTSD prevalence between men and women (Freidenberg et al., 2010).

That patients with PTSD might have lower-than average basal cortisol levels suggests that the disorder may develop in the setting of abnormally low cortisol; this hypothesis is supported by a number of studies showing that steroid administration inhibits traumatic memory formation (Bierer et al., 2006). Patients who are pretreated with stress doses of glucocorticoids before surgery and/or hospitalization in the intensive care unit are less likely to have traumatic memories of their hospital stay after discharge than patients treated with placebo (Brunner et al., 2006; Schelling et al., 2006; Weis et al., 2006). Low activity of 5-alpha reductase, a rate-limiting enzyme for

TABLE 88.2. The neurochemical response patterns to acute stress

NEUROCHEMICAL	ACUTE EFFECTS	BRAIN REGION	KEY FUNCTIONAL INTERACTIONS	ASSOCIATION WITH RESILIENCE	ASSOCIATION WITH PSYCHOPATHOLOGY POTENTIAL FOR TREATMENT?
CRH	Activated fear behaviors, increased arousal, increased motor activity, inhibited neurovegetative function, reduced reward expectations	Prefrontal cortex, cingulate cortex, amygdala, nucleus accumbens, hippocampus, hypothalamus, bed nucleus of the stria terminalis, periaqueductal gray matter, locus coeruleus, dorsal raphe nuclei	CRH-1 receptor anxiogenic, CRH-2 receptor anxiolytic, increases cortisol and DHEA, activates locus coeruleus-norepinephrine system	Reduced CRH release, adaptive changes in CRH-1 and CRH-2 receptors	Persistently increased CRH concentration may predispose to PTSD and mood disorders as well as stress-related gastrointestinal disorders CRH receptor antagonists under investigation as treatments for stress-related disorders
Cortisol	Mobilized energy, increased arousal, focused attention	Prefrontal cortex, hippocampus, amygdala, hypothalamus	Increases amygdala corticotrophin-releasing hormone (CRH), increases hypothalamic CRH	Stress-induced increase rapidly constrained by negative feedback mechanisms	Dysregulated cortisol systems (excessive cortisol release, improperly functioning negative feedback systems) seen in mood disorders and PTSD
Dehydroepiandrosterone (DHEA)	Counteracts deleterious effects of high cortisol Neuroprotective Positive mood effects	Largely unknown; hypothalamus	Antiglucocorticoid actions	High DHEA-cortisol ratios may prevent/ lessen severity of PTSD and depression.	Low DHEA response to stress may predispose to PTSD and depression and sensitize to the effects of hypercortisolemia. DHEA supplementation has shown beneficial effects on depressive symptoms.
Locus coeruleus-norepinephrine system	General alarm function activated by extrinsic and intrinsic threat; increased arousal, increased attention, fear memory formation, facilitated motor response	Prefrontal cortex, amygdala, hippocampus, hypothalamus	Activates sympathetic axis, inhibits parasympathetic outflow, stimulates hypothalamic CRH	Reduced responsiveness of locus coeruleus-norepinephrine system	Unrestrained functioning of locus coeruleus-norepinephrine system, seen in some patients with PTSD, leads to chronic anxiety, hyper-vigilance, and intrusive memories. Beta-receptor blockade shortly after trauma exposure has yielded mixed results.
Neuropeptide Y (NPY)	Anxiolytic Improves performance under stress	Amygdala, hippocampus, hypothalamus, septum, periaqueductal gray matter, locus coeruleus	Reduces CRH-related actions at amygdala, reduces rate of firing of locus coeruleus	Adaptive increase in amygdala neuropeptide Y is associated with reduced stress-induced anxiety and depression	Low NPY associated with PTSD Y-1 and Y-2 receptors may be targets for treating mood and anxiety disorders. NPY administration may protect against stress.
Galanin	Involved in anxiety and vulnerability to stress; GAL-1 receptor anxiolytic, GAL-3 anxiogenic	Prefrontal cortex, amygdala, hippocampus, locus coeruleus	Reduces the anxiogenic effects of locus coeruleus-norepinephrine system activation	Adaptive increase in amygdala galanin is associated with reduced stress-induced anxiety and depression.	Low galanin levels likely related to increased vulnerability to PTSD and depression; yet to be studied.
Serotonin (5-HT)	Mixed effects: 5-HT stimulation of 5-HT ₂ receptors is anxiogenic; 5-HT stimulation of 5-HT _{1A} receptors is anxiolytic	Prefrontal cortex, amygdala, hippocampus, dorsal raphe	High levels of cortisol decrease 5-HT _{1A} receptors	High activity of postsynaptic 5-HT _{1A} receptors may facilitate recovery.	Low activity of postsynaptic 5-HT _{1A} receptors may predispose to anxiety and depression.

Dopamine	High prefrontal cortex and low nucleus accumbens dopamine levels are associated with anhedonic and helpless behaviors	Prefrontal cortex, nucleus accumbens, amygdala	Reciprocal interactions between cortical and subcortical dopamine systems	Within optimal window of activity, preserves functions involving reward and extinction of fear	Excessive mesocortical dopamine release associated with vulnerability to stress Persistently high levels of prefrontal cortical dopamine associated with chronic anxiety and fear Low levels of circulating dopamine linked to depression
Brain-Derived Neurotrophic Factor (BDNF)	Supports neuronal growth, differentiation and survival; involved in fear conditioning, extinction, and inhibitory learning	Hippocampus, cerebral cortex, striatum	Exerts different functions in different brain regions (antidepressant and depression-like effects)	High level of BDNF in hippocampus promotes stress resilience.	Antidepressants can reverse stress-induced decrease in BDNF expression in hippocampus.
Endocannabinoids (eCBs)	Regulate HPA axis activity under basal and stressful conditions	Prefrontal cortex, hypothalamus, amygdala, hippocampus	Actions at CB1 and CB2 receptors; regulation of HPA axis activity	Optimal function of endocannabinoid signaling regulates stress hormone responses.	Enhanced action of endocannabinoids at the CB1 receptor might reduce excessive stress responses.
Glutamate	Excitatory synaptic signaling	Frontal cortex, amygdala, hippocampus, cingulate cortex	Primary receptors NMDA and AMPA; memory formation and learning	Increased AMPA receptor activation may promote antidepressant effects	NMDA receptor antagonism and AMPA receptor activation are novel approaches to depression treatment.

AMPA, alpha-amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid; CRH, corticotrophin-releasing hormone; NMDA, N-methyl-D-aspartate; PTSD, post traumatic stress disorder.

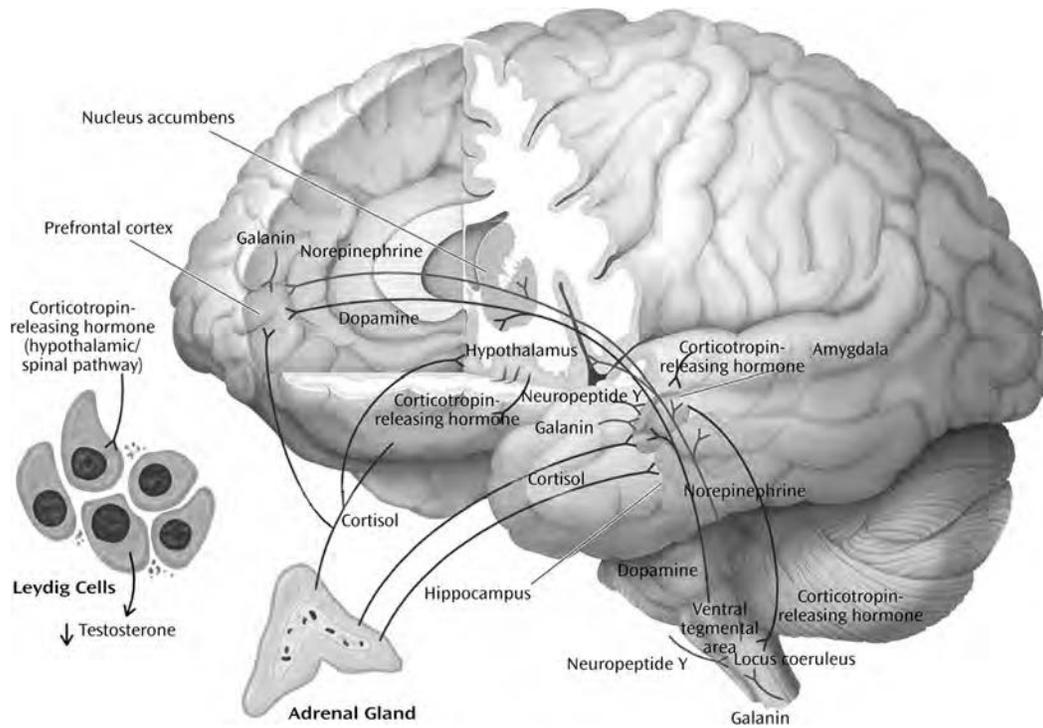

Figure 88.1 Neurochemical response patterns to acute stress. This figure illustrates some of the key brain structures involved in the neurochemical response patterns following acute psychological stress. The functional interactions among the different neurotransmitters, neuropeptides, and hormones are emphasized. The functional status of brain regions such as the amygdala (neuropeptide Y, galanin, corticotropin-releasing hormone [CRH], cortisol, and norepinephrine), hippocampus (cortisol and norepinephrine), locus coeruleus (neuropeptide Y, galanin, and CRH), and prefrontal cortex (dopamine, norepinephrine, galanin, and cortisol) depends upon the balance among multiple inhibitory and excitatory neurochemical inputs. Functional effects may vary depending on the brain region. For example, cortisol increases CRH concentrations in the amygdala and decreases concentrations in the paraventricular nucleus of the hypothalamus. As described in the text, these neurochemical response patterns may relate to resilience and vulnerability to the effects of extreme psychological stress. (Modified and reprinted with permission from Cambridge University Press, 2007.) (See color insert.)

cortisol, is associated with avoidance severity and predicts lack of response to psychological treatment for PTSD (Yehuda et al., 2009).

Although there is a great deal of data suggesting that patients with PTSD have lower basal cortisol than healthy controls and that PTSD may develop in the setting of low glucocorticoid levels, there is also conflicting evidence. Some studies have found no difference in cortisol levels between patients with PTSD and healthy controls (Metzger et al., 2008; Wheler et al., 2006); some have even found that patients with PTSD have higher-than-average basal cortisol levels, and that elevated cortisol at the time of trauma may predict subsequent PTSD development (Baker et al., 2005; Inslicht et al., 2006). A significant decrease in salivary cortisol levels has been found in PTSD treatment responders (Gerardi et al., 2010). In summary, though it is clear that cortisol is implicated in the encoding of traumatic memories and in the subsequent development of posttraumatic psychopathology, the exact nature of this effect is still under investigation. Undoubtedly though, dysregulation of cortisol secretion has adverse effects on resilience to stress.

DEHYDROEPIANDROSTERONE

Like cortisol, dehydroepiandrosterone (DHEA) is an adrenal steroid released under stress; in contrast to cortisol, DHEA

protects against the negative effects of excessive stress. DHEA is secreted episodically and synchronously with cortisol (Rosenfeld et al., 1971) and has antiglucocorticoid activity in the brain (Browne et al., 1992). DHEA and its metabolites interfere with the normal uptake of GRs in the hippocampus (Bastianetto et al., 1999; Kimonides et al., 1998; Morfin and Starka, 2001), preventing corticosteroid-induced hippocampal neurotoxicity. DHEA derivatives also amplify long-term potentiation of hippocampal neurons, likely by modulating transmission at the *N*-methyl-D-aspartate (NMDA) receptor (Chen et al., 2006a). DHEA and fluoxetine were found to have synergistic effects in promoting hippocampal progenitor cell proliferation (Pinnock et al., 2009). The steroid's neuroprotective and potentiating effects in the hippocampus help to facilitate learning and memory.

Studies have shown that DHEA is released under both acute and chronic stress, and that higher levels of DHEA are associated with PTSD and comorbid depression, whereas a higher DHEA-to-cortisol ratio may mitigate symptom severity (Gill et al., 2008; Maninger et al., 2010; Rasmusson et al., 2004). However, one study found no evidence for PTSD-related alterations in cortisol or DHEA secretion in response to stimulation by low doses of ACTH, indicating normal adrenocortical responsiveness in PTSD (Radant et al., 2009).

DHEA appears to enhance cognition and performance under stress. In a study of soldiers undergoing rigorous

training as part of military survival school, DHEA-S (dehydroepiandrosterone sulfate) to cortisol ratios were highest in those soldiers who demonstrated the best performance during training. Thus, DHEA-S to cortisol ratios may index the degree to which an individual is buffered against the negative effects of stress (Morgan et al., 2004). In another study, DHEA and DHEA-S levels predicted superior performance in active duty soldiers undergoing an underwater navigation exam (Morgan et al., 2009). Recovery from severe stress in PTSD patients also appears to be facilitated by high levels of DHEA (Rasmusson et al., 2004; Yehuda, 2006; Yang or Brand et al., 2006).

Other studies have also found a negative correlation between plasma DHEA levels and depressive symptoms (Goodyer et al., 1998; Gallagher and Young, 2002; Haren et al., 2007; Young et al., 2002). Studies of DHEA supplementation have shown some beneficial effects on depressive and PTSD symptoms, but further research is needed (Rabkin et al., 2006; Taylor et al., 2012). Animal studies suggest that the antidepressant action of DHEA is mediated via GABA-ergic modulation of the mesolimbic system (Genud et al., 2009). In a recent study, low-dose DHEA supplementation in military men undergoing survival training was found to enhance anabolic balance but did not result in differences in subjective distress (Taylor et al., 2012). More research is needed to determine whether DHEA could enhance resilience if administered prior to trauma exposure.

THE LOCUS COERULEUS–NOREPINEPHRINE SYSTEM

Stress activates the locus coeruleus (LC), which results in increased norepinephrine (NE) release in projection sites of the LC, including the amygdala, PFC, and hippocampus. The LC is activated by a variety of stressors, intrinsic (e.g., hypoglycemia, hypotension) and extrinsic (environmental threats). Such activation serves as a general alarm function and is adaptive in a life-threatening situation. Activation of the LC contributes to the sympathetic nervous system and HPA axis stimulation and inhibits parasympathetic outflow and neurovegetative function, including eating and sleep. A high level of activation of the LC–NE system inhibits function of the PFC, thereby favoring instinctual responses over more complex cognition (Charney, 2004). A recent study in rats showed that during early adolescence, social stress in the form of a resident intruder led to elevated activity of LC neurons, promoting defensive behaviors in this particular age group (Bingham et al., 2011).

The activation of the HPA and LC–NE systems under acute stress facilitates the encoding and relay of aversively charged emotional memories, beginning at the amygdala. Animal studies have shown that injections of NE into the amygdala enhance memory consolidation; on the other hand, blocking NE activity during stress impedes the encoding of fearful memories. In rats, blocking the lateral nucleus of the amygdala to the effects of NE during reactivation of a fearful memory prevents the process of memory reconsolidation and appears to permanently impair that memory (Debiec and LeDoux, 2006).

If unchecked, persistent hyperresponsiveness of the LC–NE system contributes to chronic anxiety, fear, intrusive

memories, and an increased risk of cardiovascular disease and hypertension. Findings from an imaging study in humans suggest that disinhibited endogenous NE signaling may contribute to the etiology of PTSD by eliciting exaggerated basolateral amygdala (BLA) responses to fear stimuli (Onur et al., 2009). Noradrenergic activation in the BLA is also involved in the facilitating effects of stress hormones (such as CRH) on the consolidation of emotional memory (Roosendaal et al., 2008). Interestingly, norepinephrine was shown to directly activate multipotent neural precursors in the hippocampus of adult mice via β_3 adrenoreceptors, thus facilitating hippocampal neurogenesis; these findings may pave the way for the development of new types of antidepressants (Jhaveri et al., 2010).

NEUROPEPTIDE Y

Neuropeptide Y (NPY) is an abundant peptide that is widely distributed throughout the brain and acts via at least four G-protein coupled receptors (Y1, Y2, Y4, Y5) (Wu et al., 2011) (Baker and Herkenham, 1995; Karl et al., 2006; Makino et al., 2000; Pieribone et al., 1992; Risold and Swanson, 1997). The Y3 receptor has yet to be cloned and the y6 receptor is a truncated receptor in humans (Sah and Geraciotti, 2012; Wu et al., 2011). Neuropeptide Y produces anxiolytic effects and appears to enhance cognitive functioning under stress. There are important functional interactions between NPY and CRH (Britton et al., 2000; Heilig et al., 1994;): NPY counteracts the anxiogenic effects of CRH at various locations within the stress/anxiety circuit, including the amygdala, hippocampus, hypothalamus, and LC (Sajdyk et al., 2006). It may be that the balance between NPY and CRH neurotransmission is critical to maintaining a homeostatic emotional state during stress (Eva et al., 2006; Kask et al., 1997; Sajdyk et al., 2006).

High levels of NPY appear to protect against depression and anxiety, with the Y1 and Y2 receptors playing important roles in the peptide's effects on mood (Heilig et al., 1993; Heilig, 1995, 2004). The Y1 receptor was found to be anxiolytic, whereas the Y2 receptor, a presynaptic autoreceptor, was found to be anxiogenic (reviewed in Wu et al., 2011). Neuropeptide Y activation of the Y1 receptor inhibits several metabolic and behavioral stress responses, including gastrointestinal distress, anxious behavior, and decreased sleep (Eva et al., 2006). Antidepressant drugs and electroconvulsive therapy increase NPY in rodent brains as they decrease depression; this effect is likely mediated by the Y1 receptor (Karl et al., 2006). A variety of antidepressant drugs increase NPY levels in humans as well (Husum and Mathe, 2002).

The potential role of NPY in fear conditioning is under investigation. In one study, central administration of NPY in rats inhibited fear-potentiated startle and enhanced its extinction; the latter effect was counteracted by the Y1 receptor antagonist BIBO3304 (Gutman et al., 2008). In another study, however, whereas fear conditioning was attenuated by exogenous NPY administration, BIBO3304 had no effect on conditioned fear; thus the role of endogenous NPY is more uncertain (Pickens et al., 2009).

Y2 knockout mice exhibit fewer anxious and depressed behaviors and reduced neuronal activation in response to

the emotional stressors, and are more adventurous (Carvajal et al., 2006; Nguyen et al., 2009). Site-specific deletion of the Y2 receptor gene in the central and basolateral amygdala, but not in any other amygdaloid nucleus, results in anxiolytic and antidepressant-like effects, suggesting a possible mechanism for Y2 receptor-mediated regulation of anxiety and depression (Tasan et al., 2010). The Y1- and Y2-receptors may therefore be useful targets for treating mood and anxiety disorders in humans.

Elevated NPY levels are associated with better performance under stress (Sah and Geraciotti, 2012). NPY treatment after exposure to stress significantly reduced prevalence rates of extreme behavioral responses and trauma-cue freezing responses in animals (Cohen et al., 2012). The Y1 receptor in the basolateral amygdala is implicated in the mediation effects of NPY on stress and may serve as a therapeutic target for the treatment of PTSD (Cui et al., 2008; Hendriksen et al., 2012). Preliminary work with special operations soldiers under extreme training stress indicates that high NPY levels are associated with better performance (Morgan et al., 2000). These findings suggest that the administration of NPY could be an effective intervention for the treatment of depression, anxiety disorders and PTSD, and for enhancing resilience to stress. However, it will first be necessary to design a drug delivery method that enables the peptide to penetrate into the CSF (Born et al., 2002); intranasal administration is currently being investigated.

GALANIN

Galanin, another abundant neuropeptide, has been shown to be involved in a number of physiological and behavioral functions, including anxiety, stress, and alcohol intake (Holmes et al., 2002; Moller et al., 1999). Understanding of galanin's mechanisms of action and effects is still at an early stage; however, overall the peptide appears to mitigate the effects of stress.

Three receptors for galanin have been identified, and two of these (GAL-1 and GAL-3) have been found to affect stress and anxiety (Walton et al., 2006). The GAL-1 receptor, expressed in the amygdala, hypothalamus, and bed nucleus of the stria terminalis, acts as an auto-receptor (Gustafson et al., 1996; Sevcik et al., 1993; Xu et al., 2001) and appears to be involved in anxiolysis: knockout mice for the GAL-1 receptor show increased anxiety-like behaviors (Holmes et al., 2003) and fail to gain stress-resistant responses after galanin injection (Mitsukawa et al., 2009). The GAL-3 receptor, on the other hand, produces anxiogenic effects when activated (Swanson et al., 2005). In humans, certain polymorphisms of the gene for the GAL-3 receptor have been linked with anxiety and alcoholism (Belfer et al., 2006). Few studies have looked at the stress-related effects of the GAL-2 receptor. One study found that it is involved in depressive-like but not anxiety-like behavior (Le Maitre et al., 2011), whereas another study showed that it has both antidepressant-like and anxiolytic effects (Lu et al., 2008).

It has been suggested that galanin recruitment during periods of stress may diminish negative emotions caused by hyperactivity of the noradrenergic system (Karlsson and Holmes, 2006). Galanin appears to inhibit NE, serotonin (5-HT), and DA

neurons from firing, reducing release of these neurotransmitters in forebrain target regions. Enhanced galanin expression in LC from running is associated with suppression of brain norepinephrine in runners and may contribute to the stress-protective effects of exercise (Sciolino and Holmes, 2012). Galanin also prevents toxicity-induced cell death (Counts and Mufson, 2010) and promotes neurogenesis (Abbosh et al., 2011), which may contribute to its antidepressant effect. Galanin was shown to be down-regulated in the CA1 of the hippocampus and the frontal cortex in a PTSD animal model with extreme behavioral response to stressors; immediate postexposure treatment with galanin, a galanin receptor agonist, significantly reduces prevalence rates of extreme responders and trauma-cue freezing responses (Kozlovsky et al., 2009). To our knowledge, galanin function has not been studied in patients exposed to traumatic stress or patients with PTSD or major depression.

SEROTONIN

Serotonin (5-HT) is well known as one of the neurotransmitters most relevant to mood. As a neuromodulator, 5-HT also regulates other neurotransmitter systems involved in mood and anxiety, and dysregulation of the 5-HT system may cause a cascade of changes in brain chemistry. The role of 5-HT as a neuromodulator is demonstrated in tryptophan depletion studies, whereby serotonin levels are lowered by ingestion of a tryptophan-free amino acid mixture. For example, tryptophan depletion led to failure to inhibit appropriate responses to punishing outcomes in healthy females (Robinson et al., 2012), and uncovered a potential vulnerability in never-depressed young adults at high familial risk for depression, who showed increased bias toward negative words while performing an affective go/no-go task in the depletion condition, compared to low-risk controls (Feder et al., 2011).

Acute stress results in increased 5-HT turnover in the PFC, nucleus accumbens, amygdala, and lateral hypothalamus (Kent et al., 2002). Serotonin release may have anxiogenic and anxiolytic effects, depending on the region of the forebrain involved and the receptor subtype activated. 5-HT_{1A} receptors are anxiolytic and may be responsible for adaptive responses to aversive events, whereas anxiogenic effects appear to be mediated by 5-HT_{2A} receptors (Charney and Drevets, 2002). Absence of 5HT_{1A} receptor signaling during early stages of brain maturation predisposes an organism to affective dysfunction later in life (Vinkers et al., 2010). 5HT_{1A} knock-out mice show an increase in anxiety-like behaviors (Heisler et al., 1998; Parks et al., 1998), including behavioral inhibition in ambiguous environments (settings that contain neutral and fear-conditioned cues). This type of behavior represents an inappropriate generalization of fearful behavior, a phenomenon that occurs in some human anxiety disorders, including panic disorder, specific phobias, and PTSD (Klemenhagen et al., 2006). Therefore, lower-than-normal activation of 5HT_{1A} receptors may be involved in the pathophysiology of human anxiety disorders. On the other hand, antagonism of 5HT_{2A} receptor has been shown to prevent the emergence of anxiety behavior and dysregulated stress response following early life stress (Benekareddy et al., 2011).

A scenario has been proposed in which early life stress increases CRH and cortisol levels, which, in turn, downregulate 5-HT_{1A} receptors, resulting in a lower threshold for tolerating stressful life events. Consistent with findings in rodents and non-human primates, a negative association is found between plasma cortisol levels and 5HT_{1A} receptor distribution in humans (Lanzenberger et al., 2010). Alternatively, 5-HT_{1A} receptor density may be partly genetic. Data so far have been mixed. A positron emission tomography (PET) study scanning receptor status in individuals with PTSD found no differences in 5HT_{1A} receptor distribution, binding potential, or tracer delivery (Bonne et al., 2005), whereas a more recent PET study in Rhesus monkeys showed that reduced 5HT_{1A} receptor density during development might be a factor increasing vulnerability to stress-related neuropsychiatric disorders (Sciolino and Holmes, 2012).

DOPAMINE

Dopamine (DA) is released in some areas of the brain and inhibited in others during extreme stress. Stress activates DA release in the mPFC (Cabib et al., 2002) and inhibits DA release in the nucleus accumbens, one of the regions associated with human experience of pleasure and reward (Cabib and Puglisi-Allegra, 1996). Lesions of the amygdala in a conditioned stress model block stress-induced DA activation in the mPFC, implying amygdalar control over stress-induced DA release (Cabib et al., 2002; Goldstein et al., 1996). DA D1 receptors were shown to be responsible for stress-induced deficit of emotional learning and memory (Wang et al., 2012). The degree to which an individual's DA system is activated by stress is in part genetically determined, and individuals whose genetic profile results in excessive mesocortical DA release after stressful events may have a tendency toward vulnerability to stress (Cabib et al., 2002). Variation in the dopamine transporter gene may contribute to one heritable path toward the development of PTSD (Drury et al., 2009). Polymorphisms in the dopamine D2 receptor gene might also contribute to susceptibility to PTSD (Voisey et al., 2009). As mentioned in the earlier discussion on NE, studies of individuals with low-functioning variants of the *COMT* gene, leading to less DA degradation, display higher anxiety and lower resistance to stress (Heinz and Smolka, 2006).

