SECTION IV | MOOD DISORDERS

HELEN S. MAYBERG

Depression is one of the most common of all psychiatric disorders and is a leading cause of disability worldwide. Current psychiatric tenets assume a core biological basis for this condition; however the disorder continues to be clinically defined by patient self-report, with treatments generally prescribed without consideration of etiology or pathophysiology. As presented in the following state-of-the-art chapters, there has been tremendous progress toward defining a comprehensive multidimensional neurobiology of mood disorders. The authors in this section provide critical perspective on recent basic, translational, and clinical research advances contributing to an evolving integrative understanding of illness risk and vulnerability, molecular and circuit pathophysiology, and novel diagnostic and treatment strategies.

The section opens with a comprehensive review by Fawcett and Hager of the history and changing nosology of depression diagnosis. This chapter provides broad perspective on the potential changes in the clinical research landscape anticipated by the introduction of DSM-5 (Chapter 29), as well as the need for improved clinical characterization of depression subtypes and syndromic dimensions to fully define mechanisms and develop and test novel treatments. Levinson next present an update on the genetics of depression, summarizing the challenges, limitations, and potential of various approaches including candidate gene studies, genomewide association studies, and evolving applications of sequencing and stem cell technologies (Chapter 30).

Hodes and Russo follow with a critique of the theoretical and practical applications of a wide range of genetic, developmental, and stress-based animal models currently in use to study depression. This chapter provides a comprehensive summary of behavioral endophenotypes and associated peripheral and central biomarkers and behavioral assays relevant to the human condition (Chapter 31).

Duman (Chapter 32) and Furey, Mathews, and Zarate (Chapter 33) offer complementary basic and clinical perspectives on molecular and cellular mechanisms contributing to depression pathogenesis and treatment response with a

particular emphasis on their role in development and clinical testing of a new generation of rapid-acting antidepressant agents. Price and Drevets provide important anatomical context to such molecular and cellular findings in their comprehensive review of brain circuits implicated in depression and mood regulation covering basic anatomy, structural and functional neuroimaging, and postmortem pathological studies (Chapter 34).

Krishnan (Chapter 35) extends the discussion of the neuroanatomy of depression to a late-life perspective highlighting vascular pathophysiology and both postmortem and imaging studies of depression in the elderly. Rubinow, Schmidt, and Craft (Chapter 36) focus on the role of gonadal steroids and mood disorders with a comprehensive review of cellular mechanisms, clinical syndromes, and treatment mechanisms. Benton, Blume, Crits-Christoph, Dubeé, and Evans next provide an updated perspective on depression and medical illness (Chapter 37) emphasizing studies of cardiac disease, diabetes, HIV/AIDS, and cancer. The section concludes with comprehensive summary of depression treatments by Iosifescu, Murrough, and Charney (Chapter 38), presenting an overview of treatment efficacy, side effects, and mechanisms of action of the major classes of available interventions and discussing new research on predictive biomarkers and advances in novel treatment development.

Clearly, considerable progress has occurred since publication of the last edition. Judging from this set of comprehensive reviews, the field appears poised for disruptive new advances impacting diagnosis, evidence-based treatment development, and, ultimately, improved care of patients with this common and disabling disorder.

DISCLOSURE

Dr. Mayberg has a consulting agreement with St. Jude Medical Neuromodulation, which has licensed her intellectual property to develop SCC DBS for the treatment of severe depression (US 2005/0033379A1).

29 | THE DIAGNOSIS OF MOOD DISORDERS

JAN FAWCETT AND BRANT HAGER

Every established order tends to produce (to very different degrees and with very different means) the naturalization of its own arbitrariness.... Schemes of thought and perception can produce the objectivity that they do produce by misrecognition of the limits of the cognition that they make possible, thereby founding immediate adherence ... to the world of tradition experienced as a "natural world" and "taken for granted." PIERRE BOURDIEU, *in Wilson (1993)*

INTRODUCTION

Sadness and distress are part of everyday life, as are elation, irritability, and associated fluctuations in energy, activity, enjoyment, and cognition. More severe, disabling mood traits and states, which today we conceptualize as mood disorders, have been described throughout recorded history. Ancient mood disorder diagnostic concepts served the early physician by identifying putative underlying mechanisms, guiding correspondingly appropriate treatment, and estimating patient prognosis. Modern mood disorder diagnostic concepts continue to aid the contemporary physician in similar ways. However, modern mood disorder diagnostic concepts serve many other masters, including research, public health, financial, and medico-legal endeavors.

In mental health clinical care, an optimally conceptualized categorical mood disorder diagnosis validly, accurately, reliably, and rapidly identifies an individual patient as belonging to one or more specific mood disorder diagnostic groups, and not belonging to others. For the clinician, such an optimal mood disorder diagnosis allows for rapid identification of disorder type, determination of caseness, diagnostic elimination of other conditions, concise formulation about putative underlying mechanisms, selection of optimally effective therapy, and prediction of course and prognosis.

In mental health research, an optimally conceptualized categorical mood disorder diagnosis validly, accurately, reliably, and efficiently defines a controlled, descriptively homogeneous mood disorder group for study. Making such an optimal diagnosis allows for statistically robust conclusions regarding mood disorder diagnosis-related natural history, correlations, and outcomes in response to treatment. Given the need for diagnostic homogeneity, an optimal research diagnosis values the elimination of false positives over the elimination of false negatives (Spitzer et al., 1978). Diagnostic false positives dilute the sameness of a research sample, and the exclusion of diagnostic false negatives may be mitigated by increased sample sizes. Ultimately, an optimal research diagnosis, subjected to rigorous study, may point to candidate disease mechanisms, and fruitful areas for possible intervention, control, and cure.

In addition, categorical mood disorder diagnoses also help to establish the fact that a given diagnosis is of public health significance, worthy of reimbursement for treatment, and appropriate for research funding. These latter three diagnostic purposes serve as a crucial bridge between clinical and research efforts, as the clinician's diagnostic task ultimately relies on payment for services, research into neurobiologic etiogenesis and treatments, and empirical data on diagnostic validity, accuracy, reliability, and outcomes.

As we shall see, however, current categorical diagnostic approaches to mood disorders, even ones as optimally conceptualized previously, pose problems for both clinical care and research. To explore this crucial issue, the following chapter will outline an early history of mood disorder diagnostic concepts, discuss the evolution of contemporary mood disorder diagnostic concepts up to the most current diagnostic systems, and finally address the myriad questions of how clinical description of mood disorders might be improved to further the usefulness of diagnosis for treatment and research.

What criteria are most valid and reliable for determining when sadness, distress, elation, irritability, and associated fluctuations in energy, activity, enjoyment, and cognition constitute a disorder, indicating altered pathophysiology, and requiring treatment? How might we improve mood disorder diagnosis to better advance our efforts to predict course and specific treatment response, understand underlying causes, and develop more effective treatments? This chapter will address these questions.