Although hyperactivity of the dopaminergic system may increase susceptibility to suffering negative effects of stress, it appears that underactivity of dopaminergic neurons in the PFC may be implicated in sustaining posttraumatic stress disorders. Lesions of dopaminergic neurons in the mPFC delay extinction of the conditioned fear response (Morrow et al., 1999), which can sustain PTSD symptoms. Dopamine transporter density is increased in PTSD patients, which may reflect higher dopamine turnover in PTSD (Hoexter et al., 2012).

Reduced levels of circulating DA have also been implicated in depression in a number of studies (Dunlop and Nemeroff, 2007). This link is supported by the fact that individuals with Parkinson's disease (and decreased DA production) have high rates of depression. Postmortem studies of patients who were depressed have found reduced DA metabolites in the cerebrospinal fluid and in brain areas regulating mood and motivation.

Polymorphisms in dopamine transporter and receptor genes in depressed patients appear to be associated with treatment response (Huuhka et al., 2008; Lavretsky et al., 2008).

BRAIN-DERIVED NEUROTROPHIC FACTOR

Brain-derived neurotrophic factor (BDNF) is an important neurotrophic factor that is active in brain regions including the hippocampus, cortex, and basal forebrain (Yamada and Nabeshima, 2003). BDNF helps support neuronal growth, differentiation, and survival (Huang and Reichardt, 2001). BDNF interacts with TrkB and p75 as its two main receptors (Castren and Rantamaki, 2010). The BDNF-TrkB pathway has been implicated in both PTSD in humans and in animal models of fear conditioning, extinction, and inhibitory learning (Mahan and Ressler, 2012). Inhibition of BDNF signaling in the amygdala can lead to impairment of the acquisition and consolidation of fear conditioning (Rattiner et al., 2004), and the consolidation of extinction (Chhatwal et al., 2006).

BDNF exerts different functions in different brain regions. Animal studies showed that, in the hippocampus, stress decreases BDNF expression, which is reversible by antidepressant treatment (Duman and Monteggia, 2006). Hippocampal BDNF expression has been shown to play a critical role in resilience to chronic stress (Taliaz et al., 2011). In the nucleus accumbens, however, stress increases BDNF expression, and this increase is associated with depression-like effects (Berton et al., 2006; Eisch et al., 2003).

There is also increasing evidence for an association between a single nucleotide polymorphism in the *BDNF* gene (Val66Met) and various psychiatric disorders including depression and PTSD (Mahan and Ressler, 2012). This polymorphism was found to alter BDNF stability and secretion, and might result in activation of the limbic system during memory formation and emotionally-relevant learning (Dennis et al., 2011; Egan et al., 2003; Gonul et al., 2011; Mahan and Ressler, 2012). Studies in Val66Met knock-in mice revealed that mice with the Met/Met genotype exhibited increased anxiety-related behaviors (Chen et al., 2006b).

GLUTAMATE

Glutamate is the most widely distributed excitatory neurotransmitter in the brain. Glutamate functions via activation of its receptors, including ionotropic NMDA, Kainate, and AMPA receptors, as well as metabotropic receptors (Chung, 2012). Glutamate, together with its downstream product GABA, the chief inhibitory neurotransmitter in the nervous system, plays an important role in neuroplasticity, and in modulating cognitive and affective responses to stress (Harvey and Shahid, 2012).

Acute exposure to stress rapidly increases glutamate release in limbic and cortical brain regions, including the hippocampus, amygdala, and prefrontal cortex, areas associated with memory, learning, and affect. The effects of chronic stress on glutamate release are less well understood (Popoli et al., 2011). Numerous studies have found an important role of glutamate in the mediation of stress responsivity, formation of traumatic

memories and the pathophysiology of PTSD (Cortese and Phan, 2005; Steckler and Risbrough, 2012). One study in mice found that the induction of DeltaFosB in the nucleus accumbens mediated resilience in response to chronic social defeat stress (Vialou et al., 2010). This effect is produced in part through induction of the GluR2 AMPA subunit of the glutamate receptor, decreasing nucleus accumbens neuron responsiveness to glutamate. In another study, deletion of AMPA receptor subunit GluR-A in mice was associated with increased depression-like symptoms such as learned helplessness, and decreased serotonin and norepinephrine levels (Chourbaji et al., 2008).

Glutamate system dysregulation has been implicated in the pathophysiology of mood disorders, and there is strong interest in drug development targeting the glutamatergic system (Murrough and Charney, 2010; Sanacora et al., 2008; Mathew et al., 2012; Mathews et al., 2012). The NMDA receptor antagonist ketamine has been shown to have antidepressant effects in patients with treatment-resistant depression (aan het Rot et al., 2010; Zarate et al., 2006). It is thought that NMDA receptor antagonist antidepressant effect may be related to a rapid increase in glutamate release, resulting in activation of AMPA receptors and ultimately resulting in changes in synaptic signaling and protein synthesis, and formation of new dendritic spine synapses in the PFC (Autry et al., 2011; Koike et al., 2011; Li et al., 2010). Moreover, antagonism of metabotropic glutamate receptors has also been shown to produce antidepressant-like effects (Belozertseva et al., 2007; Li et al., 2006).

ENDOCANNABINOIDS

Endocannabinoids including anandamide (AEA) and 2-arachidonoyl glycerol (2-AG) are substances naturally produced from within the body that activate cannabinoid receptors such as G protein-coupled CB₁ and CB₂ receptors. The endocannabinoid system is widely distributed throughout neural regions that regulate mood and emotion. The CB₁ receptor and endocannabinoid ligands are found at high densities in regions including the prefrontal cortex, hypothalamus, amygdala, and hippocampus (Herkenham et al., 1991; Hill et al., 2007; Tsou et al., 1998; Moldrich and Wenger, 2000). Activation of CB₁ receptors in these limbic areas can result in both excitatory and inhibitory neurotransmission, as well as the release of monoamines and neuropeptides (Azad et al., 2003; Di et al., 2003; Domenici et al., 2006). The CB₂ receptor is located predominantly in peripheral immune cells and organs (Hillard, 2000; Cota et al., 2003). A growing body of evidence demonstrates that deficits in endocannabinoid signaling may result in depressive and anxiogenic behavioral responses, which could be ameliorated by the pharmacological augmentation of endocannabinoid signaling (Hill and Gorzalka, 2009a).

Preclinical studies showed that CB₁ receptor knockout mice exhibited an increased susceptibility to the anhedonic effects of chronic stress (Martin et al., 2002), as well as increased passive stress coping behaviors in forced swim test and tail suspension test (Aso et al., 2008; Steiner et al., 2008), suggesting that the loss of CB₁ receptor signaling promotes a depressive phenotype. CB₁ receptor knockout mice also display increased

anxiety-like behaviors and impaired extinction of aversive memories (Martin et al., 2002; reviewed in Hill and Gorzalka, 2009a).

Clinical studies in patients with medical conditions showed that the use of CB₁ receptor antagonists rimonabant and taranabant can lead to adverse effects such as developing anxiety and depressive symptoms, suggesting that the disruption of endocannabinoid signaling may promote the emergence of mood and anxiety disorders (Christensen et al., 2007; Hill and Gorzalka, 2009a,b; Nissen et al., 2008). Reduction in circulating endocannabinoid ligands has also been seen in women with major depression (Hill et al., 2008). Little research has investigated the effects of endocannabinoids on symptoms of PTSD, but one study showed that the addition of the synthetic cannabinoid nabilone resulted in reduction of treatment-resistant nightmares in PTSD patients (Fraser, 2009). More research is warranted to elucidate the intricate endocannabinoid signaling in mood and emotion and to explore the therapeutic potential of pharmacological interventions acting on the endocannabinoid system in mood and anxiety disorders.

NEURAL CIRCUITRY OF REWARD: HOW REWARD PATHWAYS IMPACT RESILIENCE TO STRESS

A stable and well-functioning system of reward pathways and response to pleasant stimuli is a prerequisite for dealing successfully with stress and traumatic life experiences. The ability to respond appropriately to positive events and situations is vital to the preservation of reward expectation, optimism, and positive self-concept following stress or trauma. Resilient individuals likely have a robust reward system, which is strongly responsive to reward and/or resistant to change (Table 88.3, Fig. 88.2; see also Color Fig. 88.2 in separate insert).

The dopaminergic system is involved in mediating elements of the reward system, including motivation, incentive, and hedonic tone (Barrot et al., 2002; Wise, 2002). Dopaminergic neurons increase firing when rewards are unexpected or better than expected (Schultz, 2002) and decrease their rate of firing when rewards are absent or less than predicted. Imaging research suggests that the anticipation of reward involves mesolimbic DA pathways through the ventral striatum (Knutson and Cooper, 2005) and other subcortical limbic structures including the dorsal striatum, amygdala, and midbrain ventral tegmental area.

The roles of the orbitofrontal cortex (OFC) and mPFC in reward are somewhat more complex. The OFC, taking input from the nucleus accumbens, assists in discriminating the motivational value of rewarding stimuli (Martin-Soelch et al., 2001; Schultz, 2002). The mPFC appears to be involved in assessing the likelihood of receiving a given reward (as opposed to its magnitude) (Knutson and Cooper, 2005) and providing feedback along glutamatergic projections to the nucleus accumbens and the ventral tegmental area. The anterior insula is involved in producing aversion to risks in the pursuit of reward (Kuhnen and Knutson, 2005). In making decisions about behavior, it appears that a stimulus's potential

TABLE 88.3. Neural mechanisms related to resilience and vulnerability to extreme stress

MECHANISM	NEUROCHEMICAL SYSTEMS	BRAIN REGIONS	ASSOCIATION WITH RESILIENCE	ASSOCIATION WITH PSYCHOPATHOLOGY
Reward	Dopamine, dopamine receptors, glutamate, N-methyl-D-aspartic acid (NMDA) receptors, γ -aminobutyric acid (GABA), opioids, cAMP response element binding protein, AFosB	Medial prefrontal cortex, orbital frontal cortex, nucleus accumbens, amygdala, hippocampus, ventral tegmental area, hypothalamus	In resilient individuals, stress does not produce impairment in neurochemical or transcription factor-mediated reward.	Stress-induced reduction in dopamine and increases in cAMP response-element binding protein transcription produces a dysfunction in reward circuitry leading to anhedonia and hopelessness.
Reconsolidation	Glutamate, NMDA receptors, norepinephrine, β -adrenergic receptors, cAMP response-element binding protein	Amygdala, hippocampus	The lability of the memory trace allows a reorganization of original memory that is less traumatic.	Repeated reactivation and reconsolidation may further strengthen the memory trace and lead to persistence of trauma-related symptoms.
Extinction	Glutamate, NMDA receptors, voltage-gated calcium channels, norepinephrine, dopamine, GABA	Medial prefrontal sensory cortex, amygdala	An ability to quickly attenuate learned fear through a powerful extinction process	Failure in neural mechanisms of extinction may relate to persistent traumatic memories, reexperiencing symptoms, hyperarousal, and phobic behaviors.

cAMP, cyclic adenosine monophosphate; NMDA, N-methyl-D-aspartate. (Modified and reprinted with permission from Cambridge University Press 2007).

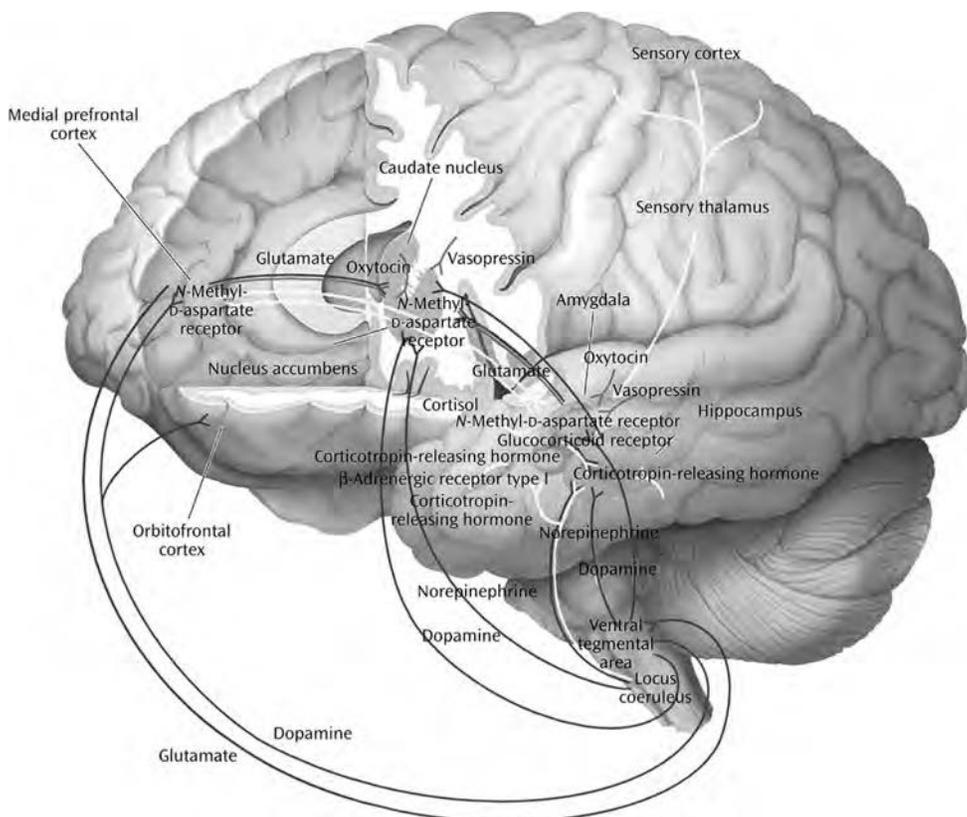

Figure 88.2 Neural circuits associated with reward, fear conditioning, and social behavior. The figure depicts a simplified summary of some of the brain structures and relevant neurochemistry mediating the neural mechanisms of reward (purple paths), fear conditioning and extinction (yellow paths), and social behaviors (blue paths). Only a subset of the many known interconnections among these various regions is shown, and relevant interneurons are not illustrated, yet it can be seen there is considerable overlap in the brain structures associated with these neural mechanisms. This suggests that there may be clinically relevant functional interactions among the circuits. For example, a properly functioning reward circuit may be necessary for the reinforcement of positive social behaviors. An overly responsive fear circuit or impaired extinction process may negatively influence functioning of the reward system. The assessment of these neural mechanisms must be considered in the context of their neurochemical regulation. Alterations in one neurotransmitter, neuropeptide, or hormone system will affect more than one circuit. Several receptors that may be targeted by new anti-anxiety and antidepressant drugs are illustrated. The functional status of these circuits has important influences on stress-related psychopathology and the discovery of novel therapeutics (see text). (Modified and reprinted with permission from Cambridge University Press, 2007) (See color insert).

rewards are assessed in subcortical areas before being analyzed in the mPFC (Knutson and Cooper, 2005).

Strength, persistence, and emotional value of reward memory are modulated by circuits formed by the amygdala, subiculum, bed nucleus of the stria terminalis, nucleus accumbens, and mPFC. Specifically, the cyclic adenosine monophosphate (cAMP) pathway and expression of cAMP response-element binding protein in the amygdala strengthen positive as well as negative associations (Hall et al., 2001; Josselyn et al., 2001). Rodents have been shown to develop persistent anhedonia when increased cAMP response element binding is present in the nucleus accumbens (Barrot et al., 2002).

Stresses, chronic and acute, are correlated with decreased sensitivity to rewarding stimuli and increased sensitivity to aversive stimuli (Bogdan and Pizzagalli, 2006; Pliakas et al., 2001). During performance of a probabilistic reward task, high school student carriers of the S allele of the 5HTTLPR gene showed a larger stress-related reduction in responsiveness to reward as school finals approached, compared with L allele homozygotes (Nikolova et al., 2012). This effect was observed only in males. In a different study, reward learning under a stressful condition was differentially influenced in healthy females depending on their CRH receptor type 1 genotype, and was associated with differential activation to reward in the anterior cingulate cortex (ACC) and OFC (Bogdan et al., 2011). Although exposure to acute stress has the potential to alter reward circuits, decreasing positive response to reward, findings from these studies suggest that some people are more sensitive to the effects of stress, and other, potentially more resilient individuals show reduced stress sensitivity, maintaining highly functional reward systems under adverse conditions. In a recent fMRI study, adolescents and young adults with a parental history of depression showed lower OFC activation to rewarding stimuli and higher lateral OFC and insula activations to aversive stimuli, compared with controls. They also showed blunted ACC activation to both rewarding and aversive stimuli (Mc Cabe et al., 2012). These neural abnormalities suggest a potential mechanism for decreased resilience in individuals at high familial risk for depression.

We thus have a beginning understanding of the neurobiology underlying robust reward systems. There is also some evidence from animal models that provides insight into potential mechanisms. In rodent models, chronic exposure to stressful stimuli will lead to an enduring aversion to social contact. Researchers have found that knocking out *BDNF* in the mesolimbic DA system of the rodents seems to produce a reward system that has lost its plasticity, remaining resistant to change when the rats are subsequently presented with stressors. After undergoing this mesolimbic DA pathway-specific knockdown of *BDNF*, mice become inoculated to the effects of repeated social aggression (Berton et al., 2006). Studies in the social defeat paradigm in mice, whereby mice are exposed to a dominant intruder placed in their cage, have demonstrated that resilient mice, who show appropriate anxiety responses but no defeat, upregulate K⁺ channels in the VTA, thereby preventing an increase in neuronal excitability and associated *BDNF* release onto the nucleus accumbens observed by contrast in vulnerable mice (Krishnan et al., 2007).

These findings highlight the major role of the reward system's plasticity in determining resilience and indicate possible mechanisms through which a resistant reward system plays a part in allowing resilient individuals to endure hardships without developing posttraumatic psychopathology.

THE NEURAL CIRCUITRY OF ANXIETY AND FEAR: THE ROLE OF FEAR LEARNING IN RESILIENCE TO STRESS

FEAR CONDITIONING

Individuals with PTSD suffer distress when they encounter traumatic reminders. Over time, patients suffering from PTSD tend to “overgeneralize” fear cues: they begin to associate more and more features in their environment with their past traumas. Often, fear cues are objectively non-threatening and unrelated to trauma. The process through which previously neutral stimuli become fear inducing is known as fear conditioning. In the terminology of fear conditioning, previously neutral stimuli become “conditioned” stimuli by virtue of their association with aversive (unconditioned) stimuli (Blair et al., 2001).

Resilience to the effects of severe stress may be characterized in part by the capacity to avoid overgeneralizing fear-inducing triggers. Resilient individuals are also likely adept at extinguishing of fearful memories; in other words, those who are resistant to stress have an easier time letting go of frightening memories and associations.

Cue-specific conditioned stimuli are transmitted to the thalamus by external and visceral pathways. Afferents reach the lateral amygdala by means of two parallel circuits: a rapid subcortical path directly from the dorsal (sensory) thalamus and a slower regulatory cortical pathway encompassing the primary somatosensory cortices, the insula, and the anterior cingulate/PFC. Contextual conditioned stimuli are projected to the lateral amygdala from the hippocampus and the bed nucleus of the stria terminalis. The lateral nucleus of the amygdala is likely a site of fear memory storage as well as fear acquisition (Schafe et al., 2005). The existence of the long loop pathway (passing through cortical regions) indicates that sensory information relayed to the amygdala undergoes substantial higher-level processing, thereby enabling assignment of significance based on prior exposure to stimuli. This potential for higher-level processing of conditioned stimuli is important because it implies that there is potential for modifying the processing of fear-conditioned stimuli with cognitive therapies.

The lateral amygdala, once engaged, projects to the central and medial nuclei of the amygdala, which project indirectly to the acoustic startle pathway in the brain stem (Davis, 2006). The central nucleus of the amygdala appears to be the primary output nucleus involved in initial memory consolidation; infusions of anisomycin, a protein synthesis inhibitor, into the central nucleus during fear training disrupt consolidation of fear memory (Debiec and LeDoux, 2006). The central nucleus projects to the hypothalamus and brain stem, triggering the cascade of autonomic, endocrine, and behavioral responses associated with fear (Schafe et al., 2001).

The molecular processes underlying fear conditioning is an area of active investigation. Consolidation of fear conditioning is thought to occur via long-term potentiation of synapses in the lateral amygdala. Fear-conditioned rats show increases in an actin polymerization protein, profilin, in dendritic spines in the lateral amygdala; this finding could contribute to a greater understanding of the specific changes underlying synaptic plasticity (Schafe et al., 2005). However, our understanding of the cellular mechanisms underlying the process remains far from complete (Sigurdsson et al., 2007). The currently accepted model to explain how long-term potentiation in the lateral amygdala might lead to the consolidation of fear conditioning was proposed by LeDoux and colleagues (LeDoux, 2000). The model proposes that calcium entry through NMDA receptors and voltage-gated calcium channels initiates the molecular processes to consolidate synaptic changes into long-term memory; short-term memory requires only calcium entry through NMDA receptors (Blair et al., 2001).

Because NMDA receptors are critical in fear learning, which is mediated by glutamate acting in the central nucleus of the amygdala (Davis, 2006), we may be able to impair fear learning by blocking NMDA receptors in the amygdala during stress. This has been demonstrated in rodents (Rodrigues et al., 2001; Walker and Davis, 2000;). Blockade of voltage-gated calcium channels may also prove useful in preventing PTSD in those who are exposed to stress. Of course, because these are mechanisms of initial fear consolidation, it would be necessary to initiate receptor blockade treatment prior to trauma exposure to prevent posttraumatic stress. This might be feasible and useful in populations that are certain to encounter severe stress, for example, soldiers to be deployed in combat, or disaster relief workers.

RECONSOLIDATION AND EXTINCTION

Existing memories, when retrieved or “reactivated” by remembering, become labile and prone to change. Reactivated memories may go down one of two pathways: they may either be strengthened by reconsolidation, or weakened by extinction (Eisenhardt and Menzel, 2007). The processes appear to be mutually exclusive, and may compete for cellular resources (Dudai and Eisenberg, 2004). The processes of memory reactivation, reconsolidation, and extinction involve NMDA and β -adrenergic receptors and require cAMP response element binding protein induction, indicating that nuclear protein synthesis is necessary (Kida et al., 2002). Reconsolidation and extinction are impaired by NMDA and β -adrenergic blockade, and enhanced by the NMDA partial agonist D-cycloserine (Charney and Drevets, 2002; Chhatwal et al., 2006; Debiec and LeDoux, 2006; Przybylski et al., 1999; Royer et al., 2000; Sotres-Bayon et al., 2007). Whether the process of reconsolidation or of extinction will be engaged appears to depend on the timing and type of memory retrieval; short memory reactivation sessions tend to lead to reconsolidation, whereas long and intensive extinction training is necessary to achieve extinction (J.L. Lee et al., 2006). Reconsolidation and extinction of a memory are affected by the age of the memory in question (Fulton, 2006). As would be expected, younger memories are

more prone to being altered by either process, although intensifying the memory reactivation process helps enhance the lability of older memories (Suzuki et al., 2004).

Similarly, the process of extinction changes over time. Extinction induced immediately after fear acquisition (between 10 minutes and 1 hour later) is thought to occur by “erasing” the learned fear (Myers et al., 2006). However, extinction induced 24–72 hours after initial fear training appears to be a new form of learning altogether (Myers and Davis, 2007). The extinction that is achieved during this later time period may be thought of as the formation of a new, safe association with the original fear cue; this new association is placed, “like a blanket,” over the older fear association (Chhatwal et al., 2006). That the original fear association still exists underneath the blanket of safety is suggested by observations that extinguished fears can return spontaneously.

Memory consolidation, reconsolidation, and extinction involve different neural circuits. The central nucleus of the amygdala and hippocampus are involved in initial memory consolidation, the lateral amygdala in reconsolidation, and the basal lateral amygdala in extinction (Bahar et al., 2004; Debiec and LeDoux, 2006). The mPFC is a critical structure in extinction. Since the 1980s, studies have found that lesions of the mPFC result in an impairment of normal extinction (cited in Sotres-Bayon et al., 2006). Failure to achieve an adequate level of activation of the mPFC might lead to persistent fear responses (Herry and Garcia, 2002). Findings from an fMRI study in healthy volunteers suggest that the ability of fear responses to adapt flexibly as threat shifts from one stimulus to another is particularly mediated by the ventromedial PFC (Schiller et al., 2008). Individuals with the capacity to function well after high-stress experiences may have potent mPFC inhibition of amygdala responsiveness. In contrast, patients with PTSD have been shown to exhibit increased left amygdala activation during fear acquisition and decreased activity of the mPFC/anterior cingulate during extinction.

Reconsolidation and extinction of traumatic memories are implicated in vulnerability and resilience to extreme stress. Individuals who are able to attenuate learned fear through extinction are likely highly stress-resilient. Due to our growing understanding of the mechanisms of memory processing, there will likely be ever more possibilities for helping trauma survivors manage their traumatic memories. In particular, recent studies suggest that during reconsolidation, previously stored information becomes labile after retrieval and thus amenable to change as new information is incorporated (Schiller et al., 2010). Recent studies in healthy volunteers, whereby participants underwent extinction during the reconsolidation window, incorporating non-fearful information to the old fear memory, have successfully prevented the expression of fear responses (Schiller et al., 2010; 2012). This effect has been shown to last for at least one year (Schiller et al., 2010) and has been replicated by a different group (Oyarzun et al., 2012). A recent fMRI study in humans demonstrated that suppression of a fear memory by conducting extinction training during the reconsolidation window works by erasing the fear memory representation in the amygdala (Agren et al., 2012). These exciting findings might lead to new interventions for

individuals with PTSD. Emerging evidence thus suggests that extinction training during reconsolidation might be a potentially effective treatment approach.