HISTORY

EARLY HISTORY OF MOOD DISORDER DIAGNOSIS

The earliest lineaments of psychiatry contain remarkable descriptors of pathological mood states and traits, and trace prescient contours of our current dilemmas in mood disorder diagnosis. Ancient physicians throughout Europe, the Middle East, South Asia, and East Asia, described sundry accounts

of what we might today call syndromes of depression, mania, psychosis, agitated excitement, anxiety, and adjustment reactions, among others (Horowitz and Wakefield, 2007; Maciocia, 2009; Sharma, 1994; Solomon, 2001). Hippocrates, writing in the 5th and 4th centuries B.C.E., illuminated several cases of melancholia, and distinguished between melancholia with and without external cause (Horowitz and Wakefield, 2007). Aristotle himself added the notion of melancholia as a temperament as well as an illness. Hippocrates also mentioned the maniacal affliction, and stated that both maniacal and melancholic diseases occur especially during spring (Hippocrates and Adams (Tr.), 2010: p. 135). Speculations about the relationship between melancholia and mania began to appear in the occidental literature circa 1st century B.C.E., and came to full fruition between the efforts of Aretaeus of Cappadocia, 2nd century C.E., and Alexander of Tralles, 6th century C.E. (Goodwin and Jamison, 2007).

Equally elaborative, yet seldom referenced in allopathic literature, are mood descriptors from Ayurvedic and Chinese medicine. The *Caraka Samhita*, a core Ayurvedic document with origins conservatively dated to the 7th century B.C.E., features a chapter on insanity, including syndromes of euphoric excitement, irritable agitation, and withdrawn despondency. The *Caraka Samhita* includes allowances for simultaneous occurrence of any combination of these three syndromes, and is replete with lists of prodromal symptoms, vivid syndromic descriptors, and references to humoral as well as exogenous mechanisms (Sharma, 1994). The *Rites of Zhou*, a 12th century B.C.E. Chinese non-medical text, mentions *Kuang*, the disease of irritable raving, and by the 2nd century B.C.E., Chinese medical texts, such as the *Spiritual Axis* and the *Classic of Difficulties*, linked irritable raving, both cyclically and mechanistically, to *Dian*, the disease of withdrawn, worried, unresponsive dullness (Maciocia, 2009). Other ancient Chinese medicine contributions, especially the *Essential Prescriptions of the Golden Chest*, circa 3rd century C.E., included additional syndromes of restless fatigue and agitated sadness (Maciocia, 2009).

Taken together, these first forays into mood diagnosis demonstrate an ostensible distillation of case-based observations, rooted firmly in humoral heuristics, without the apparent benefit of formal statistical empiricism.

The Middle Ages in Europe saw a period of supernatural etiologic speculation in medicine. Mood disorders, along with other forms of mental illness, took on the assumption and stigma of demonic possession and religious uncleanness, whose care, cure, and punishment was the ken of the priesthood (Solomon, 2001). Later, the Renaissance, the Enlightenment, and the associated Scientific Revolution in Europe heralded a resurgence of classical, case-based psychiatric observations, with humoral explanations, dovetailed with sundry attempts at anatomical correlation (Goodwin and Jamison, 2007).

These ancient forays into mood disorder diagnosis established melancholia and mania as facts of human existence, posed questions about the relationships between them, and hypothesized about the mechanisms underlying such conditions. Furthermore, they delimited a spectrum of philosophic conceptualizations of, and reactions to, mood disorders, from the Greek protomedical model of mood disorders as diseases to

be treated, to the Aristotelian notion of melancholia in particular as character to be valued, to the medieval notion of mood disorders as evil to be despised and eradicated. Such ontologic, epistemologic, nosologic, and ethical treatment issues pertaining to mood disorders persist to this day.

RECENT HISTORY OF MOOD DISORDER DIAGNOSIS

The contemporary era of empirical, medical model mood disorder diagnosis, based on systematic amassment of case-based observations without humoral assumptions, began in earnest in the 19th century C.E. In 1838 Jean Etienne Dominique Esquirol proposed the idea that the psychological faculty of mood could be disordered independently from the behavioral problems of melancholic underactivity and manic hyperactivity, laying groundwork for our current conceptions of mood rather than activity as central to mood disorder diagnosis (Healy, 2002: p. 15). In 1854, echoing Aretaeus of Cappadocia and Alexander of Tralles, Jean Pierre Falret and Jules Bailarger independently proposed that mania and depression represented manifestations of an underlying, unitary illness, which Falret termed *folie circulaire*, and Bailarger named *folie de double forme* (Healy, 2002: p. 16). In 1881 Emanuel Mendel defined hypomania as “that form of mania which typically shows itself only in the mild stages abortively, so to speak,” and in 1882 Karl Kahlbaum published his observations of a milder, cyclic, manic-depressive illness, cyclothymia (Goodwin and Jamison, 2007: p. 7). Kahlbaum is also credited as first describing dysthymia, a state of chronic unhappiness lacking the full neurovegetative manifestations of melancholia, as well as first advocating the full, historical description of all of a psychiatric patient’s signs and symptoms, in order to form diagnostic syndromes (Healy, 2002, pp. 19–20).

From the late 19th century into the first part of the 20th century, Emil Kraepelin arose as a major figure in descriptive psychiatry, melding disparate psychiatric diagnostic concepts into an overarching, comprehensive, and parsimonious classification scheme. Whereas Kraepelin did not invent nosological empiricism, he built creatively on the syndrome concept of Kahlbaum, and brought to bear a dedicated, systematic, and at the time unparalleled method of tracking and analyzing psychiatric signs and symptoms. Kraepelin leveraged detailed, longitudinal clinical observations to synthesize a unitary concept of manic-depressive illness, including the concept of mixed states, which resonates to this day in our current DSM and ICD classifications. Kraepelin’s synthetic concepts allowed for better prediction of the course and prognosis of major mental illness, and sharper delimitation of mood from psychotic disorders (Goodwin and Jamison, 2007).

In contrast with Kraepelin, Bleuler, in 1924, proposed that mood (termed affective by Bleuler) and psychotic illnesses fell along a spectrum without a firm boundary, presaging the current concepts of schizoaffective disorder and recent findings into the extensive genetic overlap between bipolar disorder and schizophrenia (Goodwin and Jamison, 2007).