ADDITIONAL NEURAL CIRCUITRY RELEVANT IN RESILIENCE

Stress resilience has been related to a greater capacity for emotion regulation (Johnstone et al., 2007; Masten and Coatsworth, 1998), thought to be mediated by ventral and dorsal neural systems (Phillips et al., 2003a, 2003b). As discussed earlier, studies have linked genetic variation with differential amygdala reactivity to negative stimuli, as well as altered functional coupling between the PFC and the amygdala, a possible mechanism mediating differential vulnerability to stress. In addition, studies of offspring at high and low familial risk for depression have found differences in neural responses to emotional stimuli (Monk et al., 2008) and in attention to negative emotional stimuli during tryptophan depletion (Feder et al., 2011). In a recent study of acutely traumatized individuals, higher trait resilience measured by the Connor-Davidson Resilience Scale was positively correlated with activation in the right thalamus, and the inferior and middle frontal gyri (BA 47), additional areas involved in emotion regulation (Daniels et al., 2012).

The neural basis of a particular form of emotion regulation, cognitive reappraisal, has been examined in several imaging studies. Activation of the lateral PFC, thought to modulate amygdala activation and thus the intensity of emotional responses, has been linked to reappraisal success (Goldin et al., 2008; Ochsner et al., 2004; Wager et al., 2008). Further, greater use of reappraisal in everyday life has been found to correlate with lower amygdala and greater PFC activation to negative stimuli (Drabant et al., 2009).

Other imaging studies have begun to delineate additional neural circuits relevant for social behavior, for example the neural circuitry mediating the capacity for empathy, thought to be comprised of the mirror neuron system in interaction with limbic brain regions (Rizzolatti and Craighero, 2004; Schulte-Rüther et al., 2007). Future studies might uncover possible relationships between the capacity for empathy and resilience. As discussed, social contact and support are known to promote health and well-being (Charuvastra and Cloitre, 2008). Imaging studies are beginning to uncover the neural mechanisms mediating reduced responses to stress in the presence of social support (Coan et al., 2006).

IMPLICATIONS FOR PREVENTION AND TREATMENT OF STRESS-RELATED PSYCHOPATHOLOGY

Our growing understanding of genetic, developmental, psychological, and neurobiological resilience factors continues to lead to the development of therapeutic interventions for enhancing resilience to stress (Southwick and Charney, 2012b).

Cognitive-behavioral therapies emphasize cognitive reappraisal of negatively viewed circumstances into more positive

perspectives, and have shown results across a broad range of populations (Beck and Dozois, 2011). Other therapies employing cognitive reappraisal include hardiness training (Maddi, 2008) and well-being therapy (Fava and Tomba, 2009), the latter also showing promising results in school interventions (Ruini and Fava, 2012). Positive psychology-based exercises, including reflecting daily on things that went well that day, were shown to increase positive affect and decrease depression levels in adults (Seligman et al., 2005). Similarly, gratitude interventions, whereby individuals are instructed to identify several things that they are grateful or thankful for in their life, have been associated with increased reports of well-being and positive affect in various populations (Wood et al., 2010).

Meaning-making interventions have been applied to help breast or colorectal cancer patients, resulting in increases in self-esteem, optimism, and self-efficacy, in comparison with a control group (Lee et al., 2006). Mindfulness training for individuals with residual depressive symptoms successfully increased their ability to experience positive emotions and was associated with a reduction in residual depressive symptoms, compared with a waitlist control condition (Geschwind et al., 2011). Research findings on psychological factors associated with resilience have been applied to design a resilience training program for the military (Reivich et al., 2011). Future studies should determine whether these interventions are successful in protecting individuals facing future stressors, thus boosting resilience in general and at-risk populations.

The military, along with first responder groups such as police or firefighters, has a strong tradition of stress inoculation training, in the form of training programs designed to maximize coping self-efficacy and mastery. This training is accomplished by means of exposure to manageable stressors including physical and mental challenges, providing opportunities for mastery by repeated practice and gradual exposure to increasingly challenging situations. A similar approach is applied in outdoor education programs for children and adolescents, such as Outward Bound.

As discussed in the preceding, recent research has made it possible to understand the process of fear extinction further, and current studies are focused on delineating windows of opportunity during memory retrieval when fear memories and responses are more receptive to extinction training, with the goal of developing novel therapeutic interventions (Karatsoreos and McEwen, 2011; Schiller et al., 2012). The principles of fear extinction have already been applied more broadly to the development of exposure therapy, a form of therapy with proven effectiveness in PTSD (Foa, 2011). Extensive investigation is also devoted to potential ways of enhancing stress-resistance and resilience with pharmacologic means, and the combination of pharmacologic and psychotherapy approaches.

Because antagonizing β receptors disrupts the process of consolidation, several trials have investigated the efficacy of β -blockers, in particular propranolol, in disrupting consolidation of traumatic memories shortly after trauma exposure. Although initial trials showed some promise (Pitman et al., 2002; Vaiva et al., 2003), later studies failed to prevent the emergence of PTSD (Hoge et al., 2012; Stein et al., 2007). One possible explanation is that propranolol was administered late

in the consolidation window, or after consolidation was already complete (Cain et al., 2012). In a separate series of studies, the *N*-methyl *D*-aspartate (NMDA) receptor partial agonist *D*-cycloserine, which enhances memory reconsolidation and memory extinction, was shown to facilitate the effects of prolonged exposure therapy in humans with anxiety disorders (Hofmann et al., 2006; Ressler et al., 2004). Results in PTSD have been mixed and await further study (Cain et al., 2012).

Animal models are currently being used to investigate the use of other cognitive enhancers that might affect fear extinction, such as agents modulating GABAergic transmission (Kaplan and Moore, 2011). A major area of interest involves the study of the endogenous cannabinoid system, its role in modulating HPA axis activation during stress, and the potential for facilitating fear extinction by targeting endocannabinoid receptors (Hill and Tasker, 2012). Other receptors known to be involved in extinction, such as the *BDNF* receptor tyrosine kinase b, have been targeted in preclinical trials (Chhatwal et al., 2006).

Additional potential approaches involve targeting the HPA axis. Trials of hydrocortisone, a glucocorticoid receptor agonist, in intensive care unit patients with septic shock or undergoing cardiac surgery resulted in reduced PTSD symptoms and improved health-related quality of life in long-term survivors (Schelling et al., 2006). A pilot study of high-dose hydrocortisone administered immediately after trauma to patients recruited from the emergency department showed promising results (Zohar et al., 2011). Thus, it might be possible to prevent PTSD with treatments administered shortly after trauma exposure or even by pretreating individuals at high risk for trauma exposure. For individuals with chronic PTSD, current trials are investigating the effects of a CRH1 receptor antagonist and the glucocorticoid receptor antagonist mifepristone in separate trials.

Continued progress in understanding the genetic, developmental, biological, and psychological underpinnings of resilience and vulnerability to stress, as well as the interactions between these factors, will aid in moving the field toward the identification, prevention, and treatment of those at risk of developing stress-related psychopathology.

DISCLOSURES

Dr. Feder has no conflicts of interest or disclosures. Her research is funded by CDC/NIOSH and USAMRAA.

Dr. Haglund has no conflicts of interest or disclosures.

Dr. Wu has no conflicts of interest or disclosures.

Dr. Southwick has no conflicts of interest or disclosures. His research is funded by NIH/NIMH, CDC/NIOSH, USAMRAA and the Department of Veterans Affairs.

Dr. Charney and Mount Sinai School of Medicine have been named on a use patent application of Ketamine for the treatment of depression. If Ketamine were shown to be effective in the treatment of depression and received approval from the Food and Drug Administration for this indication, Dr. Charney and Mount Sinai School of Medicine could benefit financially.

Dr. Charney is funded by NIH, NIH/NIMH, NARSAD, USAMRAA.

Dr. Charney is on the following scientific advisory boards with no compensation:

- 2000 Academic Advisory Board, Pfizer Postdoctoral Fellowship Program
- 2001 Scientific Advisory Board, Familial Dysautonomia Foundation
- 2002 National Education Alliance for Borderline Personality Disorder Scientific Advisory Board
- 2002 National Center for Posttraumatic Stress Disorder
- 2002 Senior Advisory Board, American Psychiatric Association/American Psychiatric Press Journal: Journal of Lifelong Learning in Psychiatry
- 2005 Institute of Medicine Committee on Stress of Military Deployment
- 2006 Institute of Medicine Subcommittee on PTSD
- 2012 Institute of Medicine Committee on DHS Workforce Resilience

Dr. Charney is also on the following editorial boards with no compensation

- 1986 Editorial Board, Journal of Affective Disorders
- 1990 International Editorial Board, Journal of Psychopharmacology
- 1993 Editorial Board, Journal of Serotonin Research
- 1994 Editorial Board, Depression and Anxiety
- 1995 Editorial Board, Seminars in Clinical Neuropsychiatry
- 1996 Editorial Board, CNS Spectrums
- 1997 Editorial Board, Human Psychopharmacology
- 2012 Editorial Board, CNS Spectrums

THOMAS B. HILDEBRANDT AND AMANDA DOWNEY

NEUROBIOLOGICAL MODELS OF ANOREXIA NERVOSA

Anorexia nervosa (AN) is an illness that is not homogenous in presentation; rather it is diagnosed upon a range of disturbed behaviors and affective states that constitute the illness. The heterogenic nature of the diagnostic group complicates the process of identifying an underlying neurobiological model for the disease. There are four main factors that make identifying a singular neurobiological model difficult. First, there is more than one source of dysregulation present in the development and maintenance of AN. Predisposing factors that lead to extreme measures to lose weight will most likely be distinct from those that prevent weight restoration and maintenance of adequate caloric intake. Second, it is ethically and scientifically difficult to determine the degree to which systems of dysregulation are a consequence of malnutrition or rather an endophenotype inherent to the individual that predisposes her or him to the illness. Third, sociocultural factors that may play a role in the development of the disorder have often been used to explain the difference in prevalence rates of AN among men and women. No neurobiological basis for this disparity has been elucidated. Finally, the development of AN is correlated with specific temperaments and personality factors. This facet of the disorder makes strict correlation between neurobiology and the disorder complicated because the role of temperament is highly complex and not unique to AN.

NEUROBIOLOGICAL MODELS OF BULIMIA NERVOSA

Bulimia nervosa (BN) is a mental disorder characterized by episodes of binge eating and attempts to compensate for these episodes by self-induced vomiting, abusing laxatives or diet pills, fasting for 24 hours or more, and/or compulsively exercising. They provide positive reinforcement and/or relief from negative symptoms and may be indicative of underlying dysregulation in the serotonergic of dopaminergic systems. A neurobiological model for BN overlaps in many ways with that of AN, although there are several essential differences. First, core behaviors in BN can be studied in the lab, allowing for a more detailed analysis with less confounding factors. Second, most women with BN are within a healthy weight range, which has eliminated the confounding effects of malnutrition on hormonal and neurotransmitter systems. Last, impulsivity is the major temperament associated with BN, as opposed to harm avoidance in AN.

DEVELOPMENT VERSUS MAINTENANCE OF ANOREXIA NERVOSA

The development of AN shows a strong relationship with the onset of puberty, with most patients meeting the full criteria for the disorder before reaching adulthood (Fig. 89.1). Although many recover from symptoms before their mid-twenties, some display behaviors characteristic of other illnesses such as bulimia nervosa. Definitive predictors that can differentiate between the large percentage of patients who remain chronically ill remain elusive, with studies citing highest weight achieved upon weight restoration, time to partial recovery, familial relationships, premorbid asociality, postdischarge weight loss, motivation to recover, and the binge-purge subtype of AN as valuable yet complex predictors (Carter et al., 2012; Strober et al., 1997). Prospective predictors for the development of AN include being female, having feeding problems in infancy, undereating, and having a perfectionist temperament (Tyrka et al., 2002). Furthermore, retrospective studies suggest that perinatal environment may impact an individual's vulnerability to AN. Obstetrical complications (e.g., low birth weight, preterm birth, neonatal cardiac problems, maternal anemia, diabetes mellitus, and preeclampsia) and neonatal dysmaturity may contribute to a dysregulation in prenatal programming of stress response systems and consequently carry some risk for the disorder (Tyrka et al., 2002).

The incidence of AN is approximately eight per 100,000 persons per year. Although considered a rare illness, it is prevalent among young women in Western countries, with a 0.9% lifetime prevalence rate. Anorexia nervosa is highly comorbid with many other DSM-IV disorders, with 56.2% of patients meeting criteria for at least one comorbid psychiatric disorder (Hudson et al., 2007). Incidence rates are highest among females 15 to 19 years old, representing nearly 40% of all cases (Smink et al., 2012). It has the highest rate of mortality among all mental disorders, rendering AN a major public health concern. The incidence of AN in males is significantly less than in females, with estimates of incidence less than one per 100,000 persons per year (Hoek, 2006). Studies have reported conflicting prevalence rates of eating disorders among minority groups, and further population studies are needed. A recent study suggests similar prevalence rates among all ethnic groups in the United States (Smink et al., 2012). Few epidemiological studies have been conducted on AN and BN outside of Western countries. However, it is possible that increased rates of intentional dieting common to

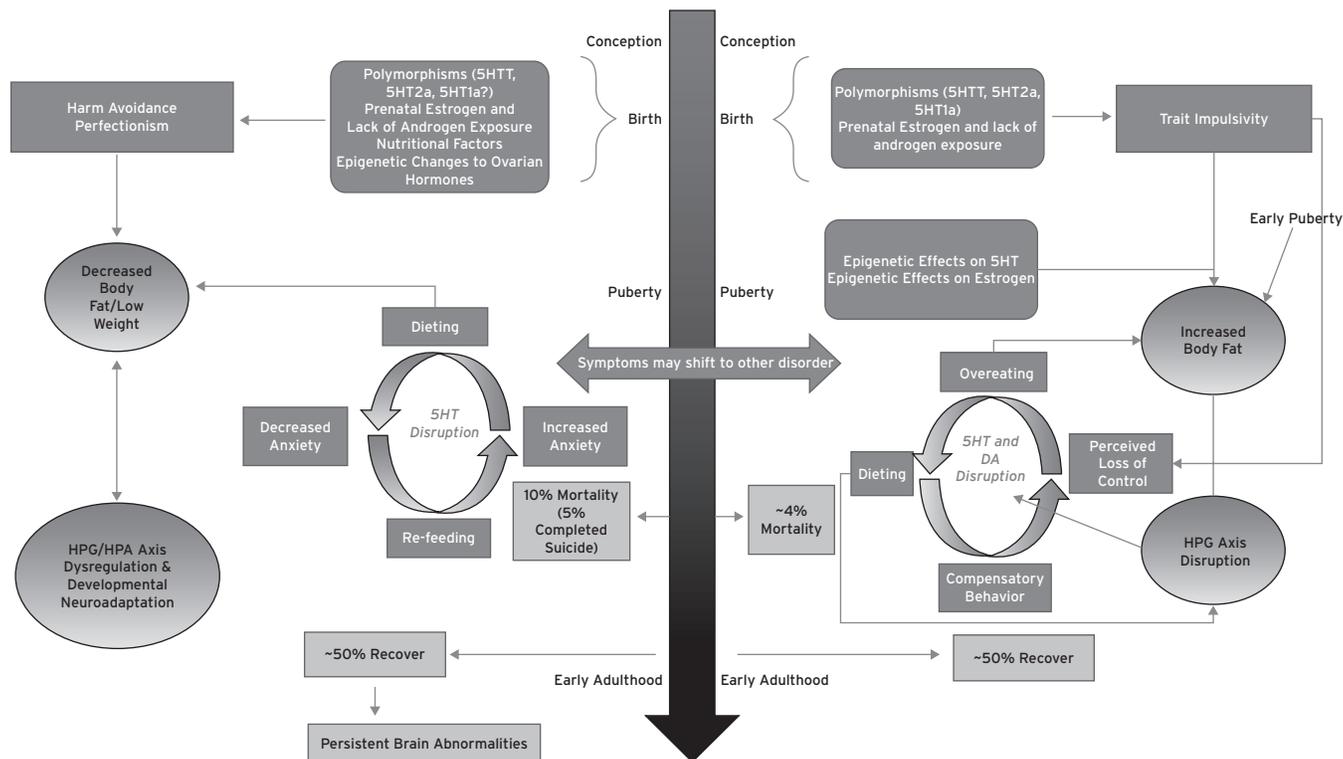

Figure 89.1 The developmental trajectories for anorexia nervosa (left) and bulimia nervosa (right) indicate periods of accumulating risk which are activated by the environmental and hormonal changes associated with puberty. The hypothalamic pituitary gonadal (HPG) and hypothalamic pituitary adrenal (HPA) axes interact with the dieting-overeating behaviors to support neuronal adaptation to the disease state evidenced by changes in serotonergic (5-HT) and dopaminergic (DA) function that may persist beyond into periods of recovery. For some individuals, the disease state leads to fatal outcomes caused by physical complications of the disease or suicide.

Western countries may lead to higher incidence rates, particularly in younger individuals.

DEVELOPMENTAL MODEL OF BULIMIA NERVOSA

The onset of bulimia nervosa is characterized by genetic, prenatal, epigenetic, and pubertal conditions (see Fig. 89.1). Vulnerability to BN may be especially influenced by dysregulation in the serotonergic, dopaminergic, and ovarian hormone systems. Furthermore, the emotional and psychosocial impact of an increased propensity for body fat deposition and the propensity for higher BMI among women with BN may contribute to the development of binge episodes and compensatory behaviors. Women with BN tend to undergo pubertal changes earlier than age-matched counterparts. The surge of estrogen accompanying pubertal changes contributes to early visceral fat deposition and weight dissatisfaction for these women (Hildebrandt et al., 2010). This phenomenon leads to both a distancing of the individual from the thin-ideal and activates a range of neurobiological changes that make behavior more difficult to regulate. Additionally, fluctuations in estrogen levels affect mood (e.g., through the serotonin system), appetite, and impulsivity (Rubinow et al., 1998). The combination of these factors within a societal context in which thinness is idealized and dieting is normative leads vulnerable women toward a pattern of dieting in which the binge-purge cycle may begin. Once initiated, the symptoms of BN can have dramatic effects on hypothalamic

regulatory systems that independently of predisposing vulnerabilities can maintain a cycle of overeating and compensatory behavior. Neuroadaptive changes in these hypothalamic hormonal systems make the regulation of mood and stress responses increasingly difficult and are likely partially responsible for alterations in corticolimbic neurocircuitry that characterizes the disorder. Symptoms persist until the individual can achieve some nutritional and affective balance.

The lifetime prevalence of BN remains close to 1%. There is a large gender disparity in the prevalence of the disorder, women being at least three times more likely than men to develop BN (Hudson et al., 2007). This disorder is also highly comorbid with other psychiatric diagnoses, with 94.5% of patients meeting the criteria for at least one disorder. Women with BN are more likely to develop comorbid conditions related to mood, anxiety, impulsecontrol, and substance use, and it is estimated that fewer than half of individuals who meet the criteria for BN seek treatment throughout their lifetime (Hudson et al., 2007).

GENETIC VULNERABILITY TO ANOREXIA NERVOSA

The search for a genetic basis of AN has yet to provide any definitive genetic markers. Family studies have consistently shown significant heritability of AN among first-degree relatives of probands, with a seven- to 12-fold increase in prevalence when compared with control subjects (Strober et al., 2000). Genetic research in AN suggests that a diverse set of genes are potentially

TABLE 89.1. Frequent genetic polymorphisms identified in patients with eating disorders

CATEGORY	GENE	VARIANT	POSSIBLE ASSOCIATION	EPIGENETICS
SEROTONIN				
	Serotonin Transporter (SERT, 5-HTT, SCL6A4)	5-HTTLPR, SLC6A4 44 bp Del/Ins (promoter)	AN/BN

involved in the pathogenesis of the disorder. Table 89.1 summarizes the essential genes implicated thus far, although the field is still awaiting completion of ongoing large-scale studies that may provide more clarity in the genetic risks to this disorder.

Candidate gene studies aim to discover consistent genetic polymorphisms that may contribute to the diagnosis of AN, but results have been inconclusive. Strong association between polymorphism and risk of developing an eating disorder could lead to targeted pharmacotherapies and preventive strategies in those at risk. Some association between polymorphism and diagnosis has been found in serotonergic, adrenergic, and dopaminergic genes, genes coding for proteins associated with the melanocortin system, genes for leptin, ghrelin, agouti-related protein, neuropeptide Y, opioids, cannabinoid receptors, potassium channels, brain-derived neurotrophic factor, and reproductive hormones (Pinheiro et al., 2010). Although significant association remains to be found, it is likely that a combination of genetic variants as well as environmental factors contribute to the development of the disorder. Additionally, candidate gene polymorphisms and single nucleotide polymorphisms (SNPs) may be better correlated to endophenotypes and personality traits that correspond to a predisposition to AN rather than finding direct association with the diagnosis itself.

Genome-wide association studies (GWAS) have identified several SNPs associated with the drive for thinness, obsessiveness, and other traits associated with AN. Four SNPs on the contactin 5 gene, as well as 1q31.3, 2p11.2, 13q13.3, and rs2048332 are common genetic variations that merit further investigation into possible association with AN (Helder and Collier, 2011).

More recent studies focusing on epigenetic processes may further illuminate the role of genetic processing and expression on the pathology of AN. Epigenetic effects include the breadth of changes to DNA processing within the cell that are not encoded within the genome and therefore reversible, perhaps accounting for the variability in genetically regulated aspects of the disorder. DNA methylation is particularly applicable to eating disorders, having established that methylation patterns in CpG islands at the 5' end of genes may control long-term regulation of gene expression (Bird, 2002). Diet, genetics, chemical exposure, environment, and other physiological states can influence methylation patterns in humans (Poirier, 2002). Serotonin transporter (5-HTT) mRNA transcription is susceptible to epigenetic modification (Philibert et al., 2008) as is the serotonin receptor 5-HT_{2a} (Polesskaya et al., 2006). Epigenetic modifications support the broad base of evidence for dysregulation in the serotonergic system in AN and likely other systems, including dopaminergic and appetite regulatory systems. Furthermore, epigenetics could account for the sexually dimorphic nature of certain hormones and neurotransmitters, which may shed light on the gender disparity in the prevalence of eating disorders (Gabory et al., 2009). More in-depth study into the mechanism of epigenetic effects on other neurotransmitter systems is warranted.

GENETIC VULNERABILITY TO BULIMIA NERVOSA

Like AN, no definitive genes have been identified that correlate with a diagnosis of BN, although patterns of heritability are evident. Table 89.1 summarizes findings from studies examining

this link. Relatives of probands with BN have an approximate four time greater lifetime risk of also developing BN (Strober et al., 2000). Linkage analysis suggests loci with specific genetic polymorphisms and SNPs associated with BN are correlated with age of menarche, body mass index, obsessionality, and concern over mistakes (Bacanu et al., 2005). Polymorphisms in the serotonergic system are particularly evident in patients with BN as compared with control subjects with potential variability residing in the serotonin transporter (5-HTT) and particular serotonin receptors (Monteleone and Maj, 2008). As in AN, epigenetic effects in DNA processing via methylation patterns are being studied both in the serotonergic and dopaminergic systems in women with BN, contributing evidence to the hypothesis that epigenetic dysregulation can affect neurotransmission and play an important role in the pathology of eating disorders (Frieling et al., 2010).

PRENATAL RISK

There is some evidence that the prenatal hormonal environment will affect vulnerability to eating disorders during puberty. Emerging research suggests that exposure to lower levels of testosterone as a fetus in the second trimester may increase sensitivity to fluctuations in estrogen concentrations during puberty, activating a predisposition toward disordered eating (Klump et al., 2006). Androgen hormone exposure in animal models has demonstrated a protective role in the central nervous system, decreasing its sensitivity to estrogens. This genetic influence is hypothesized to originate from a polymorphism within the estrogen receptor beta or in a serotonin receptor (Klump et al., 2006), although there are likely other mechanisms that contribute to this sensitivity. Additionally, higher prenatal androgen exposure may enhance the expression of cytosolic and nuclear androgen receptors, helping to explain the sexually dimorphic nature of some areas of the brain (Resko and Roselli, 1997) and consequently the disparity in prevalence rates of eating disorders between genders.

DYSREGULATION IN HORMONAL SYSTEMS

Figure 89.2 summarizes the changes in hypothalamic hormonal systems that occur during active disease states for those with AN and BN. Acute and chronic starvation produces a unique set of hormonal and neuroendocrine effects that may be involved in the pathophysiology of both AN and BN. Malnutrition induces varying states of adaptation in two hypothalamic regulatory systems—the hypothalamic-pituitary-adrenal (HPA) axis and the hypothalamic-pituitary-gonadal (HPG) axis, resulting in hyper- and hypoactivity of these systems depending on the disease state (e.g., starvation vs. overfeeding) and the associated symptoms (e.g., food avoidance, binge eating). The adaptive hormonal changes included by symptom stress may have implications in a range of cognitive or affective systems, particularly the motivation–reward system (Keating, 2011).

The rapidly changing hormonal environment induced by puberty also contributes to the development of these disorders. The initial surge of ovarian hormones at the onset of puberty may correlate with initial decreased drive to eat, as studies in female rat models have consistently shown a reduction in food intake following the sharpest rise in estrogen levels during the estrous cycle (Butera, 2010). Fluctuations in the menstrual cycle of humans also demonstrate varied caloric intake, notably correlating the luteal phase of the menstrual cycle with highest appetite and lowest levels of estrogen (Buffenstein et al., 1995). The window of vulnerability produced by hormonal fluctuations during puberty provides hormonal mechanisms that may trigger or facilitate existing restrictive or overeating feeding behaviors. The neuroendocrine sequelae of this key developmental window, and the relative impact of malnutrition, have not been completely elucidated. However, morphological changes in the brain caused by the pubertal environment and the steep rise in ovarian hormones may affect the development of several primary neurocircuits involved in motivation, emotional processing, impulsivity, and information processing. It is possible that patients with AN or BN suffer from an impairment in any or all of these pathways (Kaye et al., 2011).