Since the late 19th and early 20th centuries—with the exception of the psychoanalytic and psychobiologic influences

in American psychiatry during the majority of the 20th century, as well as the constructivist-humanist critiques of the antipsychiatry movement—mood disorder diagnosis worldwide has largely taken on a stance valuing the medical model of descriptive empiricism over models with more rationalistic explanatory power (McHugh and Slavney, 1983). However, to this day mental health clinicians treating mood disorders continue to employ a plethora of useful rationalistic diagnostics, through the lenses of psychoanalytic, psychodynamic, cognitive-behavioral, and biopsychosocial formulations, as well as through the persistent clinical assumptions of the monoamine hypothesis and associated theories of biological etiogenesis (Beck, 2011; Driessen et al., 2009; Engel, 1977, 1980; Gabbard, 2005).

EVOLUTION OF THE DSM AND ICD

The *American Diagnostic and Statistical Manual* (DSM) traces its origins to two key predecessors, *The Statistical Manual for the Use of Institutions for the Insane*, and the *Nomenclature of Psychiatric Disorders and Reactions*, *War Department Technical Bulletin, Medical 203*.

The *Statistical Manual for the Use of Institutions for the Insane* was created in 1918 through collaboration between the Committee on Statistics of the American Medico-Psychological Association and the US Census Bureau (American Psychiatric Association, 1952; Grob, 1991). Prior to this time, the US Census Bureau had made successive attempts to keep count of patients with various disorders housed in state hospitals. The Bureau's accounting of mental illness, however, was of little clinical use to practicing psychiatrists. For example, in the 1840 US Census, the Bureau recorded only one category of mental illness: "idiocy/insanity" (American Psychiatric Association, 2000). By the 1880 US Census, the Bureau distinguished seven categories of mental illness: mania, melancholia, monomania, paresis, dementia, dipsomania, and epilepsy (American Psychiatric Association, 2000). The massive expansion of asylum psychiatry in the early 19th century appears to have driven this nosological enrichment, as alienists of the day observed progressively larger numbers of institutionalized patients, and discerned increasingly differentiated shades of madness and insanity (Healy, 2002). Such efforts at continual nosological improvement, in conjunction with increasing scientific and political interest in the social, demographic, and economic correlates of mental illness, culminated in the aforementioned *Statistical Manual for the Use of Institutions for the Insane*, including 22 principle categories (Grob, 1991). However, it was not until the events of World War II that psychiatric nosology in the United States became clinically useful, and its further evolution clinically driven.

In World War II, American psychiatry—influenced by psychobiologic and psychoanalytic thinking, in combination with barbiturate-aided abreactions—asserted its usefulness by mitigating the effects of psychiatric reactions among soldiers, thus ameliorating chronic disability and consequent attrition of fighting troops. During the war, the Army Medical Corps' psychiatric division, led by Brigadier General William C. Menninger, used the *Nomenclature of Psychiatric Disorders and*

Reactions, *War Department Technical Bulletin, Medical 203*, as its primary diagnostic manual (Office of the Surgeon General, Army Service Forces, 1946). Medical 203 applied to inpatients as well as outpatients, and thus had broader clinical utility for both military and civilian psychiatric clinicians. With the exception of organic psychoses and character, intellectual, and paranoid disorders, Medical 203 conceptualized the majority of psychiatric disorders as reactions to the stresses of war, a conceptualization with clear situational pertinence and convincing rationale, traceable to both Pierre Janet and Adolf Meyer.

After World War II, the World Health Organization (WHO) began work on ICD-6, published in 1948. The release of ICD-6 represented a significant event in international psychiatric nosology. ICD-6 marked the first attempt by the WHO to attempt classification of causes of morbidity as well as mortality, including Section V, on mental, psychoanalytic, and personality disorders (Moriyama et al., 2011). Psychiatric classification in ICD-6 largely followed that used by the US military and related Veterans Administration system, and eventually by DSM-I (American Psychiatric Association, 1952).

As with the ICD-6, the concept of psychiatric disorders as reactions was incorporated into the DSM-I by the American Psychiatric Association in 1952 (American Psychiatric Association, 1952). In this way, DSM-I was influenced heavily by the psychobiologic work of Adolf Meyer, who taught that psychiatric disorders were reactions to various stresses at various phases of the life cycle. Similarly, DSM-I was also influenced strongly by psychoanalytic theories, which were pervasive at the time and originally incorporated into the language of Medical 203, leading some diagnoses to be defined in psychodynamic terms (Grob, 1991). In the Medical 203, affective (mood) disorder diagnoses included neurotic depressive reaction, manic-depressive reaction, psychotic depressive reaction, and melancholia, with related diagnostic categories of note including acute situational maladjustment, and cyclothymic personality. In DSM-I, a similar rubric obtained for mood disorder diagnoses, called affective reactions, which were also enriched by additional symptomatic descriptors to aid the diagnostician. DSM-I also further subdivided adjustment reactions into various time periods across the life span, and added a category for schizophrenic reaction, schizoaffective type.

DSM-II, appearing in 1968, retained Meyerian psychobiologic influences in the categories of psychotic depressive reaction and adjustment reactions subdivided across the lifespan. DSM-II also demonstrated increased psychoanalytic influences through the various categories of neuroses, including depressive neurosis. Cyclothymia remained as a personality disorder. However, DSM-II dropped the reaction designation for most mood disorders, and indeed divorced the occurrence of major mood disorders from their psychobiologic context. DSM-II stipulated that, regarding the major affective disorders, "The onset of the mood does not seem to be related directly to a precipitating life experience" (American Psychiatric Association, 1968, pp. 35–36). The major affective disorders in DSM-II included involuntional melancholia, manic depressive illness (manic, depressed, and circular types), and other and unspecified major affective disorders. These reorganizations of DSM-II occurred in the overarching context of

nosologic synchronization with ICD-8 (American Psychiatric Association, 1965).

The WHO adopted ICD-9 in 1975. ICD-9 expanded the list of ICD mental disorder categories, and included narrative descriptions of disorders similar to that of DSM-II (American Psychiatric Association, 1980; Moryama et al., 2011). The related ICD-9-CM, or clinical modification, released in 1978, included more detailed coding procedures, for categorizing and tracking clinical morbidity. The DSM has continued to use the ICD-9-CM coding system since release of the DSM-III, discussed next.

DSM-III, published in 1980, embodied a major departure from prior DSM and ICD editions, by focusing on operationalized symptom criteria validated by family history and follow-up studies, tested for interrater reliability, and almost totally divorced from a priori etiologic designations. DSM-III arose almost entirely from Spitzer et al.'s (1978) Research Diagnostic Criteria, which in turn evolved directly from Feighner et al.'s (1972) diagnostic criteria (Feighner et al., 1972; Spitzer et al., 1978). DSM-III dropped the etiologically presumptive diagnoses of depressive neurosis, involuntal melancholia, and psychotic depressive reaction from DSM II, although it retained synonymic mention of depressive neurosis under the new category of dysthymic disorder. DSM-III also reclassified adjustment disorders according to the type of emotional disturbance (depressed mood, anxious mood, or both), and/or disturbance of conduct.

The psychopharmacologic revolution, which burgeoned in the early 1950s and came to full fruition in the 1960s, informed the shift of DSM-III toward the medical model of diagnosis, and away from the psychobiologic and psychoanalytic stances of prior editions. The discovery and demonstration of empirical effectiveness of the neuroleptic chlorpromazine, the tricyclic antidepressant imipramine, the monoamine oxidase inhibitor isocarboxazid, and the mood stabilizer lithium carbonate served as potent stimuli for a disease-oriented approach to psychoses and mood disorders, and led to a paradigm shift that supported a proliferation of neurobiologic research into mood disorders.

Furthermore, the social, political, and economic climate of the 1960s and 1970s placed American psychiatry in a position necessitating justification of its services. The influence of the antipsychiatry movement, the failure of psychoanalysis to impact severe and persistent mental illness, and governmental budgetary tightening all exerted pressure on American psychiatry to identify itself as a useful and necessary specialty. Part of this justification included the effort to demarcate more sharply between normal and abnormal states, that is, defining those disorders requiring treatment and deserving reimbursement for care (Wilson, 1993). One unforeseen consequence of American psychiatry's need to justify its existence and funding through nosologic definition has been a tendency to pathologize as disordered what might otherwise be interpreted as normative human emotional experience (Healy, 1997; Horowitz and Wakefield, 2007).

Another important change in DSM-III comprised the shift from the diagnostic category of manic-depressive illness, which captured recurrent depression as well as mania, mixed

states, and cyclic alterations between the three, to the diagnostic category of bipolar disorder, which required only the historical presence of mania for diagnosis, and the category of major depression, which required only the historical presence of one major depressive episode for diagnosis. As Goodwin and Jamison (2007) have pointed out, this shift prioritized the polarity of a mood disorder (bipolar versus unipolar) over the recurrence or longitudinal course of a mood disorder. In DSM-III, bipolar disorders were further subdivided according to the polarity of their current episode, and included an additional category of atypical bipolar disorder, which captured the disorder of hypomania in a person with a prior major depressive episode, later designated Bipolar II Disorder in DSM-IV. DSM-III furthermore reclassified cyclothymia as an affective disorder, rather than a personality disorder (American Psychiatric Association, 1980).

Lastly, DSM-III added prognostically informative specifiers to describe the current manic or major depressive disorder, and a category of Atypical Depression. Manic Episode specifiers included In Remission, With Psychotic Features (Mood-congruent vs. Mood-incongruent), and Without Psychotic Features. Major Depressive Episode specifiers included the preceding, plus With Melancholia and Without Melancholia. The category of Atypical Depression introduced a place where clinicians could diagnose clinically significant depressive symptoms that did not meet full criteria for a previously defined specific affective disorder (American Psychiatric Association, 1980).

DSM-III-R added some changes in 1987. Notably, in an attempt to define better caseness, the diagnosis of major mood episodes now required a change from prior level of functioning (for major depressive episode), or impairment in functioning (for manic episode) (American Psychiatric Association, 1987).

DSM-IV updated these changes in 1994, and made further revisions leading to DSM-IV-TR in 2000. DSM-IV was fashioned based on 150 literature reviews, including data-reanalyses, field trials comparing DSM-III, DSM-III-R, ICD-10, and proposed DSM-IV criteria (American Psychiatric Association, 1994). Proposed changes had to be supported by published empirical data. For example, in one DSM-IV mood disorders field trial, 91% of subjects, who presented with depressed mood plus two other depressive disorder symptoms, met the criteria for current or lifetime major depression or dysthymia, suggesting to the authors that additional categories for milder forms of depression were not needed to account for the vast majority of depressive morbidity (Keller et al., 1995). As a result, the categories of minor depressive disorder and recurrent brief depressive disorder did not rise to the level of independent diagnoses, but instead remained under the rubric of depressive disorder, not otherwise specified. In 2000, DSM-IV-TR was completed to correct factual errors in DSM-IV, and include relevant research data developed since 1994.

The release of ICD-10 in 1995 brought the ICD system up to date regarding operationalized psychiatric diagnostic criteria (World Health Organization, 1993). Although their coding differs, the diagnostic criteria for mood disorders in ICD-10 largely correspond to those of DSM-IV-TR, as outlined in the following.

CURRENT MOOD DISORDER DIAGNOSTIC SYSTEMS

Following the example of DSM-III and its progeny, current mood disorder diagnostic systems, including the DSM IV-TR and ICD-10 Diagnostic Criteria for Research, emphasize the recognition of discrete, non-overlapping syndromes, comprising various combinations of core, prototypal mood episodes. An abbreviated list of mood disorder diagnostic criteria from ICD-10 Diagnostic Criteria for Research may be found in Table 29.1. For comparison with current DSM mood disorder diagnostic criteria, the reader is directed to DSM-IV-TR (American Psychiatric Association, 2000), described in brief in the following text, and the imminent DSM-5, scheduled for release in May 2013.

The DSM-IV-TR chapter on mood disorders stresses the exclusion of medically induced conditions, substance-induced conditions, stress-induced conditions such as bereavement, other mood disorders, and symptomatically similar psychotic disorders. ICD-10 stipulates the exclusion of other mood disorders, and medically induced or substance-induced conditions. DSM-IV-TR requires the presence of clinically significant distress or impairment for mood disorder diagnosis, whereas ICD-10 does not. In both texts, bipolar syndromes assume hierarchical precedence over unipolar syndromes, and syndromes with higher symptom counts assume hierarchical precedence over syndromes with lower symptom counts. In DSM-IV-TR, a variety of prognostically informative specifiers add further characterization to the current mood episode, and to the overarching mood disorder. Both the DSM-IV-TR and the ICD-10 attempt to capture dimensionality in mood disorder diagnosis by identifying, for the current episode, polarity (manic, mixed, or depressed), severity (mild, moderate, or severe), and presence or absence of psychotic features (assumed to occur only during severe mood episodes, an assumption disentangled by the upcoming DSM-5). Dimensionality in diagnosis is also implied by a spectrum covering syndromes with fewer to greater symptom counts (dysthymic disorder, cyclothymic disorder, major depressive disorder, bipolar II disorder, bipolar I disorder).

The structure of both current nosologic systems relies on syndromic prototypology, with diagnoses based on the presence of one or more core stem criteria, and the addition of any combination of a defined number of associated criteria. This prototypal approach inherently results in diagnostic heterogeneity, with hundreds of possible combinations underlying a single clinical diagnosis. Another consequence of this prototypal approach is the assumption of symptomatic equivalence amongst the criteria. In DSM-IV-TR major depressive episode, for example, depressed mood and anhedonia assume equivalent and interchangeable importance as stem criteria, and the remaining seven symptoms/signs also carry equal diagnostic weight as associated criteria.