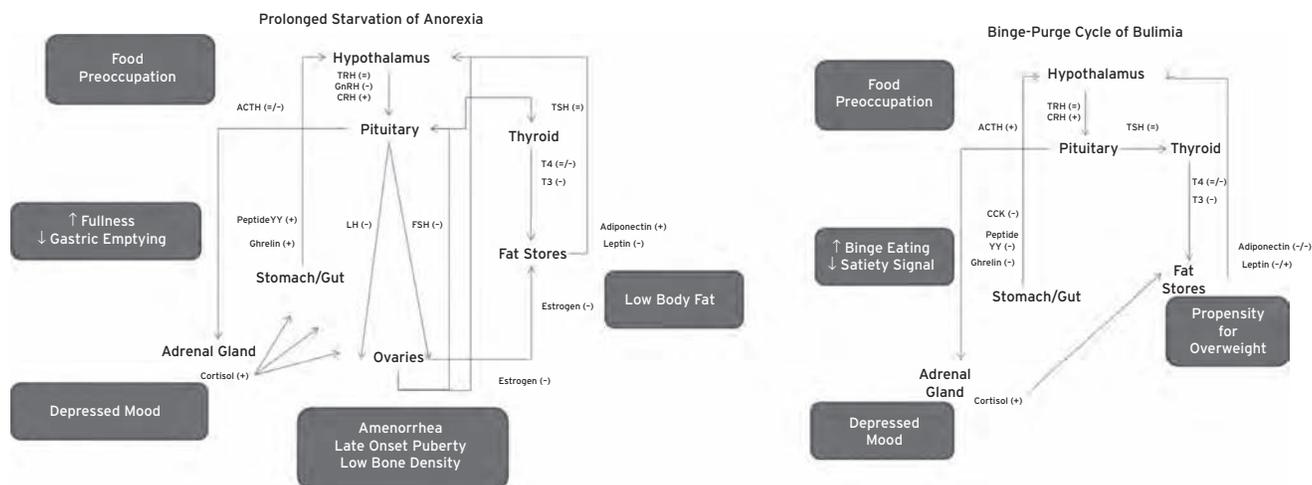

Figure 89.2 The disturbances in gastric, adrenal, and gonadal hormones/peptides are summarized for anorexia nervosa (left) and bulimia nervosa (right) in their relative disease states. TRH = thyrotropin releasing hormone. GnRH = gonadotropin releasing hormone. CRH = corticotropin releasing hormone. TSH = thyroid stimulating hormone. LH = luteinizing hormone. FSH = follicle stimulating hormone. ACTH = Adrenocorticotropic hormone. CCK = Cholecystokinin.

OVARIAN HORMONES

Hyperactivity of the HPA axis that accompanies the malnutrition associated with AN can attenuate the action of the HPG axis, possibly leading to amenorrhea and a reversion in sexual development, including decreased levels of serum estradiol (Stoving et al., 1999). Hyperactivity of the HPA axis leads to increased secretion of cortisol from the adrenal glands, stimulating the release of dopamine from mesolimbic neurons in the brain, thus enhancing the reward system that may reinforce AN (Keating, 2011). Additional studies reinforce this hypothesis and link estrogen levels to the reward–punishment system, correlating lower concentrations of estrogen (hypogonadism secondary to hyperactive HPA axis) with higher levels of dopamine and decreased serotonin secretion, the consequences of which may affect food intake (Keating, 2011). In a state of hypogonadism, it follows that lower rates of estrogen release resulting from HPA axis suppression of the HPG axis would result in increased levels of dopamine and increased sensitivity to the reward system in which eating disordered behaviors are positively reinforced (Barbato et al., 2006).

The ability of estradiol to centrally regulate food intake is dependent upon its interactions with estrogen receptors in the central nervous system, particularly in the hypothalamus and hindbrain (Butera, 2010). The estrogen receptor has two types, alpha and beta, and it remains unclear which of these is primarily responsible for the estrogenic effects on appetite and food intake. Estrogen may centrally modulate the processing of gastrointestinal and hypothalamic neuropeptides, leading to alterations in feeding behavior. There is mounting evidence that serotonergic neurons in the central nervous system are sensitive to and dependent upon exogenous and endogenous estradiol levels (as well as LH, FSH, and GnRH) and are critical to the modulation of affect and mood (Pae et al., 2009).

Recently, the effects of rapid estrogen signaling on AN have come under investigation. Estrogen receptors in the nuclear membrane regulate the transcription of genes in the nucleus and have been extensively studied. New studies show that estrogen receptors in plasma membranes (mERs) may mediate more immediate effects through calcium channels and estrogen-induced protein kinase signaling (Raz et al., 2008). For example, some mERs may increase the excitability of POMC and dopamine neurons (Roepke et al., 2009), whereas others may down-regulate 5-HT_{1a} function (Mize et al., 2001), both having effects on energy homeostasis and food intake. These membranous estrogen receptors may mediate more rapid signaling of estrogen in the brain, and their dysregulation may play a role in AN.

In BN, there is strong evidence for correlation between the frequency of self-induced vomiting and irregular menses (Austin et al., 2008). Frequent vomiting may have a direct effect on hormonal systems. Furthermore, binge eating episodes occur with higher frequency during times in the menstrual cycle when estrogen is the lowest (premenstrual and midluteal phases) (Klump et al., 2008), consistent with aforementioned studies citing the ability of estrogens to centrally inhibit food intake through satiety signals produced by cholecystokinin (CCK) and other regulatory peptides.

APPETITE AND WEIGHT-REGULATING PEPTIDES AND HORMONES

There is evidence that central and peripheral regulatory peptides and hormones function in an altered, dysregulated state in patients with AN and BN. These substances influence feeding motivation for the purposes of weight balance, and the implications of their dysregulation have not yet been fully explored. Substances of interest and ongoing clinical investigation include ghrelin, obestatin, peptide YY, neuropeptide Y, adiponectin, endocannabinoids, IGF-1, cholecystokinin, and insulin.

Cholecystokinin

Cholecystokinin (CCK), an anorexigenic peptide hormone produced in the enteroendocrine cells of the small intestine, functions to inhibit feeding once it has been initiated by enhancing satiation signaling, among other gastrointestinal functions (Chandra and Liddle, 2007). Cholecystokinin-1 receptors relay satiety signals via the vagus nerve to the hind-brain (Chandra and Liddle, 2007). In women with BN, there is evidence that CCK dysregulation may be indicative of gastric dysfunction induced by binge eating episodes. Once CCK has been released in response to a meal, it is released more slowly and in lower concentrations in women with bulimia nervosa as compared with controls (Geraciotti and Liddle, 1988). This dysregulation may contribute to the binge–purge cycle, as binge episodes are exacerbated by this dysregulation.

Ghrelin

Ghrelin, a peptide hormone secreted from enteroendocrine cells of the stomach, is unique in its ability to initiate food intake. It reaches sufficiently high circulating levels before a meal and falls drastically a short time afterward. Circulating ghrelin levels are higher in those in acute and chronic starving states secondary to AN as compared with controls and reflect the enteroendocrine system attempting to counteract the state of malnutrition induced by eating-disordered behavior (Monteleone, 2011). Ghrelin is also implicated as a ligand in the secretion of growth hormone (GH) and IGF-1 in maintenance of lean body mass, but has different effects under the catabolic conditions created by malnutrition, implicating further dysregulation in the ghrelin system (Hasan and Hasan, 2011).

Obestatin

Obestatin, another peptide hormone produced from enteroendocrine cells of the gastrointestinal tract, is derived from the same precursor prohormone from which ghrelin is synthesized. Several studies show that obestatin has a complimentary but opposite effect to ghrelin, serving to induce satiety (Monteleone, 2011). Although the functionality of obestatin remains controversial, studies have shown that the ghrelin to obestatin ratio is increased in patients with AN as compared with control subjects, implying further adaptation under conditions of malnutrition to increase the peripheral hunger signal. Altered gene expression of the prohormone from which ghrelin and obestatin originate may also contribute to the apparent dysregulation of ghrelin and obestatin in patients with AN (Monteleone et al., 2008; Zhang et al., 2005).

Neuropeptide Y

Neuropeptide Y (NPY) is a neurotransmitter released in the hypothalamus that serves a role in stimulating appetite and enhances the release of corticotropin-releasing hormone (CRH) (Kaye et al., 1990). Neuropeptide Y in the cerebrospinal fluid of patients with BN is equivalent with that of controls, whereas patients with AN show higher levels of CSF NPY as compared with controls (Kaye et al., 1990). In long-term recovered women with AN and BN, NPY and PYY concentrations return to normal. This suggests that alterations in these systems are secondary to the illness and not traits that may predispose one to the development of an eating disorder (Gendall et al., 1999). Although not a predisposing trait, further study of their influence on metabolic and reproductive systems in the environment of an eating disorder is warranted.

Peptide YY

Peptide YY (PYY) is a peptide hormone secreted by the colon primarily to induce a sensation of satiety following the intake of food. It binds to the receptor of neuropeptide Y, an orexigenic peptide, blocking its ability to signal and functioning as an anorexigenic hormone. Additionally, PYY is able to reduce plasma levels of ghrelin, also contributing to its anorexigenic properties. In several studies of circulating levels of PYY in patients with AN, increased levels of PYY were detected (Misra et al., 2006; Utz et al., 2008). Although earlier studies yielded more inconclusive results, alternate functions of PYY merit investigation (Tong and D'Alessio, 2011). In bulimic patients who had abstained from bingeing and purging, CSF PYY was significantly increased as compared with controls and patients with AN, perhaps demonstrating dysregulation in this system as contributory to the drive to binge eat in BN (Kaye et al., 1990). Recent functional magnetic resonance imaging (fMRI) studies have shown correlation between elevated PYY concentrations and changes in neural activity in the caudolateral orbitofrontal cortex, allowing researchers to predict feeding behaviors independently of food intake (Batterham et al., 2007). Given that corticolimbic and higher-cortical areas of the brain are influenced by PYY concentration, further research is warranted into the effects of this hormone.

Leptin

Largely synthesized in adipose tissue, leptin is an adipocytokine expressed in various tissues throughout the body. Plasma concentration of leptin is indicative of the adiposity of an individual, especially in females. Levels are low during conditions of starvation, like in AN, and higher in conditions of obesity (Mantzoros et al., 1997). Leptin plays a role in regulating several neuroendocrine functions and promoting energy homeostasis in conditions of starvation, thus it has regulatory properties over the HPA axis. In conditions of starvation, it follows that reproductive and thyroid hormone secretion would be suppressed, to prevent procreation and metabolism, respectively. New approaches to pharmacological therapy in AN under investigation include infusions of leptin as a means of reversing amenorrhea (Chan and Mantzoros, 2005).

Because of the variability in fat percentage and BMI in patients with bulimia nervosa, serum concentrations of leptin

have not yielded definitive evidence for dysregulation in these women. In a study of untreated bulimic women, plasma leptin levels were significantly decreased as compared to control subjects which may imply impaired sensitivity to changes in caloric intake or dysregulation in the synthesis of leptin (Monteleone et al., 2000). This dysregulation could play an important role in the pathogenesis of BN.

Adiponectin

Adiponectin is a serum protein synthesized and secreted exclusively by adipocytes. As central and peripheral adiposity increase, adiponectin levels uniformly decrease. Studies have found that acute states of starvation do not significantly affect circulating levels of adiponectin, and adiponectin levels under conditions of chronic starvation remain controversial. Additionally, some studies have demonstrated that adiponectin plays a role in regulating insulin sensitivity, correlating increased adiposity with lower levels of adiponectin and less sensitivity to insulin, but no such studies have been replicated in conditions of starvation (Tagami et al., 2004). There has been some evidence in mouse models of the sexually dimorphic nature of both adiponectin and leptin, making these molecules interesting targets of research into the widely varying rates of prevalence among males and females (Gui et al., 2004).

The Endocannabinoid System

The endocannabinoid system is a lipid signaling system critical to many processes, both physiological and neurological. One emerging role of the endocannabinoid system is in energy balance and lipid metabolism, both within the central nervous system and in peripheral tissues. Two receptors (CB1 and CB2) and two primary endogenous ligands (anandamide and 2-arachidonylglycerol, or 2-AG) comprise the main effectors of the system (Bermudez-Silva et al., 2010). Plasma anandamide concentrations have been found to be significantly elevated in patients with restricting AN as compared with controls, whereas 2-AG has not shown significant fluctuations between patients and controls. The significance of these findings remains under debate. Although higher levels of circulating anandamide should correlate with increased desire for food intake, new hypotheses suggest that the abundance of anandamide may be enhancing the reward system by which pleasure is derived from restrictive behaviors, given the high density of CB1 receptors in areas of the brain associated with the reward system (Kirkham et al., 2002).

Melanocortin

The melanocortin system presents another set of regulators with significant implications in a reward pathway that may serve to reinforce restrictive behaviors in patients with AN in addition to modulating food intake. Agouti related peptide (AGRP) is an orexinergic inverse agonist of melanocortinergic receptors that should encourage food intake. Repeated studies have demonstrated significantly more loss-of-function mutations and polymorphisms within the gene coding for this peptide in patients with AN as compared with controls, although the significance of this finding warrants further study (Scherag et al., 2010).

HYPOTHALAMIC–PITUITARY–ADRENAL AXIS

Hyperactivation of the HPA axis in response to stress caused by acute and chronic starvation leads to elevated secretion of cortisol. Corticotropin-releasing hormone (CRH) is synthesized in the hypothalamus and transmitted to the pituitary via the portal system, stimulating the synthesis and secretion of substances like adrenocorticotrophic hormone (ACTH) and beta-endorphin. Adrenocorticotrophic hormone is transmitted to the adrenal glands, stimulating secretion of cortisol. Hyperactivation of this pathway in patients with AN leads to a state of hypercortisolism through an increased half-life of cortisol and increased pulsatile secretions of cortisol, which enhances gluconeogenesis in the body, helping the body to reestablish glucose stores under conditions of malnutrition (Lo Sauro et al., 2008). Additionally, cortisol stimulates protein breakdown, increases in plasma glucose and insulin, and regulates body adiposity (Licinio et al., 1996). Urine and serum cortisol concentrations have been shown to be positive predictors of truncal adiposity in weight restoration and of the severity of depressive symptoms in patients with AN (Miller, 2011). Hypersecretion of CRH and/or increased sensitivity to CRH at the pituitary may account for increased secretion of cortisol, considering that feedback mechanisms of the HPA axis appear to remain intact (Lo Sauro et al., 2008).

Thyrotropin-Releasing Hormone

Thyrotropin-releasing hormone (TRH) is a hormone synthesized in the hypothalamus and is responsible for the stimulation of secretion of thyroid-stimulating hormone (TSH) from the anterior pituitary. Ultimately, it is responsible for regulation of the thyroid gland. Research has shown that transient hypothyroidism occurs in chronic states of malnutrition, as measured by reduced serum concentrations of T3 and, to a lesser extent, T4 (Swenne et al., 2009). Because hypothyroidism has been linked to feelings of dysphoria, this could account for the symptomatology of dysphoria reported by a subset of patients with AN (Korzekwa et al., 1996).

Endorphins

Beta-endorphin (derived from POMC) and dynorphin are opioid peptides that have recently come under investigation for their role in the regulation of reward-related behaviors and regulation of food intake (Monteleone, 2011). Beta-endorphin levels were detected as reduced in the cerebrospinal fluid of patients with AN and no significant change has been found in the levels of dynorphin (Kaye, 1996). Dysregulation in the opioid system may also contribute to conditions of hypercortisolism in AN (Kaye, 1996). Recent studies show that beta-endorphins have rewarding and reinforcing properties that may be mediated through the mesolimbic dopaminergic system. Additionally, beta-endorphins may play a role in learning and memory (Roth-Deri et al., 2008). These findings further suggest dysregulation in certain opioid peptides may influence the reward system in patients with AN.

Hypothalamic-pituitary-adrenal axis dysregulation in the context of BN has centered around an altered stress response to impulsivity manifesting as self-injury, binge eating, suicidality, depressive symptoms, and so on. Although hyperactivity of

the HPA axis is highly prevalent in women with AN, dysregulation of this axis among patients with bulimia nervosa has shown more heterogeneous outcomes. Numerous studies have shown normal, increased, and decreased secretion of cortisol in women with BN, which may imply a dysregulation in the circadian release of cortisol depending on the disease state or the physiological state of the individual. Infusion with exogenous CRH in relapsed and recovered women with BN show stronger ACTH secretory response as compared with control subjects, indicating a hypersensitive HPA response to stress, even after recovery (Birketvedt et al., 2006).

NEUROTRANSMITTER DYSREGULATION

The monoamine neurotransmitters have been extensively studied as part of the attempt to explain a number of traits in AN and BN, including increased anxiety, harm avoidance, perfectionism, impulsivity, mood regulation, and more. Understanding the pathophysiology of these neurotransmitters may help researchers to develop targeted pharmacotherapies in the treatment of eating disorders. Both the dopaminergic and serotonergic systems demonstrate dysregulation in patients with AN, yet there has been no formal integration of the two pathophysiologies to date, only speculation as to their interaction. In BN, serotonergic dysregulation is thought to be the primary factor in the pathology of the illness.

Evidence suggests a severe decrease in serotonergic tone in women with AN. Figure 89.3 demonstrates the cycle by which dysregulation of this system may contribute to the development and maintenance of AN. Those predisposed to developing the disorder might have an imbalance in the ratio between 5-HT_{1A} (inhibitory) and 5-HT_{2A} (excitatory) receptors (Kaye et al., 2005). This imbalance, in conjunction with a predisposition for increased extracellular serotonin (5-HT), may contribute to several traits widely seen in patients with AN, such as harm avoidance, anxiousness, impulse control, and dysregulated feelings of satiety. Positron emission tomography imaging studies suggest that postsynaptic 5-HT_{1A} receptors within mesial temporal and subgenual cingulate regions of the brain are significantly correlated with harm avoidance (Bailer et al., 2005). Extracellular serotonin (and serotonin metabolites in the CSF) are reduced in the starving state because of decreased intake of tryptophan in the diet, an essential amino acid that is a precursor in the synthesis of serotonin, thus reducing anxiety and feelings of dysphoria. This may help to explain why starvation may be reinforced in patients with dysregulated serotonergic systems. In the weight restoration phase of recovery from AN, patients experience surges in serotonin production and excess stimulation of 5-HT_{1A} and 5-HT_{2A} postsynaptic receptors, again increasing dysphoric mood and adding to the challenge of food intake. Although it is logical to assume that selective serotonin reuptake inhibitors (SSRIs) may alleviate symptoms associated with a dysregulated serotonergic system, significant efficacy has not been demonstrated, possibly because of the depleted state of synaptic serotonin caused by severe malnutrition (Kaye et al., 2009). It is important to note that most studies of the serotonergic system and AN are conducted with

weight-restored women to avoid the confounding effects of malnutrition on the physiology of the body.

Dysregulation and dysfunction have also been noted in the dopaminergic system of patients with AN. Dopamine is involved in reward pathways, decision-making capabilities, motor movement, and food intake, and thus may have profound effects on the maintenance and development of a disorder like AN. Reduced metabolites in the cerebrospinal fluid of patients both recovered and acutely ill reflect a decrease in dopamine in the extracellular fluid. Additionally, common genetic polymorphisms in dopamine receptors (D2 and D3) are a recurrent finding in patients and PET scans show increased dopamine receptor density in the ventral striatum, a region of the brain heavily involved in reward signaling. These findings correlate with traits of harm avoidance and failure to appropriately respond to salient stimuli (Montague et al., 2004). Recent fMRI studies confirm this theory, showing that patients had difficulty in affective response to salient stimuli but have hyperactive neurocircuits concerned with planning, consequences, and rules (Zastrow et al., 2009).

Modulatory defects in 5-HT function may explain the extremes of mood and binge eating cycles in patients with BN. Although restriction in food intake may lead to reduced synaptic serotonin release and a reduced dysphoric state,

less serotonin may lead to unstable mood and a predisposition toward uncontrolled binge episodes (Kaye et al., 1998). Furthermore, serotonergic tone may be dysregulated in patients with BN as evidenced by the genetic polymorphisms associated with serotonergic genes as compared with control subjects. Accumulating PET and fMRI data suggest an imbalance in the expression of specific serotonin receptors and transporters in women with BN that results in functional deficits in impulse control, particularly in response to disease specific stimuli such as food or body evaluation.

The serotonin transporter (5-HTT) is responsible for the reuptake and subsequent conservation of 5-HT from the synaptic cleft (Zhao et al., 2006). Polymorphisms within the allele coding for 5-HTT have been associated with phenotypes associated with patients with bulimia nervosa, like harm avoidance, increased anxiety, and impulsivity. In mice with a mutation in the C-terminus of the 5-HTT resulting in its absence, significantly decreased levels of serotonin were found in the brain. These mice demonstrated anxiety and depression-related behaviors, which confirms that dysfunction in the serotonin transporter correlates with emotional abnormalities (Zhao et al., 2006) that may play a role in the pathogenesis of BN. *In vivo* studies have found decreased hypothalamic and thalamic serotonin transporter availability in patients with BN,

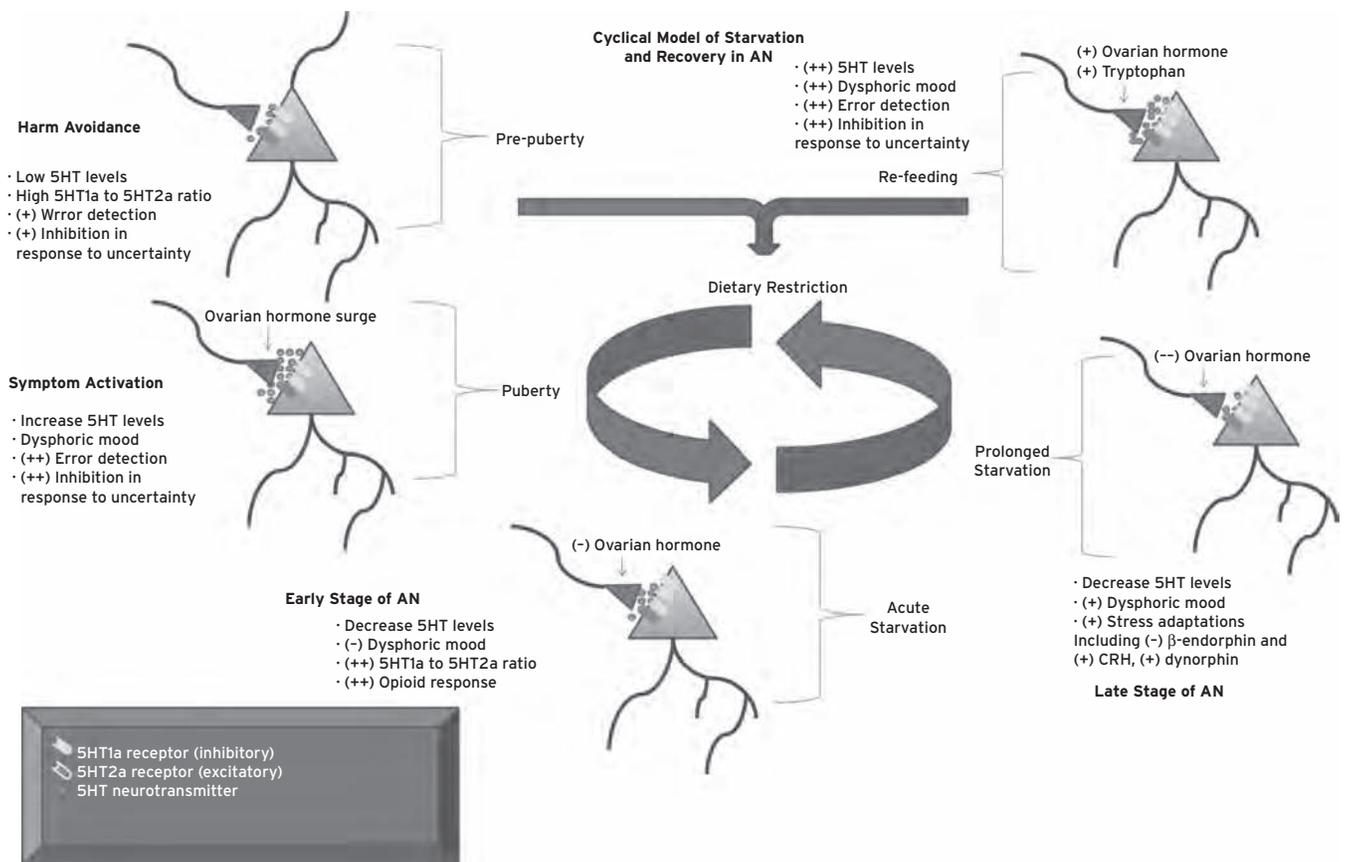

Figure 89.3 The theoretical changes to relevant serotonergic changes that accompany the cycle of starvation and recovery among individuals with anorexia nervosa are thought to be influenced by the increase in ovarian hormones which alter sensitivity to serotonergic signaling. Starvation provides temporary relief which is exacerbated early in recovery by weight gain. The alterations in serotonergic function contribute to cognitive changes in sensitivity to error detection and inhibitory control, particularly in the context of uncertainty.

providing the tangible link between mouse models and the pathology of decreased 5-HTT in patients with bulimia nervosa (Tauscher et al., 2001).

The 5-HT_{2A} receptor is an excitatory postsynaptic serotonin receptor that increases neuronal firing in a number of brain regions involved in the regulation of emotional states within corticolimbic circuits. Studies report conflicting results as to the significance of this receptor in women with bulimia nervosa, but recent PET studies suggest that a decreased receptor density in the acutely ill may result in impaired communication in neurocircuits regulating emotion and impulsivity, which may be a result of a polymorphism in the receptor's gene (Nomura et al., 2006).