EPISODES

MAJOR DEPRESSIVE EPISODE

Depressed mood and/or anhedonia comprise the core stem criteria for DSM-IV-TR major depressive episode. Additional criteria for major depressive disorder in DSM-IV-TR include: weight

loss/gain or appetite increase/decrease; insomnia or hypersomnia; psychomotor agitation or retardation; fatigue or loss of energy; feelings of worthlessness or inappropriate guilt; diminished ability to think or concentrate, or indecisiveness; and recurrent thoughts of death or recurrent suicidal ideation or suicide attempt or suicide plan. The DSM-IV-TR diagnosis of a major depressive episode requires the presence of at least one core stem criterion, plus four of the other listed depressive signs or symptoms, for at least two weeks. The DSM-IV-TR diagnosis of a major depressive episode furthermore stipulates that criteria are not currently met for a mixed episode, that depressive symptoms cause clinically significant distress or impairment, and that symptoms are not better accounted for by substance use, a general medical condition, or bereavement. ICD-10 criteria for a depressive episode echo most of the DSM-IV-TR criteria, with the exceptions that ICD-10 also recognizes diminished energy or increased fatigability as a core stem criterion, ICD-10 does not stipulate a bereavement exclusion, ICD-10 excludes patients who have ever met criteria for a lifetime hypomanic or manic episode, ICD-10 recognizes loss of confidence and self-esteem as an additional criterion, ICD-10 does not require clinically significant distress or impairment, and ICD-10 has a diagnostic threshold of four total symptoms instead of five. ICD-10 may thus pick up less severe depressive states than DSM-IV-TR.

MANIC EPISODE

In both DSM-IV-TR and ICD-10, core stem criteria for a manic episode include elevated, expansive, or irritable mood. Elevated or expansive mood carry more weight as core criteria, as their presence requires only three additional associated criteria to make the diagnosis, whereas irritable mood requires four. Additional criteria for manic episode in DSM-IV-TR include: inflated self-esteem or grandiosity; decreased need for sleep; flight or ideas or racing thoughts; distractibility; increase in goal directed activity or psychomotor agitation; and excessive involvement in pleasurable activities with high potential for painful consequences. The diagnosis requires syndromic duration of one week, or lesser duration if hospitalization is required. Again, DSM-IV-TR also requires clinically significant distress or impairment for diagnosis, whereas ICD-10 does not. DSM-IV-TR and ICD-10 also differ in some of their additional criteria for a manic episode. For example, ICD-10 recognizes as an additional criterion the loss of normal social inhibitions with resultant inappropriate behavior. ICD-10 also separates marked sexual energy or indiscretions from foolhardy or reckless behavior with a high degree of risk, whereas in DSM-IV-TR these phenomena are subsumed under one criterion.

MIXED EPISODE

The diagnosis of mixed episode in DSM-IV-TR requires the simultaneous presence of criteria for a major depressive episode and a manic episode. In ICD-10, a mixed episode is captured under the diagnosis of F38.0, mixed affective episode, and bipolar disorder current episode mixed. ICD-10 does not require the full depressive and manic syndromes to be present concurrently for a mixed episode diagnosis, but rather the

TABLE 29.1. ICD-10 mood disorders (World Health Organization, 1993)

F30–F39 MOOD [AFFECTIVE] DISORDERS
F30 MANIC EPISODE
<i>F30.0 Hypomania</i>
A. The mood is elevated or irritable to a degree that is definitely abnormal for the individual concerned and sustained for at least four consecutive days.
B. At least three of the following must be present, leading to some interference with personal functioning in daily living:
(1) increased activity or physical restlessness;
(2) increased talkativeness;
(3) difficulty in concentration or distractibility;
(4) decreased need for sleep;
(5) increased sexual energy;
(6) mild spending sprees, or other types of reckless or irresponsible behavior;
(7) increased sociability or overfamiliarity.
C. The episode does not meet the criteria for mania (F30.1 and F30.2), bipolar affective disorder (F31.-), depressive episode (F32.-), cyclothymia (F34.0), or anorexia nervosa (F50.0).
D. Most commonly used exclusion criteria: the episode is not attributable to psychoactive substance use (F1) or any organic mental disorder, in the sense of F0.
<i>F30.1 Mania without psychotic symptoms</i>
A. A mood that is predominantly elevated, expansive, or irritable, and definitely abnormal for the individual concerned. This mood change must be prominent and sustained for at least a week (unless it is severe enough to require hospital admission).
B. At least three of the following must be present (four if the mood is merely irritable), leading to severe interference with personal functioning in daily living:
(1) Increased activity or physical restlessness;
(2) Increased talkativeness (“pressure of speech”);
(3) Flight of ideas or the subjective experience of thoughts racing;
(4) Loss of normal social inhibitions resulting in behavior that is inappropriate to the circumstances;
(5) Decreased need for sleep;
(6) Inflated self-esteem or grandiosity;
(7) Distractibility or constant changes in activity or plans;
(8) Behavior that is foolhardy or reckless and whose risks the subject does not recognize, e.g., spending sprees, foolish enterprises, reckless driving;
(9) Marked sexual energy or sexual indiscretions.
C. The absence of hallucinations or delusions, although perceptual disorders may occur (e.g., subjective hyperacusis, appreciation of colors as specially vivid, etc.).
D. Most commonly used exclusion criteria: the episode is not attributable to psychoactive substance use (F1) or any organic mental disorder, in the sense of F0.
<i>F30.2 Mania with psychotic symptoms</i>
A. The episode meets the criteria for mania without psychotic symptoms (F30.1) with exception of criterion C.
B. The episode does not simultaneously meet the criteria for schizophrenia (F20) or schizoaffective disorder, manic type (F25.0).
C. Delusions or hallucinations are present, other than those listed as typical schizophrenic in F20 G1.1b, c, and d (i.e., delusions other than those that are completely impossible or culturally inappropriate, and hallucinations that are not in the third person or giving a running commentary). The commonest examples are those with grandiose, self-referential, erotic, or persecutory content.

(Continued)

TABLE 29.1. (Continued)

F30–F39 MOOD [AFFECTIVE] DISORDERS
D. Most commonly used exclusion criteria: the episode is not attributable to psychoactive substance use (F1) or any organic mental disorder, in the sense of F0.
A fifth character may be used to specify whether the hallucinations or delusions are congruent or incongruent with the mood:
F30.20 mania with mood congruent psychotic symptoms (such as grandiose delusions or voices telling the subject that he has superhuman powers)
F30.21 mania with mood incongruent psychotic symptoms (such as voices speaking to the subject about affectively neutral topics, or delusions of reference or persecution)
F30.8 Other manic episodes
F30.9 Manic episode, unspecified
F31 BIPOLAR AFFECTIVE DISORDER
Note: Episodes are demarcated by a switch to an episode of opposite or mixed polarity or by a remission.
F31.0 Bipolar affective disorder, current episode hypomanic
A. The current episode meets the criteria for hypomania (F30.0).
B. There has been at least one other affective episode in the past, meeting the criteria for hypomanic or manic episode (F30.-), depressive episode (F32.-), or mixed affective episode (F38.00).
F31.1 Bipolar affective disorder, current episode manic without psychotic symptoms
A. The current episode meets the criteria for mania without psychotic symptoms (F30.1).
B. There has been at least one other affective episode in the past, meeting the criteria for hypomanic or manic episode (F30.-), depressive episode (F32.-), or mixed affective episode (F38.00).
F31.2 Bipolar affective disorder, current episode manic with psychotic symptoms
A. The current episode meets the criteria for mania with psychotic symptoms (F30.2).
B. There has been at least one other affective episode in the past, meeting the criteria for hypomanic or manic episode (F30.-), depressive episode (F32.-), or mixed affective episode (F38.00).
A fifth character may be used to specify whether the psychotic symptoms are congruent or incongruent with the mood:
F31.20 with mood-congruent psychotic symptoms
F31.21 with mood-incongruent psychotic symptoms
F31.3 Bipolar affective disorder, current episode moderate or mild depression
A. The current episode meets the criteria for a depressive episode of either mild (F32.0) or moderate severity (F32.1).
B. There has been at least one other affective episode in the past, meeting the criteria for hypomanic or manic episode (F30.-) or mixed affective episode (F38.00).
A fifth character may be used to specify the presence of the somatic syndrome as defined in F32, in the current episode of depression:
F31.30 without somatic syndrome
F31.31 with somatic syndrome
F31.4 Bipolar affective disorder, current episode severe depression without psychotic symptoms
A. The current episode meets the criteria for a severe depressive episode without psychotic symptoms (F32.2).
B. There has been at least one well-authenticated hypomanic or manic episode (F30.-) or mixed affective episode (F38.00) in the past.
F31.5 Bipolar affective disorder, current episode severe depression with psychotic symptoms
A. The current episode meets the criteria for a severe depressive episode with psychotic symptoms (F32.3).
B. There has been at least one well-authenticated hypomanic or manic episode (F30.-) or mixed affective episode (F38.00) in the past.
A fifth character may be used to specify whether the psychotic symptoms are congruent or incongruent with the mood:
F31.50 with mood-congruent psychotic symptoms
F31.51 with mood-incongruent psychotic symptoms

(Continued)

TABLE 29.1. (Continued)

F30–F39 MOOD [AFFECTIVE] DISORDERS
F31.6 Bipolar affective disorder, current episode mixed
A. The current episode is characterized by either a mixture or a rapid alternation (i.e., within a few hours) of hypomanic, manic, and depressive symptoms.
B. Both manic and depressive symptoms must be prominent most of the time during a period of at least 2 weeks.
C. There has been at least one well-authenticated hypomanic or manic episode (F30.-), depressive (F32.-) or mixed affective episode (F38.00) in the past.
F31.7 Bipolar affective disorder, currently in remission
A. The current state does not meet the criteria for depressive or manic episode in any severity, or for any other mood disorder in F3 (possibly because of treatment to reduce the risk of future episodes).
B. There has been at least one well-authenticated hypomanic or manic episode (F30.-) in the past and, in addition, at least one other affective episode (hypomanic or manic (F30.-), depressive (F32.-), or mixed (F38.00).
F31.8 Other bipolar affective disorders
F31.9 Bipolar affective disorders, unspecified
F32 DEPRESSIVE EPISODE
G1. The depressive episode should last for at least 2 weeks.
G2. There have been no hypomanic or manic symptoms sufficient to meet the criteria for hypomanic or manic episode (F30.-) at any time in the individual's life.
G3. Most commonly used exclusion clause: The episode is not attributable to psychoactive substance use (F10–F19) or to any organic mental disorder (in the sense of F00–F09).
SOMATIC SYNDROME
Some depressive symptoms are widely regarded as having special clinical significance and are here called "somatic." (Terms such as "biological," "vital," "melancholic," or "endogenomorphic" are used for this syndrome in other classifications.) A fifth character (as indicated in F31.3; F32.0 and F32.1; F33.0 and F33.1) may be used to specify the presence or absence of the somatic syndrome. To qualify for the somatic syndrome, four of the following symptoms should be present:
(1) marked loss of interest or pleasure in activities that are normally pleasurable;
(2) lack of emotional reactions to events or activities that normally produce an emotional response;
(3) waking in the morning 2 hours or more before the usual time;
(4) depression worse in the morning;
(5) objective evidence of marked psychomotor retardation or agitation (remarked on or reported by other people);
(6) marked loss of appetite;
(7) weight loss (5% or more of body weight in the past month);
(8) marked loss of libido.
In <i>The ICD-10 Classification of Mental and Behavioural Disorders: Clinical Descriptions and Diagnostic Guidelines</i> , the presence or absence of the somatic syndrome is not specified for severe depressive episode, since it is presumed to be present in most cases. For research purposes, however, it may be advisable to allow for the coding of the absence of the somatic syndrome in severe depressive episode.
F32.0 Mild depressive episode
A. The general criteria for depressive episode (F32) must be met.
B. At least two of the following three symptoms must be present:
(1) depressed mood to a degree that is definitely abnormal for the individual, present for most of the day and almost every day, largely uninfluenced by circumstances, and sustained for at least 2 weeks.
(2) loss of interest or pleasure in activities that are normally pleasurable;
(3) decreased energy or increased fatigability.

(Continued)

TABLE 29.1. (Continued)