The 5-HT_{1A} receptor is an inhibitory postsynaptic serotonin receptor implicated in the termination of signaling between two serotonergic neurons. High densities of this receptor are found in limbic brain areas, like the hippocampus, lateral septum, cortical areas, and the mesencephalic raphe nuclei. Receptors are located both on post- and presynaptic neurons (Barnes and Sharp, 1999). Reduced 5-HT_{1A} binding is implicated in many anxiety disorders, with dysregulation manifesting in enhanced harm avoidance. Both over- and under-expression of the receptor has been shown in relation to a variety of mental illnesses related to anxiety (Akimova et al., 2009). In women with BN, 5-HT_{1A} receptor binding is increased in areas of high receptor density, reflecting dysregulation associated with impulse control as it may relate to impulsive binge eating (Tiihonen et al., 2004). Colocalization and dysregulated ratios of 5-HT_{1A} and 5-HT_{2A} receptors in the medial prefrontal cortex may further illuminate the complexities of behavioral disinhibition in BN (Carli et al., 2006).

The dopaminergic system, like in AN, has also been implicated in the pathogenesis of BN. Positron emission tomography studies have demonstrated that dopamine in the dorsal striatum is involved in food motivation, as well as regulating reward pathways involving food in the nucleus accumbens (Volkow et al., 2002). Recent PET imaging studies have found decreased D₂ receptor density in women with BN, indicative of inhibited dopamine response. This blunted response may reflect an adaptation in the motivation–reward system that seeks more potent reinforcers, impairing the ability of women with BN to use alternate reinforcers of behaviors like binge eating and/or purging (Broft et al., 2012). These findings are consistent with findings in individuals with substance abuse illnesses, although the link between the disorders remains complicated by a plethora of hormonal, cerebral, and sociocultural factors.

NEUROCIRCUITRY IMPLICATED IN ANOREXIA NERVOSA

A number of corticolimbic thalamic circuits are dysregulated in AN and they are likely to play a significant role in primary and secondary features of the illness. These complex circuits are involved in the regulation and integration of appetite, energy, emotional processing, and the motivation–reward pathway. Functional neuroimaging has helped to illuminate potential sources of dysregulation among these systems, but the data collected from these imaging studies are increasingly complicated

by a number of factors. First, the wide array of morphological changes to the brain during the acute illness phase of AN make functional imaging of the brain difficult to interpret. Enlarged ventricles, cerebral atrophy, decreased total gray matter volume, and decreased cerebrospinal fluid are observed morphological changes that recover with weight restoration, but at varying rates. The anterior cingulate cortex (ACC) and insular cortex regions of the brain, for example, may be slower to recover as compared with other regions, complicating data comparisons (Muhlau et al., 2007). Second, investigations into neurocircuits tend to compare activity to some baseline, or control, measurement, while failing to study the relationships between neurocircuits in a starved state. Therefore, there is a failure to formally integrate cause and effect relationships that may exist and give insight into the functionality of certain neurocircuits.

With the many brain regions and neurocircuits being investigated in the pathogenesis of AN, the anterior insula stands out as an integrative center incorporating them all. It has been hypothesized that this region is the key to the dysregulation of these neurocircuits (Nunn et al., 2008). The insula has been described as a bridge, facilitating connections between the frontal, temporal and parietal lobes, and the limbic system. This strategic location implicates that the insula is involved in regulation of the autonomic nervous system, the regulation of appetite and eating, taste and visceral memory, monitoring of the body state, integration of thoughts and feelings, the regulation of the experience of pain, the experience of disgust, interoceptive processing and anxiety, and empathy (Nunn et al., 2011). Disease-specific effects of puberty, dieting, genetics, societal pressures, and early developmental are hypothesized to carry some pathogenic effect on the insula (Nunn et al., 2011). Particularly intriguing to this insula hypothesis is the association between feelings of disgust and activation of the anterior insula (Phillips et al., 1997). Enhanced disgust responses to food in patients with AN as compared with control subjects suggest an important impairment in the insula that may play a role in the pathogenesis of the illness (Aharoni and Hertz, 2012).

NEUROCIRCUITRY IMPLICATED IN BULIMIA NERVOSA

Much of the neurocircuitry implicated in BN follows that of AN. Similar patterns of dysregulation are found in both illnesses, which are likely to reflect similarities in trait disturbances found in both disorders. Patients with BN have increased volume in the medial orbitofrontal cortex (mOFC) and enlarged nucleus accumbens (Schafer et al., 2010). Enlarged mOFC may represent altered reward processing because this region has much to do with the processing of rewards and punishments (Kringelbach and Rolls, 2004). The enlarged gray matter of the nucleus accumbens has been positively correlated with frequency of purging, although there is no clear causal link between this region and purging. It may be that chronic use of this area of the brain in the context of negative reinforcement strategies and compensatory behaviors like purging may lead to the increased volume (Schafer et al., 2010).

NEUROCIRCUITS INVOLVED IN APPETITE

Appetite is a complex drive that relies on many psychobiological processes. To understand such processes, a number of studies have focused on imaging to quantify the activity of brain regions involved in the regulation of appetite. Patients undergoing an fMRI scan are administered a sweet-taste perception task mediated by tongue receptors. Signals travel via a number of neural pathways to the primary gustatory cortex and the anterior insula, which is responsible for responding to various physical properties of the food. Food deprivation in controls activates the insula and associated regions, like the amygdala, anterior cingulate cortex (ACC), and the orbitofrontal cortex (OFC). A self-reported rating of the pleasantness of sweet foods also positively correlates with activity of the insula (Schoenfeld et al., 2004). Conversely, weight-restored women with AN show a significantly reduced activation level of the insula and associated regions. Additionally, self-reported rating of the pleasantness of sweet foods provided no correlation with activity of the insula, giving credibility to the argument that perception of taste may be altered in AN (Wagner et al., 2008).

The ability of the central nervous system to integrate physiological sensations and sensory information is a process known as interoceptive processing and primarily occurs in the anterior insula. Because of the strong body of evidence demonstrating the dysregulated neurocircuitry of the anterior insula as well as its crucial role in interoceptive awareness, some believe the pathology of AN is best studied in the context of the anterior insula. Dysregulation in this part of the brain may suggest that women suffering from this disorder have a fundamentally and physiologically altered sense of self (Kaye et al., 2009).

In BN, sweet-taste perception tasks show hypoactivation of the reward system, regulated by hyperactivation of the anterior insula. Patients with BN show reduced responsiveness to taste reward stimuli, as evidenced by hyperactivation of the insula and amygdala, which leads to reduced activation of the ventral putamen, which may correlate to reduced dopaminergic activity via down-regulation of D2 receptors (Frank et al., 2011). This dopaminergic taste reward system functions in much the same way as that seen in substance abuse. Speculation has been made as to an addiction state mediated by dysregulation of the dopaminergic system in women with BN in which episodically the drive for food stimulation leads to binge eating, and the consequent fears of excessive weight gain trigger excessive exercise or purging (Frank et al., 2011).

NEUROCIRCUITS INVOLVED IN EMOTIONAL PROCESSING

The ventral neurocircuit mentioned previously, including regions of the amygdala, insula, ventral striatum, ventral regions of the ACC, and the prefrontal cortex, is important in assigning emotional significance to stimuli as well as regulating affect and response to these stimuli (Kaye et al., 2009). Positron emission tomography imaging studies have demonstrated that this cognitive-limbic neurocircuit contains increased densities of 5-HT1A inhibitory neurons and decreased densities of 5-HT2A excitatory neurons in weight-restored women, thus locating a major source of dysregulation in the serotonergic system (Frank et al., 2002). Although suggestive of a mechanism

for the personality disturbances that may be associated with AN, it does not help to clarify whether the dysregulation is a consequence of starvation or rather a genetic predisposition.

An additional dorsal neurocircuit that includes the hippocampus, dorsal regions of the caudate, and the dorsolateral prefrontal cortex (DLPC) is the cognitive neurocircuit involved in more strategic processes like sequencing, planning, and the modulation of attention. This neurocircuit is also shown to be dysregulated in weight-restored women with AN. The emotional salience of food is further dysregulated as evidenced by fMRI research showing hyperactivity of the ACC and medial PFC (mPFC) in both acutely ill and weight-restored women (Fisher et al., 2009).

During tasks that require behavioral inhibition, women with BN display dysregulation in neurocircuitry implicated in emotional regulation like the ACC (Penas-Lledo et al., 2007). Self-regulatory processes are altered in these women as evidenced by their failure to activate frontostriatal circuitry (left inferolateral prefrontal cortex, lenticular nucleus, inferior frontal gyrus, ACC, putamen, and caudate regions) as compared with control subjects during conflict trials that required self-regulatory control for appropriate responses (Marsh et al., 2009). These activation deficits may correlate with decreased or dysfunctional serotonin metabolism and neurotransmission. Diminished activity within these areas may also explain the loss of control sensation of binge episodes reported by women with BN.

NEUROCIRCUITS INVOLVED IN BODY IMAGE PERCEPTION

The parietal cortex plays a vital role in proprioception and the development and maintenance of one's own body image. When presented with body image stimuli, acutely ill patients show decreased activity in the parietal cortex that is reversed with weight restoration. Positron emission tomography imaging studies suggest that these observations are consistent with the increased density of 5-HT2A receptors and the decreased density of 5-HT1A receptors in this region (Fisher et al., 2009). Additionally, patients with AN have a higher negative affective reaction when looking at images of another's body and reduced activation of relevant brain areas when looking at their own body as measured by fMRI, suggestive of body-related avoidance behaviors (Vocks et al., 2010). They also demonstrate emotionally bound body-size perception deficiencies (Cash and Deagle, 1997). Other studies suggest that dysregulation in body image perception lies in an impaired cognitive ability to mentally rotate objects and dysregulation when reconstructing or manipulating shapes (Skrzypek et al., 2001). Another psychopathology exhibiting this type of dysregulation is body dysmorphic disorder.

Many of the findings from fMRI studies of body image stimuli in patients with AN is applicable to bulimia nervosa as disturbances in neurocircuitry pertaining to body image are similar in both disorders. For BN, the anterior insula plays an especially crucial role in the construct of body image disturbance when estimating body size, which may serve to maintain the illness (Mohr et al., 2011). Women with BN may also demonstrate special perception deficiencies, as evidenced by

nonactivation of the middle frontal gyrus during body size estimation tasks as compared with control subjects, reflecting a less functional spatial manipulation capacity (Mohr et al., 2011). Body image disturbance in eating disorders is not yet fully understood.

STARVATION VERSUS PSYCHOPATHOLOGY

Many of the aforementioned morphological, hormonal, and neurotransmitter changes described in the pathology of AN are reversed upon weight restoration, insinuating that they are consequences of starvation rather than predisposing factors to illness. The observed reduction in brain matter in starving individuals is consistent with the hyperactive HPA axis that induces catabolic changes in conditions of stress, leading to other effects such as hypercortisolism and decreased secretion of brain derived neurotrophic factor (BDNF), which is crucial to neuronal outgrowth and differentiation, synaptic connectivity, and neuronal repair (Monteleone, 2011). There is emerging evidence that some changes induced by starvation are not reversed upon weight restoration, including ACC volume and anterior insula volume. There is also evidence of permanently reduced metabolism in the prefrontal, parietal, temporal, and cingulate cortices, manifesting as larger ventricles and wider gaps between sulci as compared with controls (Muhlau et al., 2007). Although most studies investigate pathologies in weight-restored women with AN to avoid the confounding factors associated with starvation, it remains an ethical and practical challenge to differentiate between those pathologies that predispose one to develop AN and those factors that are a result of starvation.

GENDER DIFFERENCES

Females are more commonly affected by AN than are males with a female-to-male ratio of greater than ten to one (Hoek and van Hoeken, 2003). Interestingly, no published data exist as to the neurobiology and psychopathology of the illness specifically in males; therefore, no credible explanation exists for the gender disparity in prevalence rates of AN. Only speculation as to the possible sources of gender differences can be made. Further study into sexually dimorphic regulation systems is warranted (e.g., of the endocannabinoid system) and may implicate that peripheral differences between men and women account the disparity in prevalence. Furthermore, different gonadal hormones and hypothalamic axis differences would be a valid beginning for exploration into the gender-specific neurobiology of AN.

TEMPERAMENT AND ANOREXIA NERVOSA HARM AVOIDANCE AND PERFECTIONISM

Harm avoidance and perfectionism remain two of the most prevalent traits among patients with AN and as such are considered predisposing factors in the development of the disorder, although they are also common among women with BN. Harm avoidance, a heritable trait, has been correlated with

specific brain regions and neurotransmitter dysregulation, like increased 5-HT_{1A} receptor density (Bailer et al., 2004). More recently, decreased intrasynaptic dopamine and increased dopamine receptor density have also been linked to characteristic harm avoidance (Bailer et al., 2004). Overall perfectionism, when quantified using different analyses, is highly correlated with AN. Several genes associated with predisposition to AN have also been associated with perfectionism and may help to explain the endophenotype (Bachner-Melman et al., 2005).

IMPULSE CONTROL

The inability to inhibit impulsive behaviors is a temperament associated with certain groups of women with AN, although the trait is less pervasive than that of perfectionism and harm avoidance. These patients may exhibit behaviors of self-harm, trauma, binge eating and purging, substance abuse, lack of self-control, and aggression. The neurobiological basis for dysregulation in impulse control may also lie within the serotonergic system. Genetic polymorphisms in the serotonin transporter (5-HTT) have been linked to issues of impulse control (Kaye et al., 1991).

ACTIVITY-BASED ANOREXIA

There are no credible animal models of self-induced starvation and consequently a limit to many of the translational models of eating disorders. One exception is the activity-based anorexia (ABA) model, which capitalizes on the phenomena of increased physical activity found among starved rodents. Inducing hyperactivity, decreasing caloric intake, and enhancing activity of the HPA axis in adolescent rats creates an environment of ABA in which anxiety behaviors can be measured over subsequent weeks into rat adulthood. To date, it has been shown that exposure to ABA in adolescent rats produces symptoms of heightened anxiety into adulthood, paralleling the increased anxiety found in those with adolescent onset AN. Although causality has not been established, human studies have also correlated anxiety symptoms with high levels of exercise (Klein et al., 2004). These studies may have implications for patient care and treatment in the future (Kinzig and Hargrave, 2010).

BINGE EATING DISORDER

Binge eating disorder (BED) is characterized by periods of binge eating in which an abnormally large amount of food is consumed and accompanied by a feeling of being out of control. The disorder is similar to BN except that patients do not engage in compensatory behaviors following a binge episode. Lifetime prevalence rates of BED are 3.5% among women, and 2% among men (Hudson et al., 2007). This disorder remains a public health concern because of its associated comorbidities, including obesity and depression (Mathes et al., 2009). There is, however, opposition to characterizing binge eating as a disorder, questioning the validity of the distinction between BED and other behaviors of overeating. Research shows that

BED individuals and obese control subjects both exhibit high sensitivity to rewards and display enhanced anxiety, impulsivity, and addictive personality traits as compared with control subjects, which complicates the categorization of BED as a psychiatric illness. There is evidence that BED patients differ from obese controls in that binge episodes are significantly more hedonic, which may imply neurobiological dysregulation that merits further investigation (Davis et al., 2008).

FOOD ADDICTION

With the current advances in our knowledge of neurobiological mechanisms and neuroimaging, the link between binge eating and food addiction is being explored and debated. More than half of patients with BED meet self-reported diagnostic criteria for food addiction (Gearhardt et al., 2012). These patients may respond to clinical intervention based on the neurobiological dysregulation associated with their disorder. The heterogeneous nature of overeating and obesity has others questioning the validity of the studies that find significant correlation between food addiction and binge eating, focusing on neuroimaging studies like PET ligand studies and fMRI studies that present inconclusive and conflicting results in the context of a unified neurobiological profile of patients with BED demonstrating food addiction (Ziauddeen et al., 2012). Careful and sound investigation into the mechanism of binge eating and food addiction is warranted to avoid hasty categorization and subsequent clinical practices that could be costly and ineffective.

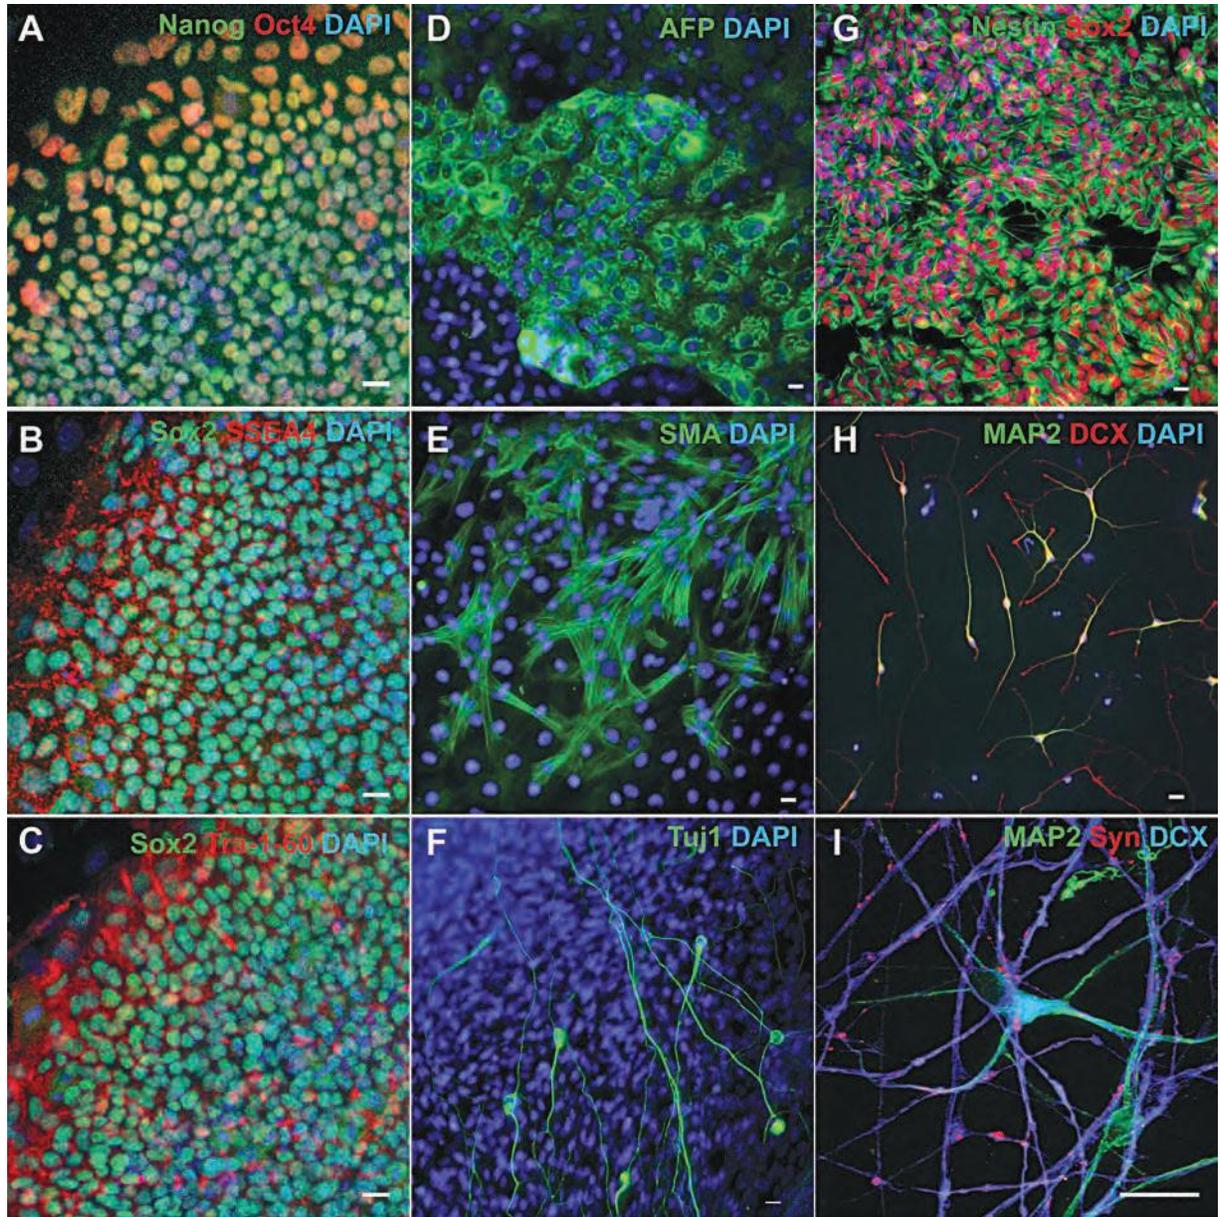

Figure 9.1 Generation of neurons from human iPSCs. (A–C) Confocal images of iPSC colonies expressing pluripotency markers: (A) Nanog (green), Oct4 (red), DAPI (blue); (B) Sox2 (green), SSEA4 (red), DAPI (blue); (C) Sox2 (green), Tra-1-60 (red), DAPI (blue). (D–F) In vitro differentiation into three embryonic germ layers revealed by immunostaining for markers of α -fetoprotein (endoderm) (D), α smooth muscle actin (mesoderm) (E), and Tuj1 (ectoderm) (F). (G–I) Neuronal differentiation: (G) Neural progenitors cells 7 d after neural induction stained for Nestin (green), Sox2 (red), and DAPI (blue); (H) immature neurons 7 d after differentiation, stained for MAP2 (green), DCX (red), and DAPI (blue); (I) 4 week-old neurons stained for MAP2 (green), DCX (blue), and synapsin (red). Scale bar = 20 μ m.

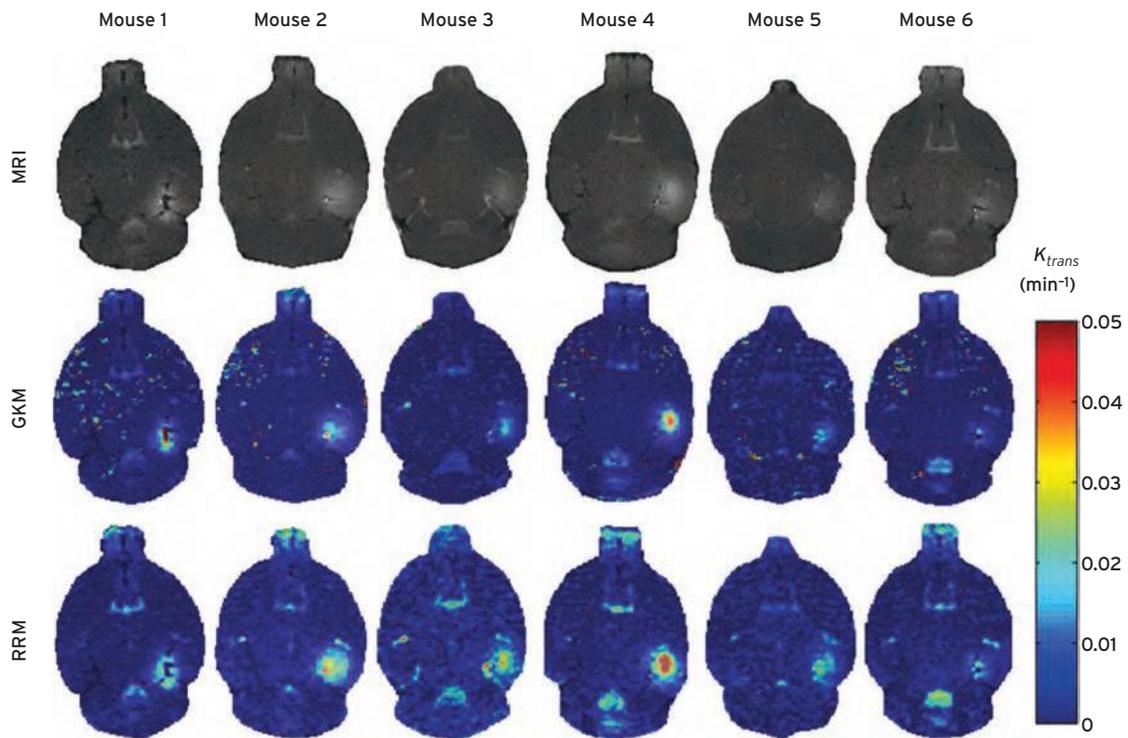

Figure 11.5 T1 images (first row) and their corresponding permeability maps generated from GKM (second row) and RRM (third row) for all mice. The transverse slice with maximum T1 signal enhancement is selected. The K_{trans} values are indicated in the color bar. The maps have been superimposed over the corresponding DCE-MR images. In the case of Mouse 1, the last acquired DCE-MR image is presented instead of a regular T1[61].