F30–F39 MOOD [AFFECTIVE] DISORDERS
C. An additional symptom or symptoms from the following list should be present, to give a total of at least four:
(1) loss of confidence and self-esteem;
(2) unreasonable feelings of self-reproach or excessive and inappropriate guilt;
(3) recurrent thoughts of death or suicide, or any suicidal behavior;
(4) complaints or evidence of diminished ability to think or concentrate, such as indecisiveness or vacillation;
(5) change in psychomotor activity, with agitation or retardation (either subjective or objective);
(6) sleep disturbance of any type;
(7) change in appetite (decrease or increase) with corresponding weight change
A fifth character may be used to specify the presence or absence of the “somatic syndrome” (as defined in F32):
F32.00 Without somatic syndrome
F32.01 With somatic syndrome
F32.1 Moderate depressive episode
A. The general criteria for depressive episode (F32) must be met.
B. At least two of the three symptoms listed for F32.0, criterion B, must be present.
C. Additional symptoms from F32.0, criterion C, must be present, to give a total of at least six.
A fifth character may be used to specify the presence or absence of the “somatic syndrome” as defined in F32:
F32.10 Without somatic syndrome
F32.11 With somatic syndrome
F32.2 Severe depressive episode without psychotic symptoms
Note: If important symptoms such as agitation or retardation are marked, the patient may be unwilling or unable to describe many symptoms in detail. An overall grading of severe episode may still be justified in such a case.
A. The general criteria for depressive episode (F32) must be met.
B. All three of the symptoms in criterion B, F32.0, must be present.
C. Additional symptoms from F32.0, criterion C, must be present, to give a total of at least eight.
D. There must be no hallucinations, delusions, or depressive stupor.
F32.3 Severe depressive episode with psychotic symptoms
A. The general criteria for depressive episode (F32) must be met.
B. The criteria for severe depressive episode without psychotic symptoms (F32.2) must be met with the exception of criterion D.
C. The criteria for schizophrenia (F20.-) or schizoaffective disorder, depressive type (F25.1) are not met.
D. Either of the following must be present:
(1) delusions or hallucinations, other than those listed as typically schizophrenic in F20, criterion G1(1)b, c, and d (i.e., delusions other than those that are completely impossible or culturally inappropriate and hallucinations that are not in the third person or giving a running commentary); the most common examples are those with depressive, guilty, hypochondriacal, nihilistic, self-referential, or persecutory content;
(2) depressive stupor.
A fifth character may be used to specify whether the psychotic symptoms are congruent or incongruent with mood:
F32.30 With mood-congruent psychotic symptoms (i.e., delusions of guilt, worthlessness, bodily disease, or impending disaster, derisive or condemnatory auditory hallucinations)
F32.31 With mood-incongruent psychotic symptoms (i.e., persecutory or self-referential delusions and hallucinations without an affective content)

(Continued)

TABLE 29.1. (Continued)

F30–F39 MOOD [AFFECTIVE] DISORDERS
F32.8 Other depressive episodes
Episodes should be included here that do not fit the descriptions given for depressive episodes in F32.0–F32.3, but for which the overall diagnostic impression indicates that they are depressive in nature. Examples include fluctuating mixtures of depressive symptoms (particularly those of the somatic syndrome) with non-diagnostic symptoms such as tension, worry, and distress, and mixtures of somatic depressive symptoms with persistent pain or fatigue not due to organic causes (as sometimes seen in general hospital services).
F32.9 Depressive episode, unspecified
F33 RECURRENT DEPRESSIVE DISORDER
G1. There has been at least one previous episode, mild (F32.0), moderate (F32.1), or severe (F32.2 or F32.3), lasting a minimum of 2 weeks and separated from the current episode by at least 2 months free from any significant mood symptoms.
G2. At no time in the past has there been an episode meeting the criteria for hypomanic or manic episode (F30.-).
G3. Most commonly used exclusion criteria: the episode is not attributable to psychoactive substance use (F1) or any organic mental disorder, in the sense of F0.
It is recommended to specify the predominant type of previous episodes (mild, moderate, severe, uncertain).
F33.0 Recurrent depressive disorder, current episode mild
A. The general criteria for recurrent depressive disorder (F33) are met.
B. The current episode meets the criteria for depressive episode, mild severity (F32.0).
A fifth character may be used to specify the presence of the somatic syndrome, as defined in F32, in the current episode:
F33.00 without somatic syndrome
F33.01 with somatic syndrome
F33.1 Recurrent depressive disorder, current episode moderate
A. The general criteria for recurrent depressive disorders (F33) are met.
B. The current episode meets the criteria for depressive episode, moderate severity (F32.1).
A fifth character may be used to specify the presence of the somatic syndrome, as defined in F32, in the current episode:
F33.10 without somatic syndrome
F33.11 with somatic syndrome
F33.2 Recurrent depressive disorder, current episode severe without psychotic symptoms
A. The general criteria for recurrent depressive disorders (F33) are met.
B. The current episode meets the criteria for severe depressive episode without psychotic symptoms (F32.2).
F33.3 Recurrent depressive disorder, current episode severe with psychotic symptoms
A. The general criteria for recurrent depressive disorders (F33) are met.
B. The current episode meets the criteria for severe depressive episode with psychotic symptoms (F32.3).
A fifth character may be used to specify whether the psychotic symptoms are congruent or incongruent with the mood:
F33.30 with mood congruent psychotic symptoms
F33.31 with mood incongruent psychotic symptoms
F33.4 Recurrent depressive disorder, currently in remission
A. The general criteria for recurrent depressive disorder (F33) have been met in the past.
B. The current state does not meet the criteria for a depressive episode (F32.-) of any severity, or for any other disorder in F3 (the patient may receive treatment to reduce the risk of further episodes).
F33.8 Other recurrent depressive disorders
F33.9 Recurrent depressive disorder, unspecified

(Continued)

TABLE 29.1. (Continued)

F30–F39 MOOD [AFFECTIVE] DISORDERS
F34 PERSISTENT MOOD [AFFECTIVE] DISORDERS
F34.0 Cyclothymia
A. A period of at least 2 years of instability of mood involving several periods of both depression and hypomania, with or without intervening periods of normal mood.
B. None of the manifestations of depression or hypomania during such a 2-year period should be sufficiently severe or long-lasting to meet criteria for manic episode or depressive episode (moderate or severe); however, manic or depressive episode(s) may have occurred before, or may develop after, such a period of persistent mood instability.
C. During at least some of the periods of depression at least three of the following should be present:
(1) A reduction in energy or activity;
(2) Insomnia;
(3) Loss of self-confidence or feelings of inadequacy;
(4) Difficulty concentrating;
(5) Social withdrawal;
(6) Loss of interest or enjoyment in sex and other pleasurable activities;
(7) Less talkative than normal;
(8) Pessimistic about the future or brooding over the past.
D. During at least some of the periods of mood elevation at least three of the following should be present:
(1) Increased energy or activity;
(2) Decreased need for sleep;
(3) Inflated self-esteem;
(4) Sharpened or unusually creative thinking;
(5) More gregarious than normal;
(6) More talkative or witty than normal;
(7) Increased interest and involvement in sexual and other pleasurable activities;
(8) Overoptimism or exaggeration of past achievements.
Note: If desired, specify whether onset is early (in late teenage or the twenties) or late (usually between age 30 to 50 subsequent to an affective episode).
F34.1 Dysthymia
A. A period of at least 2 years of constant or constantly recurring depressed mood. Intervening periods of normal mood rarely last for longer than a few weeks and there are no episodes of hypomania.
B. None, or very few, of the individual episodes of depression within such a 2-year period are severe enough, or last long enough, to meet the criteria for recurrent mild depressive disorder (F33.0).
C. During at least some of the periods of depression at least three of the following should be present:
(1) A reduction in energy or activity;
(2) Insomnia;
(3) Loss of self-confidence or feelings of inadequacy;
(4) Difficulty concentrating;
(5) Often in tears;
(6) Loss of interest or enjoyment in sex and other pleasurable activities;