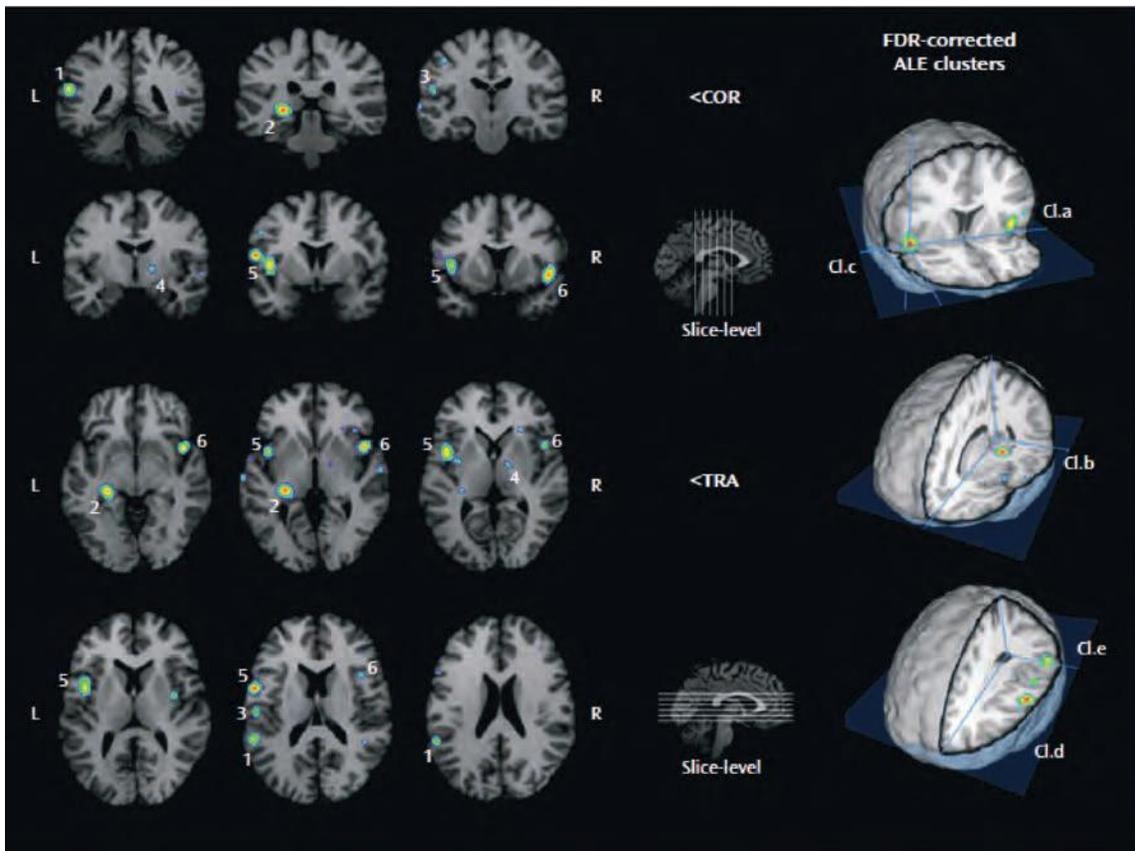

Figure 20.2 Functional brain activity associated with auditory verbal hallucinations in schizophrenia. The first three columns depict the activation likelihood estimation (ALE) results on coronal (COR) views (upper panel) as well as on transverse (TRA) views (lower panel) of the brain anatomy. The fourth column depicts slice levels shown on sagittal views. The fifth column shows clusters (Cl.a to Cl.e) of consistent activity among patients with schizophrenia spectrum disorders experiencing auditory verbal hallucinations. Reproduced from: Jardri, R., A. Pouchet, et al. (2011). "Cortical activations during auditory verbal hallucinations in schizophrenia: a coordinate-based meta-analysis." *The American Journal of Psychiatry* 168(1): 73–81; used with permission.

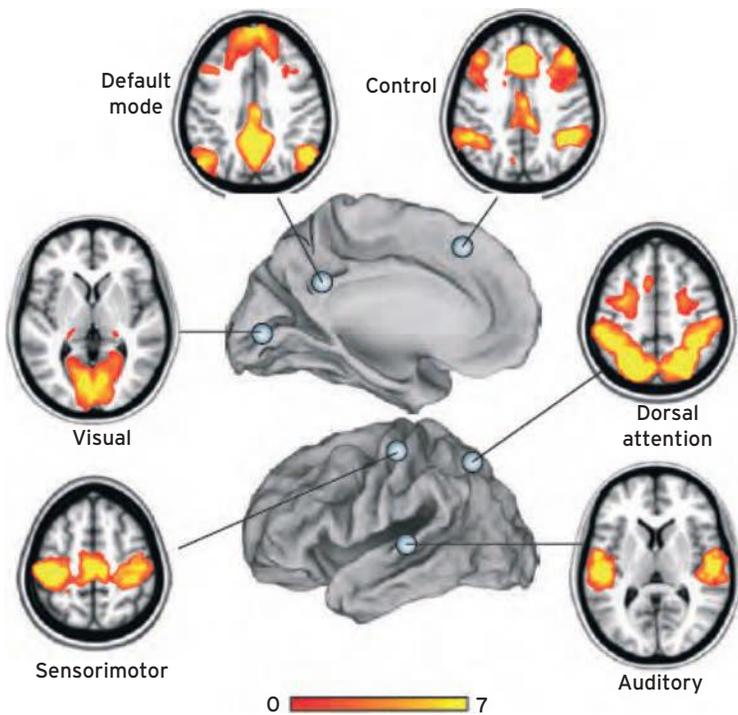

Figure 20.3 Intrinsic neuronal activity of the brain. Correlation of neuronal activity between a seed region (each circle) and the rest of the brain reveals six major networks: visual, sensorimotor, auditory, default mode, dorsal attention, and executive control. The scale numbered 0–7 indicates relative correlation strength. Reproduced from: Zhang, D. and M. E. Raichle (2010). "Disease and the brain's dark energy." *Nat.Rev.Neurol.* 6(1): 15–28 with permission from Nature Publications Group.

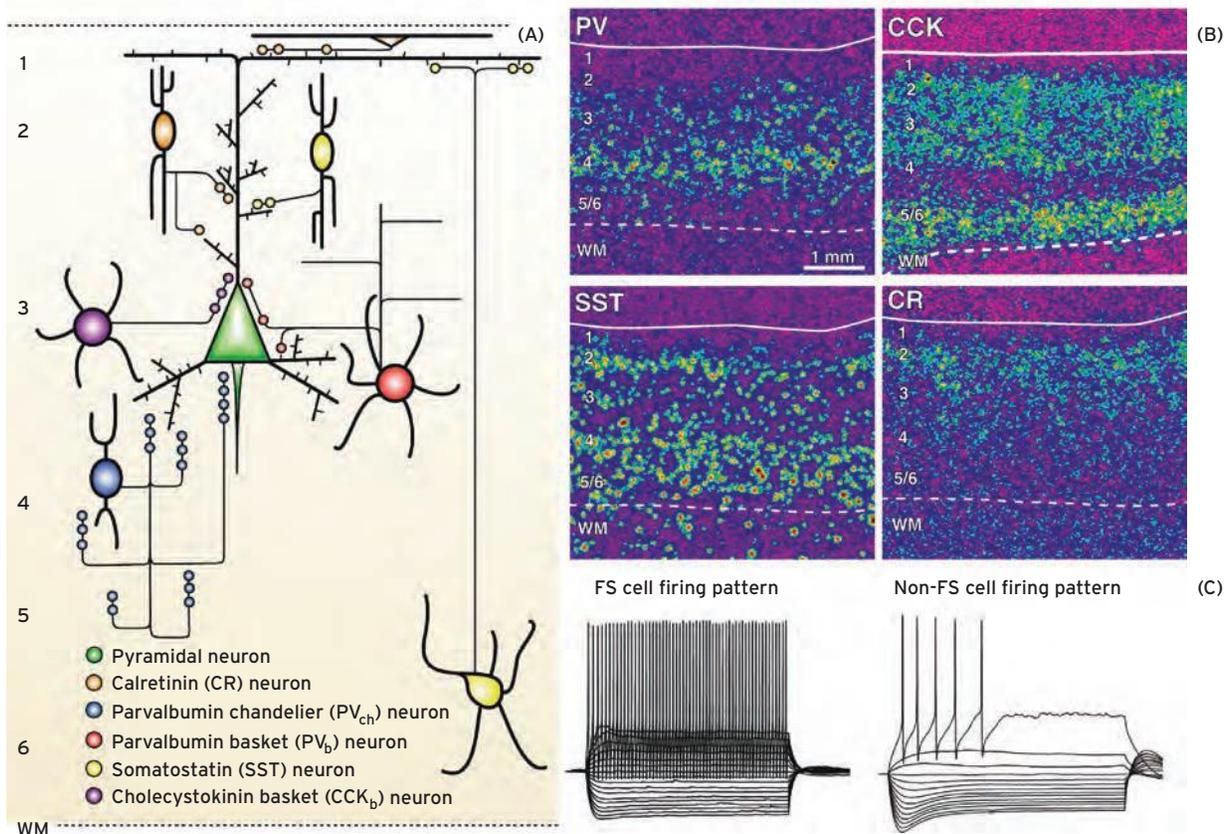

Figure 23.1 Diversity of cortical GABA neurons. GABAergic interneurons can be classified based on morphological (A), molecular (B), and electrophysiological (C) properties. Some interneurons express the calcium binding proteins parvalbumin (PV) or calretinin (CR), whereas others contain the neuropeptides somatostatin (SST) or cholecystikinin (CCK). (A) PV and CCK neurons target the perisomatic region of pyramidal cells, while SST and CR neurons target pyramidal neuron dendrites. PV neurons can be divided into chandelier (PV_{ch}) and basket (PV_b) cells based on their morphology. The axon terminals of PV_{ch} cells exclusively target the pyramidal cell axon initial segment, while the terminals of PV_b cells synapse onto the soma and proximal dendrites. (B) The different interneuron subtypes are distributed distinctively across the layers of the cortex, as evidenced by the different expression patterns of their mRNAs. (C) PV cells exhibit a fast spiking (FS) firing pattern, characterized by a high firing frequency and constant interval between action potentials, while the remaining subclasses are classified as non-FS cells that fire at a lower frequency and exhibit progressively increasing intervals between action potentials. (Image adapted from Gonzalez-Burgos et al. *Am J Psychiatry* (2007) 164 (1):12; and Hashimoto et al. *Mol Psychiatry* (2008) 13:147–161.)

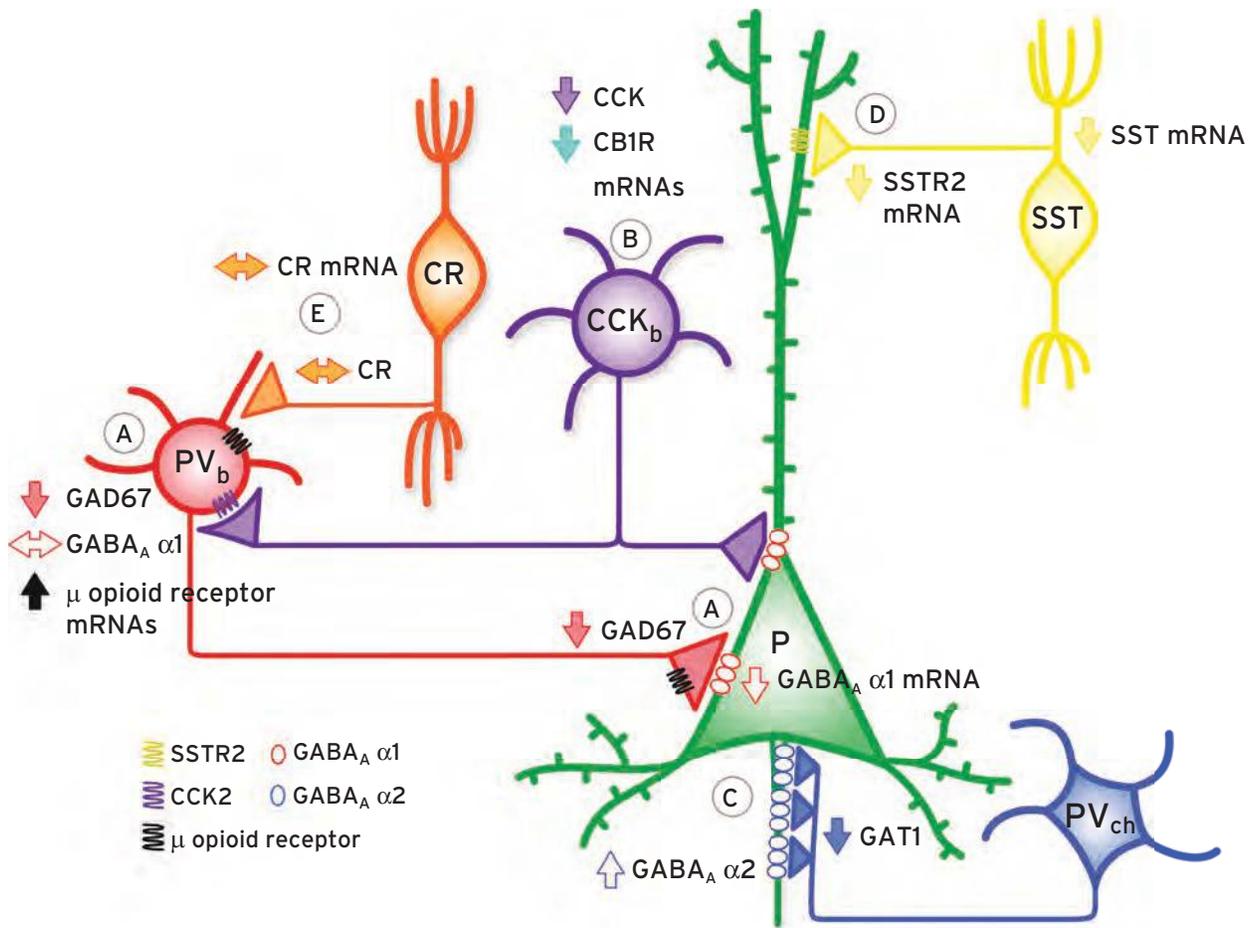

Figure 23.3 Schematic summary of alterations in neuronal circuitry in the PFC of subjects with schizophrenia. (A) The perisomatic inhibition of pyramidal (P) neurons by parvalbumin basket (PV_b) cells is lower due to (1) lower GAD67 mRNA and protein, and therefore less GABA synthesis; (2) higher levels of μ opioid receptor expression in PV_b cells that reduces their activity and suppresses GABA release; (3) reduced expression of cholecystokinin (CCK) mRNA, which stimulates the activity of, and GABA release from, PV_b cells; and (4) less mRNA for, and presumably fewer, postsynaptic GABA_A α 1 receptors in pyramidal neurons. (B) The perisomatic inhibition of pyramidal neurons by cholecystokinin-expressing basket (CCK_b) cells is enhanced due to lower levels of CCK and cannabinoid 1 receptor (CB1R) mRNAs that reduce depolarization-induced suppression of inhibition (DSI). Levels of GAD67 in CCK_b cells are unknown, but are thought to be very low, relative to PV cells, in the healthy state. (C) PV-expressing chandelier (PV_{ch}) cells have decreased GABA membrane transporter 1 (GAT1) protein in their axon terminals and increased postsynaptic GABA_A α 2-containing receptors at pyramidal neuron axon initial segments. The levels of GAD67 protein in PV_{ch} cells in schizophrenia are not known. (D) Somatostatin (SST)-containing cells contain lower mRNA levels of SST, and expression of its receptor, SSTR2, is also lower. Levels of GAD67 in SST cells have not been measured. (E) Calretinin (CR)-containing cells are thought to be unaffected, since levels of CR mRNA and protein are unchanged. GAD67 levels in CR cells are unknown.

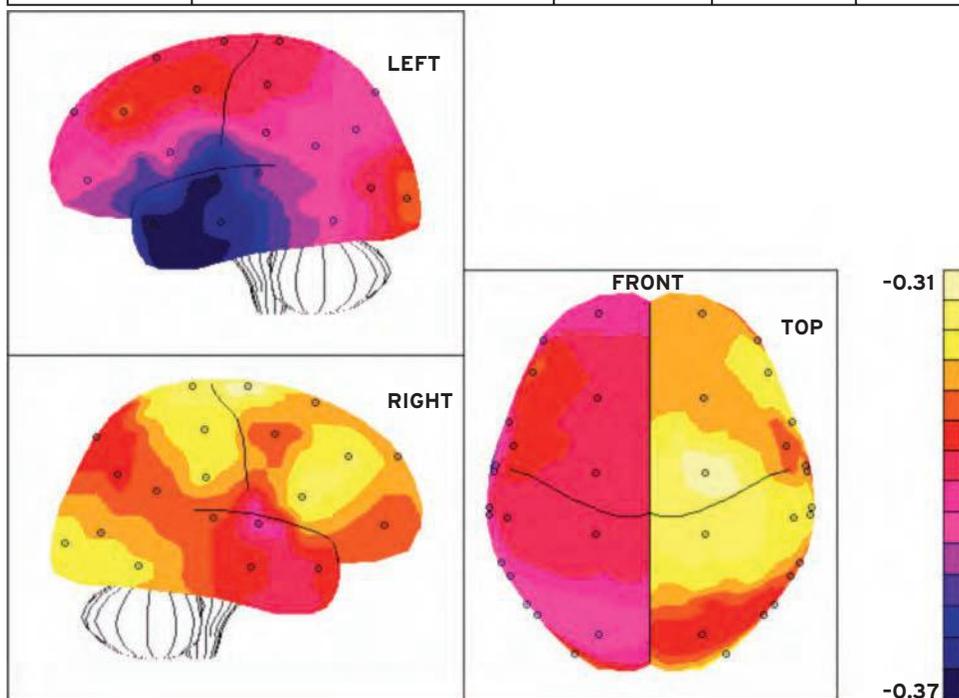

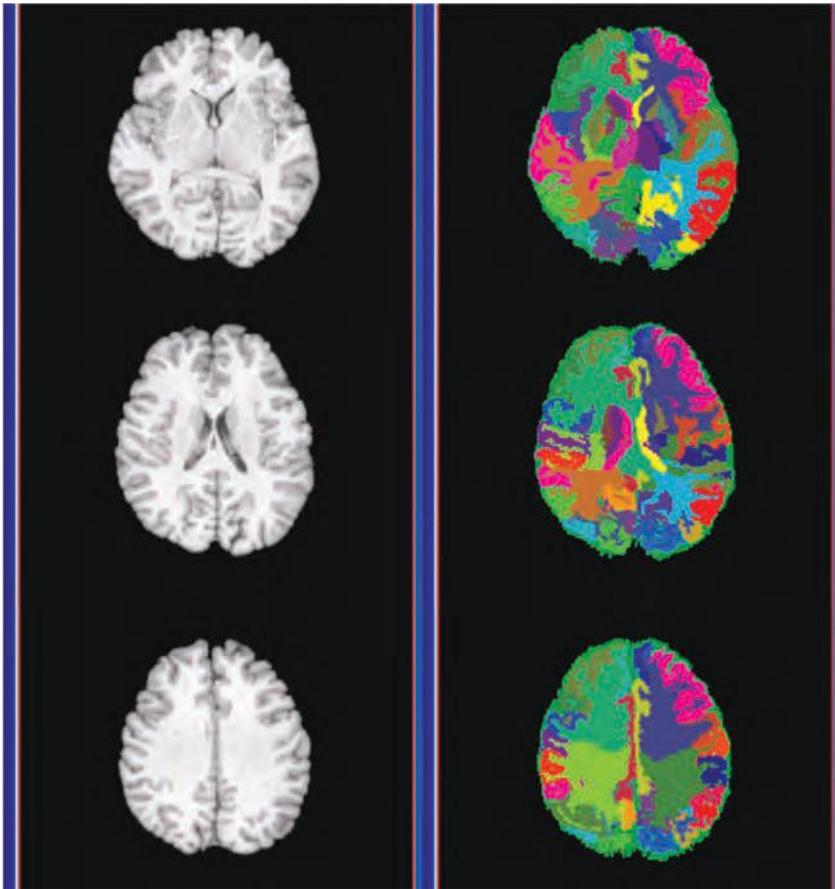

Figure 26.1 Behavioral Image displays of left hemisphere, right hemisphere, and top view. Values are based on the meta-analyses of tests examined and summarized in the table. The color scale indicates effect sizes of psychosis prone individuals relative to healthy controls.

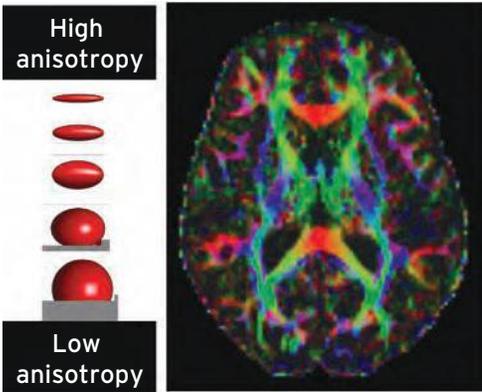

Original Image
(skull removed)

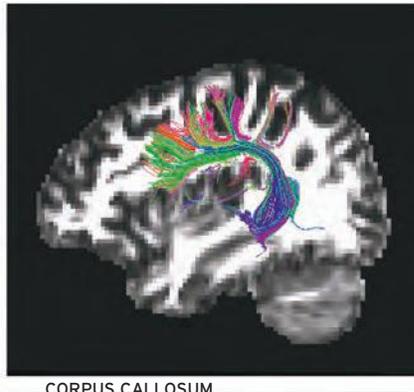

Labelled Image
(each color represents a Region of Interest)

Figure 26.2 MRI template-warping for parcellating regions of interest. A template in which regions are labeled and demarcated is warped into an individual's MRI recording the extent of changes required. As a result, axial slices such as seen on the left are labeled as seen on the right column. Regional volumes can then be calculated for quantitative analysis allowing, for example, comparison between psychosis prone and healthy participants.

FRACTIONAL ANISOTROPY

TRACTOGRAPHY
SUPERIOR LONGITUDINAL FASCICULUS

CORPUS CALLOSUM

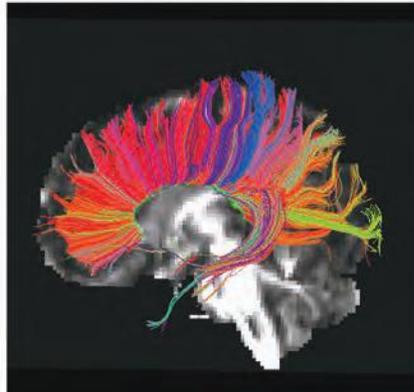

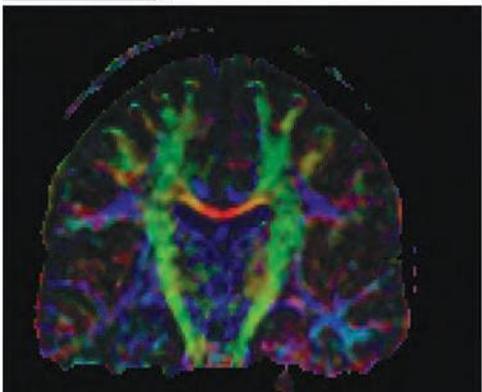

Figure 26.3 Diffusion tensor imaging (DTI) illustrates fractional anisotropy (left) and tractography (right). Fractional anisotropy reveals white matter architecture while tractography depicts the integrity of fiber tracts.

$\alpha 5$ GABA_A receptor distribution

Pyramidal cell dendrite

Figure 42.4 Left: Immunohistochemical distribution of the $\alpha 5$ -subunit GABA_A receptor in parasagittal sections of adult mice with the enlargement of the hippocampal formation showing its prominent dendritic localization (Crestani et al., 2002). Right: Schematic distribution of GABA_A receptor subtypes at pyramidal cell dendrites. In balancing the excitatory input, phasic inhibition is mediated via $\alpha 2$ and $\alpha 3$ GABA_A receptors, while $\alpha 5$ GABA_A receptors, located at the base of dendritic spines and the adjacent dendritic shaft, mediate tonic inhibition.

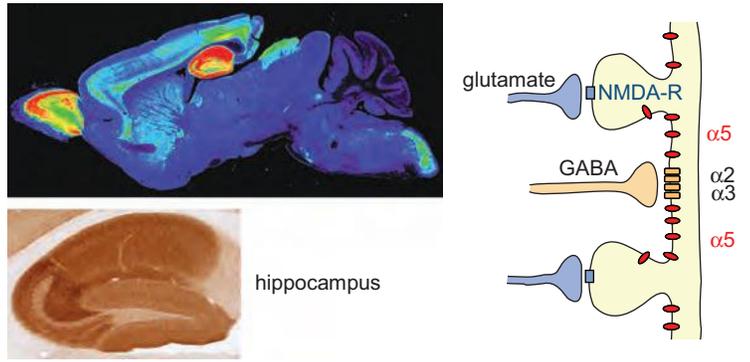

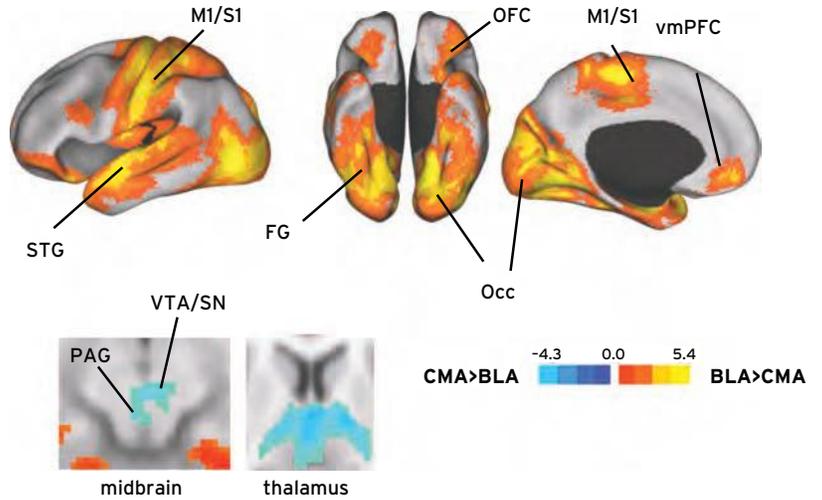

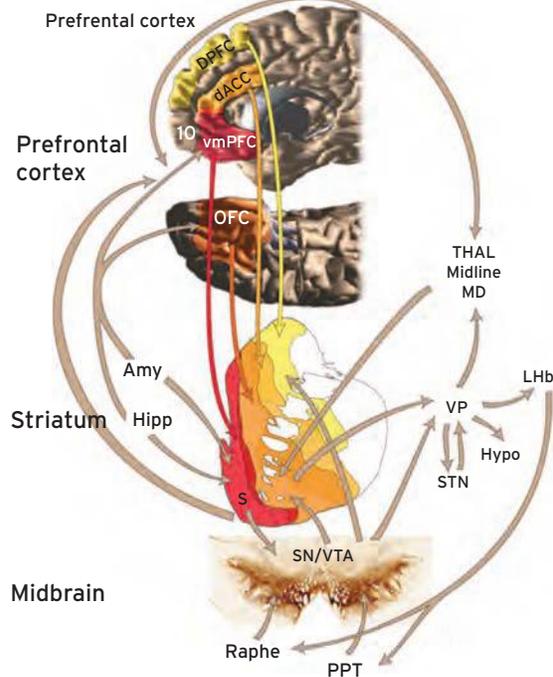

Figure 45.2 Differential connectivity of the basolateral (BLA) and centromedial (CMA) amygdalar subregions during resting-state fMRI. Findings are from a conjunction of two cohorts of healthy participants. The BLA connectivity was primarily cortical; CMA connectivity was primarily subcortical. Color scales represent t scores for the main effect of region in a voxelwise analysis. Red indicates that BLA connectivity is increased compared with CMA connectivity; blue, CMA connectivity is increased compared with BLA connectivity. FG, fusiform gyrus; M1/S1, primary somatosensory and motor cortices; Occ, occipital cortex; OFC, orbitofrontal cortex; PAG, periaqueductal gray; STG, superior temporal gyrus; vmPFC, ventromedial prefrontal cortex; and VTA/SN, ventral tegmental area/substantia nigra.

(A)

(B)

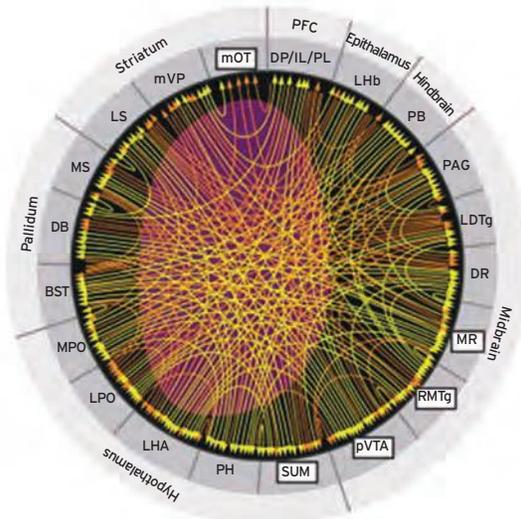

Figure 55.1 The reward circuit and its complexity. (A) Brain regions identified as being key players in the reward circuit, including striatal, midbrain, and prefrontal regions and, more recently, the amygdala, hippocampus, lateral habenula, and brainstem structures. (B) The connectivity between proposed brain reward regions is incredibly complex and has rendered identifying the roles of individual components difficult. Orange lines indicate unidirectional connection and yellow lines reciprocal connections. Purple area represents the medial forebrain bundle, the stimulation of which results in rewarding brain stimulation. (A from Haber S.N., Knutson B. (2010). The reward circuit: linking primate anatomy and human imaging. *Neuropsychopharmacology* 35:4–26. B from Ikemoto S. (2010). Brain reward circuitry beyond the mesolimbic dopamine system: a neurobiological theory. *Neurosci Biobehav Rev* 35:129–150.)

A. Healthy Patient

B. MCI Patient with Atrophy

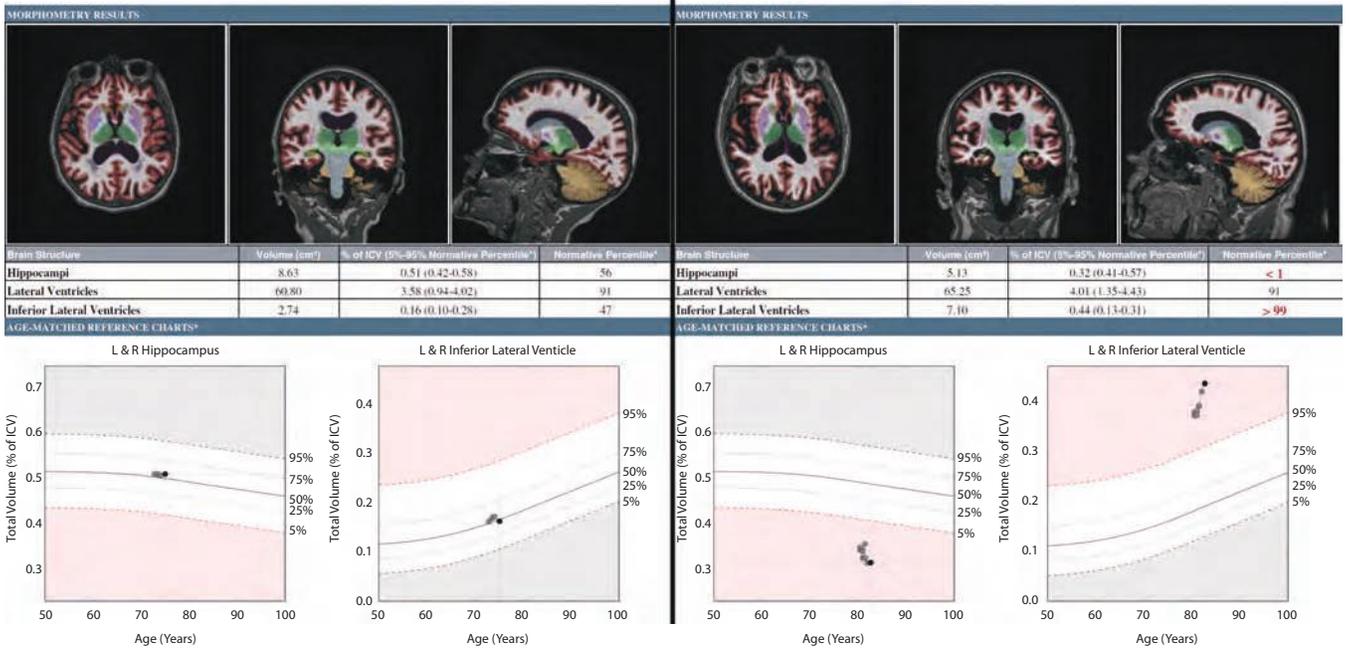

Figure 62.1 Example volumetric reports for two subjects enrolled in a longitudinal quantitative imaging study. (A) A 75-year-old healthy subject who remained stable and was without evidence of hippocampal neurodegeneration or temporal horn enlargement during scanning over two years. (B) An 82-year-old, cognitively impaired subject who progressed from MCI to AD at the third year of follow-up. This patient was a non-carrier of APOE4 genotype who, by CSF testing, had elevated phospho-tau and reduced levels of amyloid beta 42 in cerebrospinal fluid. vMRI shows evidence of hippocampal neurodegeneration and ex vacuo dilatation of the temporal horns during scanning over two years.

**PIB follow-up
from healthy control to MCI/AD**

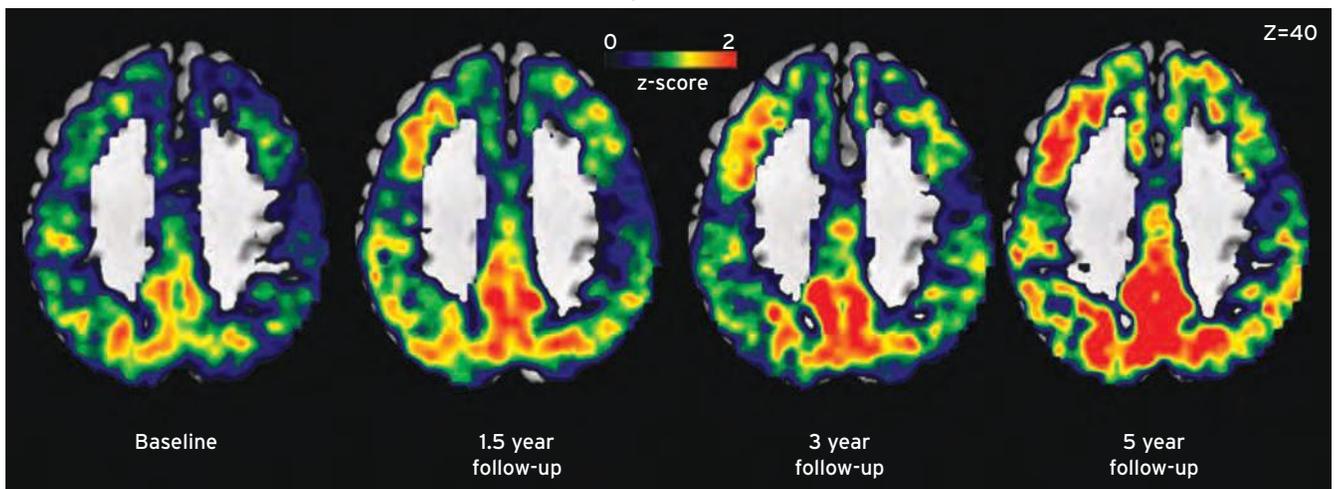

Figure 62.2 Longitudinal PET amyloid imaging of an individual subject who progressed from healthy to dementia.

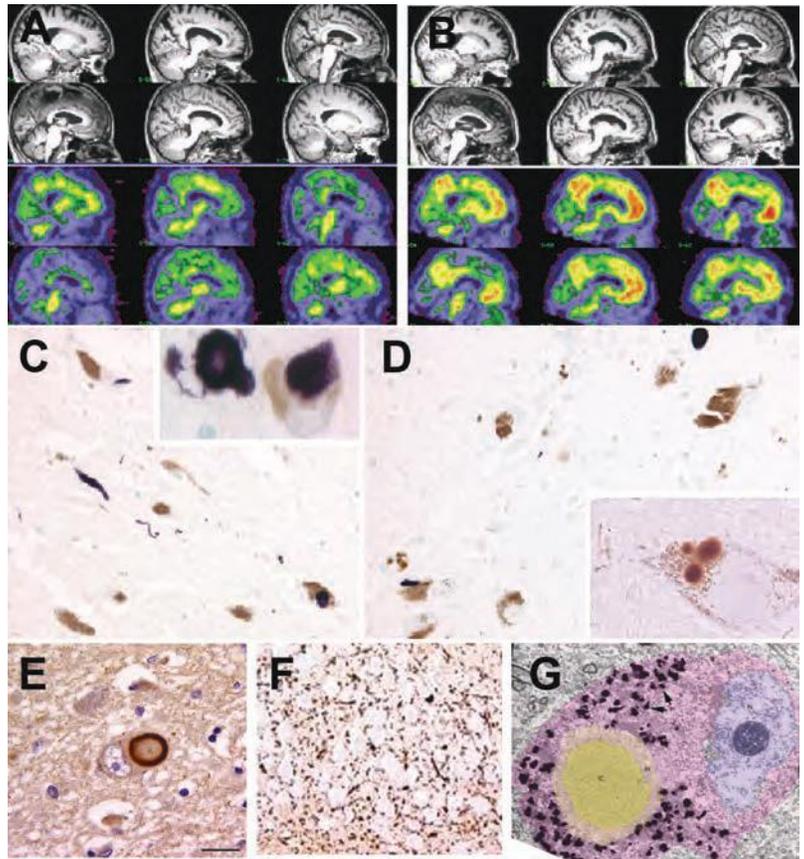

Figure 66.1 Imaging and pathology in Lewy body dementia. (A) Sagittal sections of MRI and amyloid imaging in a case of PDD. There is mild cortical atrophy largely sparing the hippocampus. Amyloid imaging reveal minimal to no uptake of the PIB. (B) Sagittal section of MRI and amyloid imaging in a case of mixed LBD and AD. There is slightly more prominent atrophy of the hippocampus with significant uptake of PIB. (C) Photomicrograph of substantia nigra in DLB patient stained with α -synuclein. Note dystrophic neurites. Insert shows higher power magnification of two Lewy bodies in the nigral neurons. (D) Photomicrograph of substantia nigra in PDD patient stained with α -synuclein. Insert shows higher power magnification of a nigral neuron with multiple Lewy bodies. (E) Photomicrograph of Lewy body in the cingulate cortex of a LBD patient stained with α -synuclein. (F) Photomicrograph of dystrophic neurites in the CA 2–3 region of the hippocampus in a LBD patient. (G), Electron micrograph of a Lewy body. Note the dense core (gray) surrounded by a paler halo.

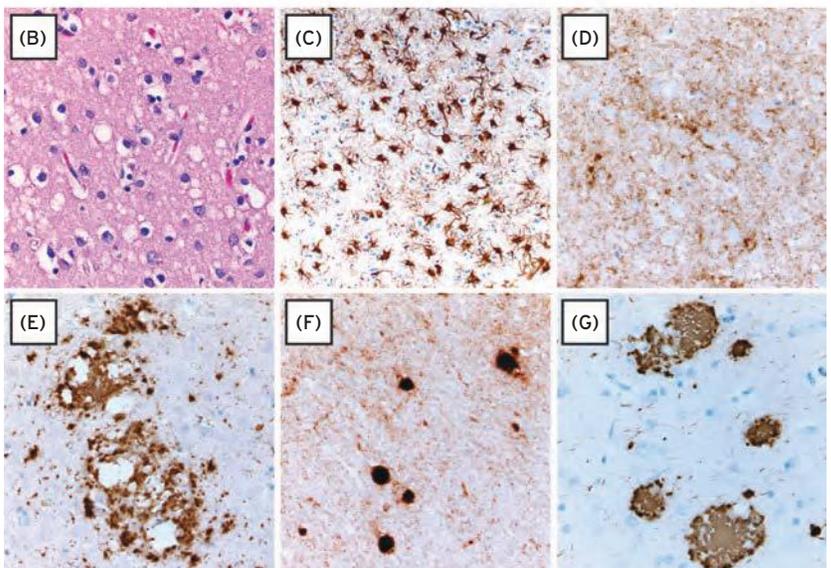

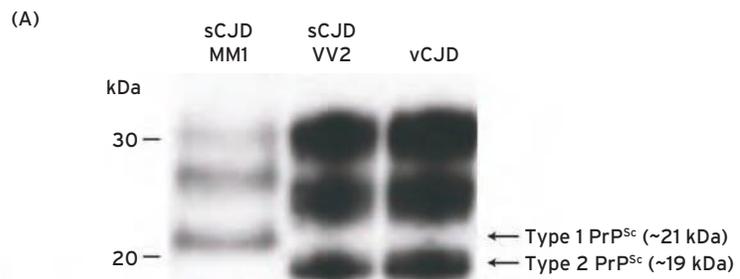

Figure 69.4 Biochemical and neuropathological hallmarks of human prion disease. (A–F) The neuropathological hallmarks of prion disease. Spongiform change (A) and reactive astrocytic gliosis (B) in the parietal cortex of a patient with sporadic CJD (subtype MM1). (C) The synaptic pattern of PrPSc deposition in the frontal cortex of a patient with sporadic CJD exhibiting the MM1 subtype. (D) Perivacuolar PrPSc deposition in the parietal cortex of a patient with MM2 sporadic CJD. (E) Kuru-like PrPSc plaques in the molecular layer of the cerebellum in a patient with MV2 sporadic CJD. (F) PrPSc amyloid plaques in the hippocampus of a GSS patient with the A117V mutation. (G) As revealed by immunoblotting, protease-resistant PrPSc, the biochemical signature of prion disease, is observed in the brains of patients with CJD. In sporadic CJD subtype MM1, type 1 PrPSc is present, whereas type 2 PrPSc is observed in sporadic CJD subtype VV2 and variant CJD.

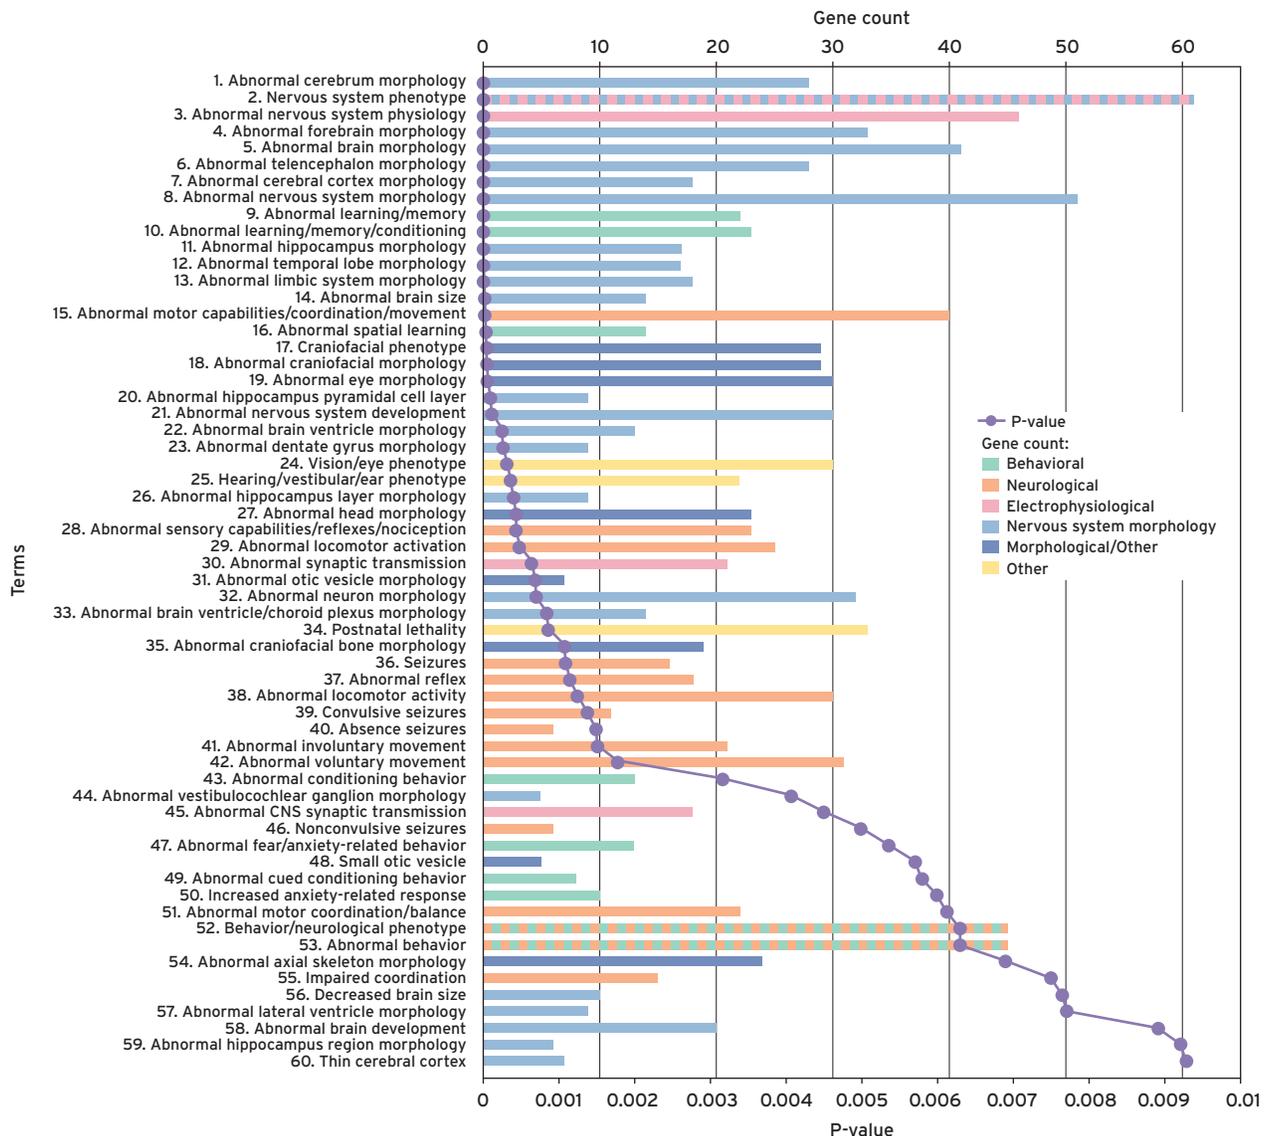

Figure 73.1 Mouse phenotype categories associated with ASD genes. ASD genes (N = 112) were analyzed for enrichment in mouse phenotypes using ToppGene with a Bonferroni corrected p value cutoff of 0.01. Categories are arranged from most significant and downwards (purple line), and for each category, the number of genes in the ASD112 list for which there were murine models with the associated category are indicated by the length of the horizontal bars (gene count). To highlight differing phenotypic categories, bars are color-coded as indicated in the inset to the figure. Categories relating to nervous system morphology phenotype domains are colored light blue, whereas other morphological categories are colored dark blue, electrophysiological categories are colored pink, neurological categories are colored peach, and higher-order behavioral categories are colored green. Categories corresponding to more than one phenotyping domain are presented as alternating colors, and categories that do not relate to the phenotyping scheme are colored yellow. (Adapted from Buxbaum J.D., Betancur C., Bozdagi O., et al. (2012) Optimizing the phenotyping of rodent ASD models: enrichment analysis of mouse and human neurobiological phenotypes associated with high-risk autism genes identifies morphological, electrophysiological, neurological, and behavioral features. *Mol. Autism*, 3(1):1.

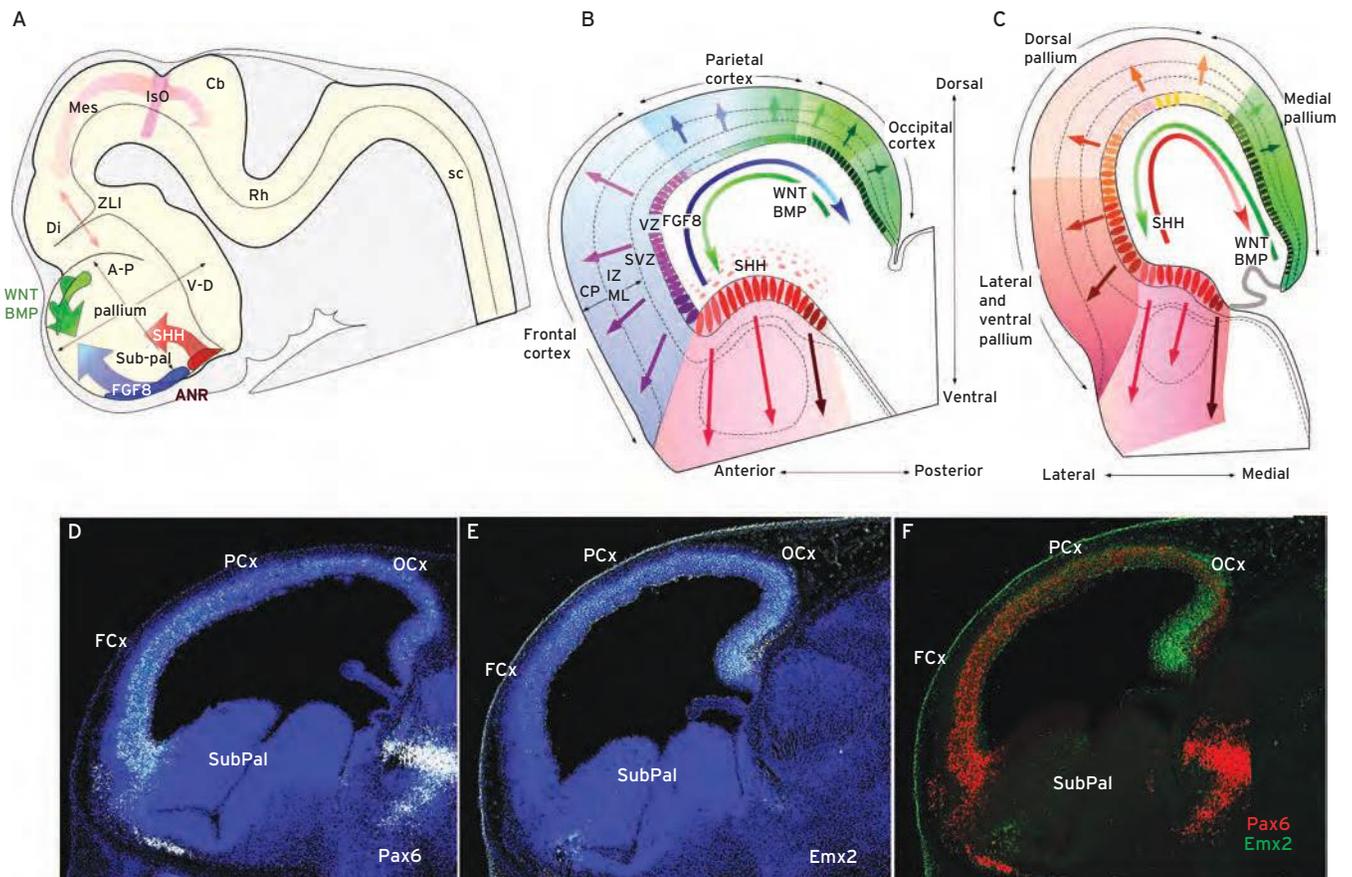

Figure 74.2 Morphogenetic signals and telencephalic regionalization. (A) Schematic representation of neural tube (lateral view) where the main brain regions have been identified and morphogenetic signals regulating telencephalic regionalization have been represented by colors and arrows. *Wnt* and *Bmp* are dorsalizing signals, *Fgf8* is a rostralizing signal, and *Shh* is a ventralizing signal, acting upon dorsal (pallial) telencephalon to specify cortical functional areas in the epithelium. (B,C) Schematic representation of a section in anteroposterior (B) and coronal (C) planes of the dorsal telencephalon (pallium and subpallium) that were color coded in neuroepithelial cells. Colored arrows in the ventricle and the dashed area (B) represent morphogenetic gradients that were translated through the neural wall by radial migration of neural cells into the different cortical regions (radial arrows and color gradient domains). (D–F) Sagittal sections showing the gradient expression pattern of two transcription factors: *Pax6* regulated by rostral and ventralizing signals (D), and *Emx2* regulated by dorsalizing signals (E). F, A combinatory Photoshop reconstruction of both gradient patterns.

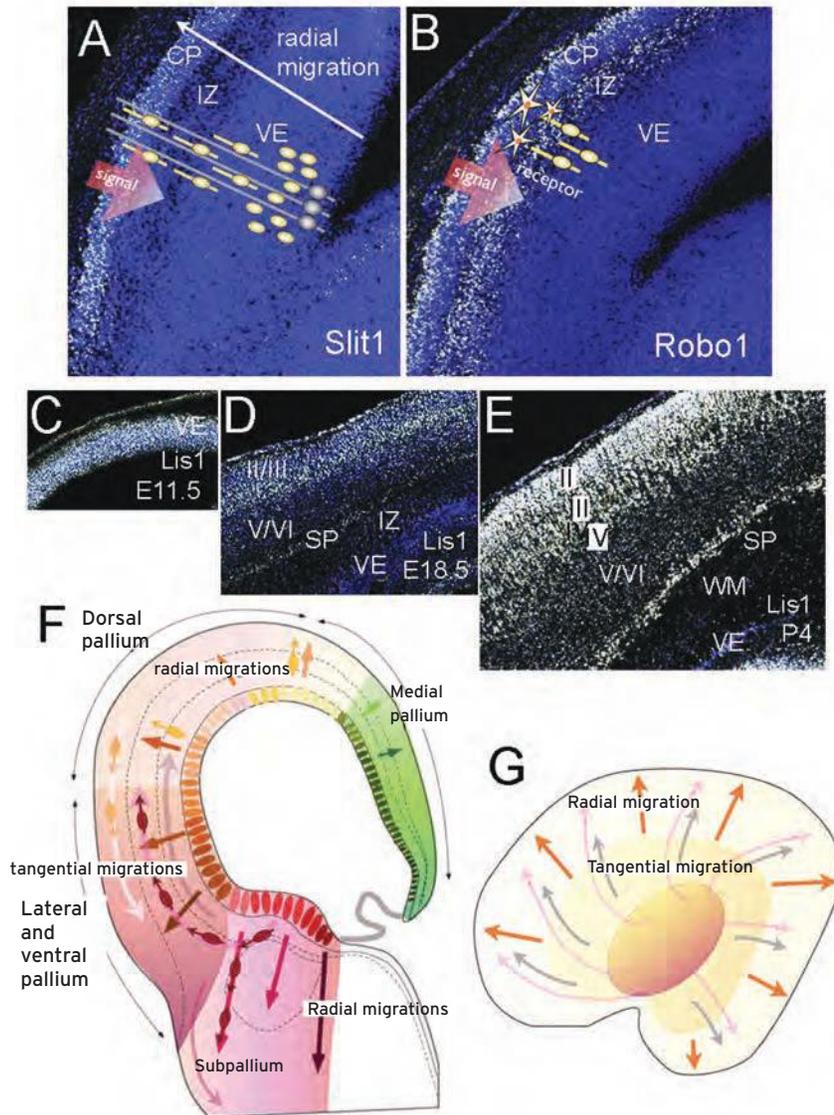

Figure 74.4 Neuronal migration in the pallium: cortical development. (A,B) Signal: *Slit1* expression in E15.5 mouse embryo in the cortical plate. Neural progenitors proliferate in the ventricular epithelium (VE) and subventricular zone (yellow ovoid cells), radial glia cells are schematized in gray with long radial processes crossing the neural wall from ventricular to pail surface. Migrating neurons were distributed in between radial glia processes in the intermediate zone (IZ; yellow ovoid soma with processes) toward the cortical plate (CP). In an equivalent section the receptor of *Slit1*, *Robo1* is expressed in migrating cells of the IZ. (C–E) Expression of *Lis1* gene in developing and postnatal mouse cortex. (F) Schematic representation of a coronal section were different lateromedial (ventrodorsal) pallial domains are represented by colored fields. Radial migration is represented by radial arrows and tangential migrations are represented by concentric distributed arrows. Migrating cells were represented by ovoid soma and arrows. (G) Planar representation of the telencephalic vesicle where radial migrations are represented by orange arrows; pallio-pallial tangential migration is represented by grey arrows; subpallio-pallial tangential migration, coming from the subpallium (central orange ovoid).

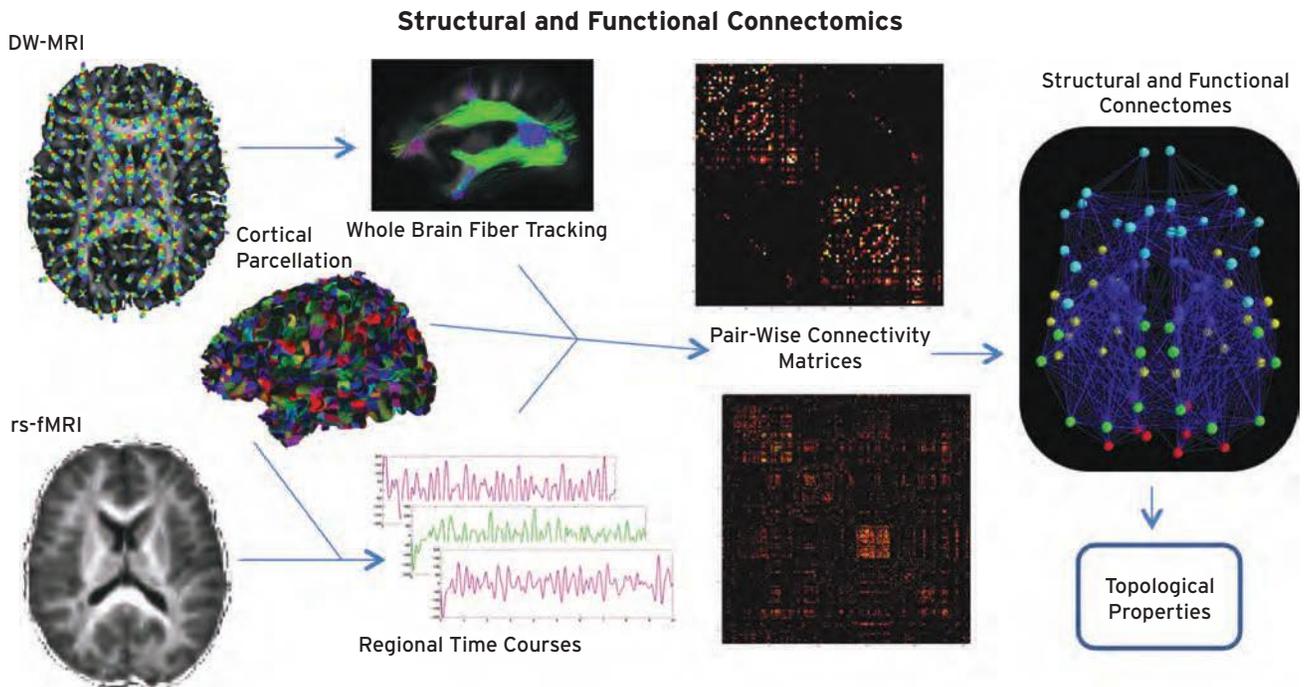

Figure 75.1 Functional and structural connectomics. The computation of structural and functional connectomes begins with the acquisition of either DW-MRI or rs-fMRI datasets and the parcellation of the cortex into the regions of interest (ROIs). Each modality undergoes specific preprocessing to remove artifacts. For DW-MRI, tractography algorithms are used to identify anatomical pathways connecting the ROIs and information related to these is collected into the pairwise connectivity matrix. Using the rs-fMRI datasets, ROI time courses are extracted and the pairwise connectivity matrix is formed by computing the temporal correlation between each ROI time course. These connectivity matrices can then be combined into a joint structural/functional connectome that can be used in subsequent analysis to represent the brain networks of the subject.

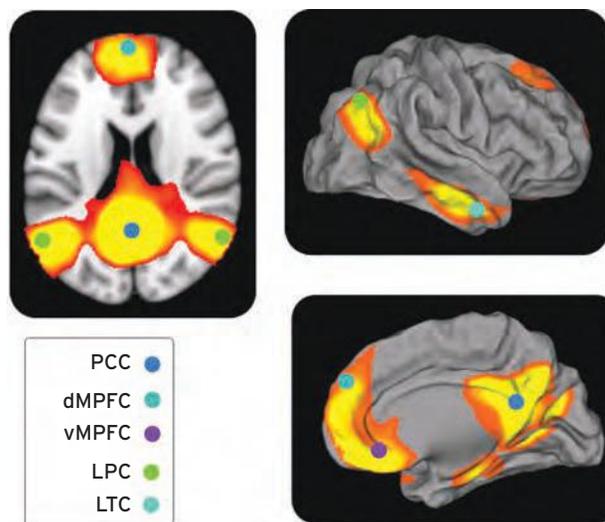

Figure 75.2 Default mode network. Temporally correlated activity in regions of the default mode network (DMN) has been shown to increase during non-goal-oriented activities and to decrease during goal oriented activities. The areas of the DMN is illustrated via a group averaged ($n = 225$) temporal correlation map generated by using the posterior cingulate cortex (PCC) as the seed region. The prominent regions of the DMN, the dorsal and ventral medial prefrontal cortices (dMPFC and vMPFC), the lateral temporal cortex (LTC), and the lateral parietal cortex (LPC) are clearly indicated as being positively correlated with activity in the PCC.

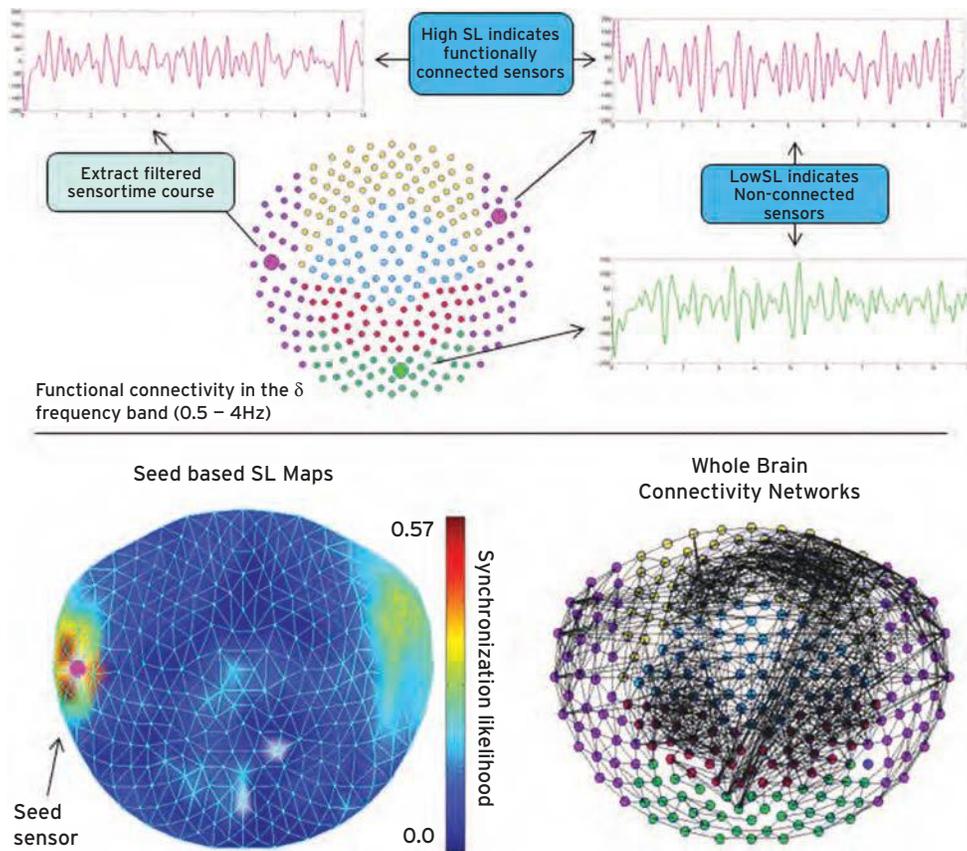

Figure 75.3 MEG based functional connectivity. Measuring function connectivity with electrophysiologic modalities like MEG proceeds by extracting time courses of interest from the MEG sensor data. The high temporal resolution of MEG allows users to focus on connectivity within particular frequency bands; for instance, this figure focuses on connectivity in the delta (0.5 to 4 Hz) frequency band. The high resolution also allows for quantifying functional connectivity using complex measures, such as synchronization likelihood (SL). These measures can be computed on time courses from selected regions, shown at the top. Functionally connected sensors, such as those above the right and left motor areas, indicated by purple time courses, have higher SL values, whereas the SL between non-functionally connected regions, such as the occipital lobe and motor areas, have lower SL values. Maps showing connectivity to a particular seed region can also be computed. Similarly, whole brain networks can be determined by examining all of the pair-wise connectivity measures.

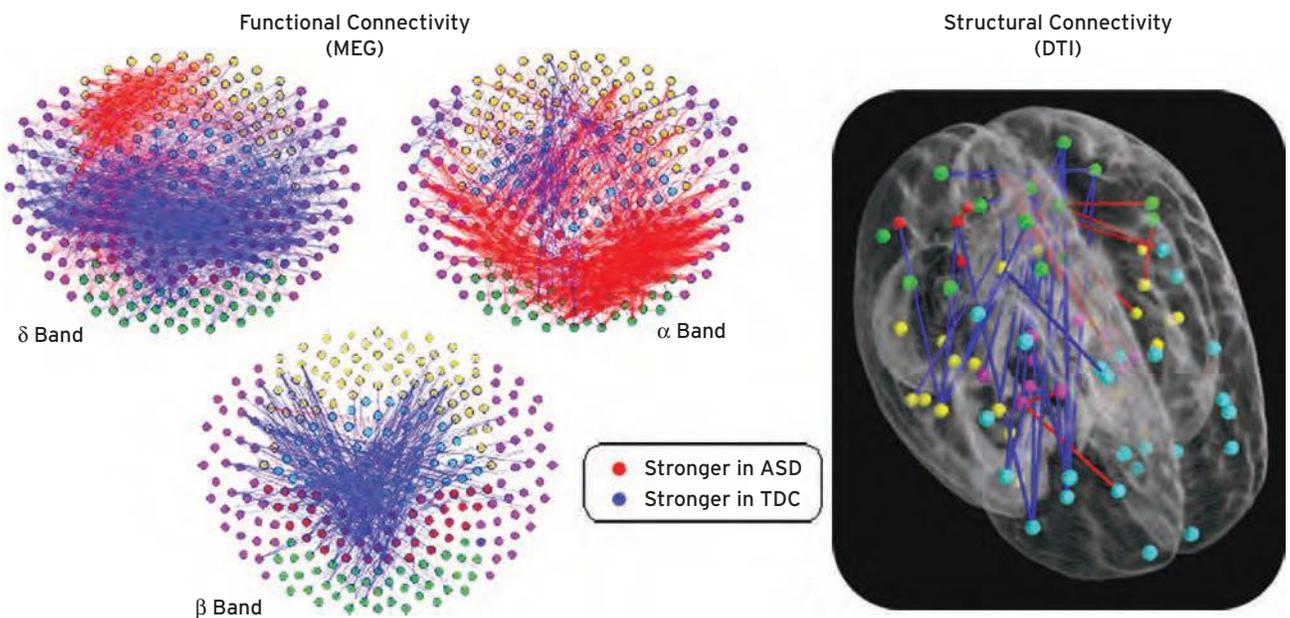

Figure 75.4 Structural and functional connectivity differences between ASD subjects and TDCs. Probabilistic tractography was used to compute DTI-based structural connectivity networks for each subject, which were then subjected to statistical analysis. Synchronization likelihood was used to compute functional connectivity networks in five frequency sub-bands of resting state MEG time courses. Shown are the significant different connections in the δ (0.5 to 4 Hz), α (8 to 13 Hz), and β (13 to 30 Hz). Light gray lines indicate connections that are stronger in the ASD population (predominantly shorter range frontal delta-band connections and posterior alpha-band connections), whereas dark gray lines indicated stronger connections in the TDC population (predominantly longer range and interhemispheric connections).

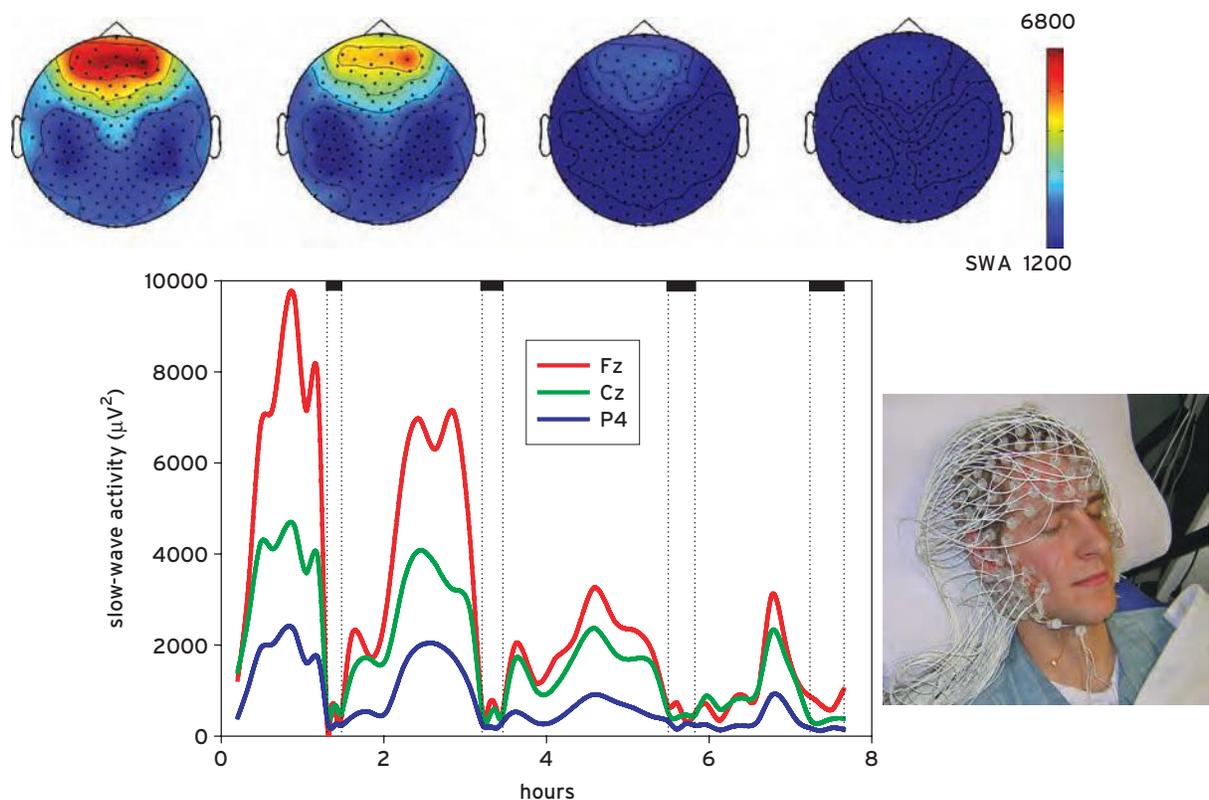

Figure 87.4 Sleep slow waves as a marker of sleep pressure. Bottom panel: During early sleep, at the end of a day of wakefulness, sleep pressure is maximal. This is reflected in frequent and large sleep slow waves, measured here as slow wave activity (power in the 0.5–4 Hz band, in red for a frontal electroencephalogram (EEG) channel, green for a central channel, and blue for an occipital channel). During sleep slow wave activity decreases exponentially, reflecting a reduction of sleep pressure. The transitory drops in slow-wave activity correspond to episodes of rapid-eye-movement (REM) sleep. Top panel: Topographic display of slow wave activity over the scalp for the four sleep cycles. Notice the frontal predominance and the progressive decline in the course of the night.

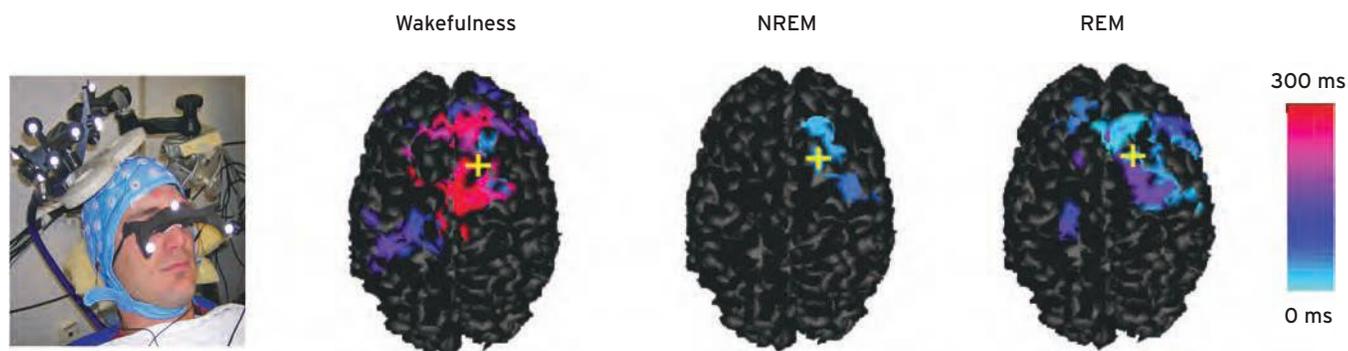

Figure 87.7 Spatiotemporal cortical current maps of transcranial magnetic stimulation (TMS)-induced activity during wakefulness, non-rapid eye movement (NREM), and REM sleep. On the left is the setup for TMS/EEG. From the electroencephalogram (EEG) data, maximum current sources corresponding to periods of significant activations were plotted and color-coded according to their latency of activation (light blue, 0 ms; red, 300 ms). The yellow cross marks the TMS target on the cortical surface. Note the rapidly changing patterns of activation during wakefulness, lasting up to 300 ms and involving several different areas; the brief activation that remains localized to the area of stimulation during NREM sleep; and an intermediate pattern of activation during REM sleep. (From Massimini M., Ferrarelli F., Huber R., et al., 2005. Breakdown of cortical effective connectivity during sleep. *Science* 309:2228–2232.)

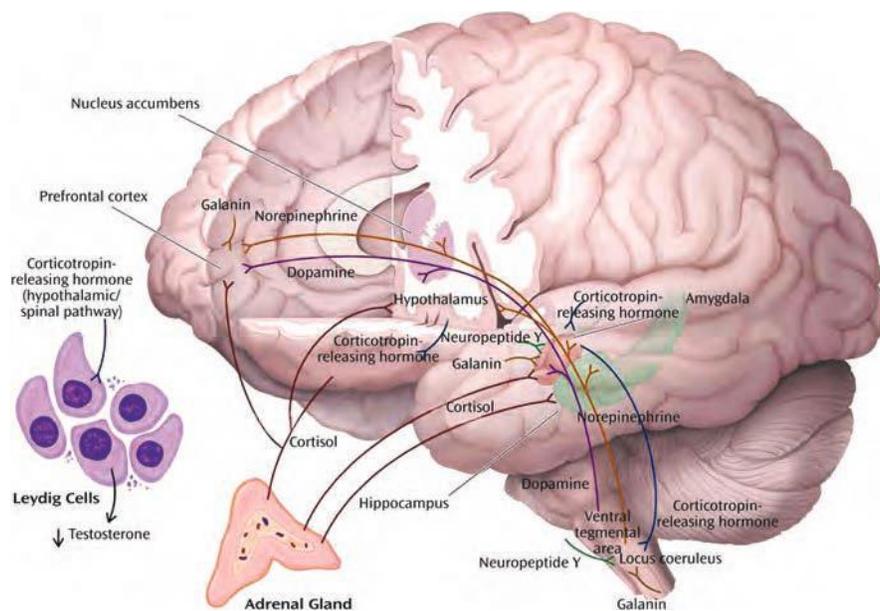

Figure 88.1 Neurochemical response patterns to acute stress. This figure illustrates some of the key brain structures involved in the neurochemical response patterns following acute psychological stress. The functional interactions among the different neurotransmitters, neuropeptides, and hormones are emphasized. The functional status of brain regions such as the amygdala (neuropeptide Y, galanin, corticotropin-releasing hormone [CRH], cortisol, and norepinephrine), hippocampus (cortisol and norepinephrine), locus coeruleus (neuropeptide Y, galanin, and CRH), and prefrontal cortex (dopamine, norepinephrine, galanin, and cortisol) depends upon the balance among multiple inhibitory and excitatory neurochemical inputs. Functional effects may vary depending on the brain region. For example, cortisol increases CRH concentrations in the amygdala and decreases concentrations in the paraventricular nucleus of the hypothalamus. As described in the text, these neurochemical response patterns may relate to resilience and vulnerability to the effects of extreme psychological stress. Figure 88.2 Neural circuits associated with reward, fear conditioning, and social behavior. The figure depicts a simplified summary of some of the brain structures and relevant neurochemistry mediating the neural mechanisms of reward (purple paths), fear conditioning and extinction (yellow paths), and social behaviors (blue paths). Only a subset of the many known interconnections among these various regions is shown, and relevant interneurons are not illustrated, yet it can be seen there is considerable overlap in the brain structures associated with these neural mechanisms. This suggests that there may be clinically relevant functional interactions among the circuits. For example, a properly functioning reward circuit may be necessary for the reinforcement of positive social behaviors. An overly responsive fear circuit or impaired extinction process may negatively influence functioning of the reward system. The assessment of these neural mechanisms must be considered in the context of their neurochemical regulation. Alterations in one neurotransmitter, neuropeptide, or hormone system will affect more than one circuit. Several receptors that may be targeted by new anti-anxiety and antidepressant drugs are illustrated. The functional status of these circuits has important influences on stress-related psychopathology and the discovery of novel therapeutics (see text).