(Continued)

TABLE 29.1. (Continued)

F30–F39 MOOD [AFFECTIVE] DISORDERS
(7) Feeling of hopelessness or despair;
(8) A perceived inability to cope with the routine responsibilities of everyday life;
(9) Pessimistic about the future or brooding over the past;
(10) Social withdrawal;
(11) Less talkative than normal.
Note: If desired, specify whether onset is early (in late teenage or the twenties) or late (usually between age 30 to 50 subsequent to an affective episode).
F34.8 Other persistent mood [affective] disorders
A residual category for persistent affective disorders that are not sufficiently severe or long-lasting to fulfill the criteria for cyclothymia (F34.0) or dysthymia (F34.1) but that are nevertheless clinically significant. Some types of depression previously called “neurotic” are included here, provided that they do not meet the criteria for either cyclothymia (F34.0) or dysthymia (F34.1) or for depressive episode of mild (F32.0) or moderate (F32.1) severity.
F34.9 Persistent mood [affective] disorder, unspecified
F38 OTHER MOOD [AFFECTIVE] DISORDERS
There are so many possible disorders that could be listed under F38 that no attempt has been made to specify criteria, except for mixed affective episode (F38.00). Investigators requiring criteria more exact than the Diagnostic Guidelines should construct them according to the requirements of their study.
F38.0 Other single mood [affective] disorders
F38.00 Mixed affective episode
A. The episode is characterized by either a mixture or a rapid alternation (i.e., within a few hours) of hypomanic, manic, and depressive symptoms.
B. Both manic and depressive symptoms must be prominent most of the time during a period of at least 2 weeks.
C. No previous hypomanic, depressive, or mixed episodes.
F38.1 Other recurrent mood [affective] disorders
F38.10 Recurrent brief depressive disorder
A. The disorder meets the symptomatic criteria of either mild (F32.0), moderate (F32.1), or severe depressive episode (F32.2)
B. The depressive episodes occur about once a month over the past year.
C. The individual episodes last less than 2 weeks (typically 2 to 3 days).
D. The episodes do not occur solely in relation to the menstrual cycle.
F38.8 Other specified mood [affective] disorders
This is a residual category for affective disorders that do not meet the criteria for any other categories F30-F38.
F39 Unspecified mood [affective] disorder

mixture or rapid alternation of manic and depressive *symptoms* for two weeks, with the number and intensity of symptoms not defined. As such, ICD-10 may pick up a wider variety of mixed states, including agitated depressive episodes or subsyndromal hypomanic states concurrent with depressive episodes.

HYPOMANIC EPISODE

In DSM-IV-TR, the diagnosis of hypomanic episode differs from that of manic episode only in required duration (minimum four days versus minimum one week), and degree of dysfunction (hypomanic episode defined as not severe enough to cause hospitalization or marked impairment). ICD-10 criteria for a hypomanic episode share the same duration requirements as

DSM-IV-TR, but require only three additional symptoms, regardless of whether the core mood is elevated or irritable. ICD-10 furthermore does not recognize expansive mood as a core criterion for a hypomanic episodes, yet recognizes some different additional criteria, such as increased sociability or overfamiliarity.

DISORDERS

MAJOR DEPRESSIVE DISORDER AND RECURRENT DEPRESSIVE DISORDER

The DSM-IV-TR diagnosis of major depressive disorder requires the presence of one or more major depressive episodes, and the exclusion of other mood disorders, concurrent

psychotic disorders, or medically induced or substance-induced mood disorders. The diagnosis of ICD-10 recurrent depressive disorder requires at least two depressive episodes, and exclusion of medically induced or substance-induced mood disorders, whereas exclusion of bipolar mood disorders is already implied in the ICD-10 criteria for depressive episode.

BIPOLAR I AND II DISORDERS, AND BIPOLAR AFFECTIVE DISORDER

Bipolar I disorder in DSM-IV-TR requires the presence of at least one manic or mixed episode, although the current episode may be specified as hypomanic, manic, mixed, or depressed. Bipolar II disorder is defined as the presence of one or more major depressive episodes, and at least one episode of hypomania, without history of full mania or mixed episodes. For both bipolar I and II disorders, schizoaffective disorders and psychotic disorders must not better account for the disorder at hand. ICD-10 bipolar affective disorder stipulates the presence of a hypomanic, manic, mixed, or depressive episode, plus at least one other mood episode, which must be hypomanic or manic if the current episode is depressed. In this way, ICD-10 groups together the DSM-IV-TR diagnoses of bipolar I and II disorders.

DYSTHYMIC DISORDER AND CYCLOTHYMIA

Dysthymic disorder in DSM-IV-TR requires the presence of a predominantly depressed mood, plus two or more additional depressive symptoms, whose total does not meet or exceed the threshold for major depressive disorder, plus no more than two months of euthymia, during a period of at least two years. Additional criteria for dysthymic disorder in DSM-IV-TR include: poor appetite or overeating; insomnia or hypersomnia; low energy or fatigue; poor concentration or difficulty making decisions; and feelings of hopelessness. Major depressive episodes or other mood episodes may supervene after two years of the diagnosis of DSM-IV-TR dysthymic disorder. Of course, all the usual DSM-IV-TR mood disorder exclusionary criteria apply. ICD-10 defines dysthymia in largely the same way as DSM-IV-TR, although in addition to the stem core criterion of depressed mood, ICD-10 requires at least three additional depressive symptoms. ICD-10 also allows for the possibility of a full depressive episode during the initial diagnostic period of dysthymia, and recognizes a greater diversity of additional diagnostic criteria, such as tearfulness, loss of interest or enjoyment in pleasurable activities, perceived inability to cope, pessimism or brooding, social withdrawal, and diminished talkativeness.

DSM-IV-TR cyclothymia requires the presence of two years of alternating periods of hypomania and depressive symptoms not meeting criteria for major depressive episode, without more than two months of euthymia at any time during the disturbance. The patient must not have evidence of full mania, mixed states, or major depressive episodes for the first two years of the disorder, but may go on to develop full blown bipolar disorder after this time. The usual exclusion of other mood disorders, psychotic disorders, and medically induced as well as substance-induced disorders apply. ICD-10 defines cyclothymia in much the same fashion as DSM-IV-TR, although without the two-month limit on euthymic periods, and with specifically spelled-out symptom criteria for the periods of

hypomania and depressive symptoms, including some unique hypomanic symptoms such as sharpened or unusually creative thinking, increased gregariousness, increased wittiness, and overoptimism or exaggeration of past achievements.

MEDICALLY INDUCED AND SUBSTANCE-INDUCED MOOD DISORDERS

Mood disturbances comprise common manifestations of many general medical conditions, substance use syndromes, and treatment with prescribed medical therapies. Medically ill patients require screening for and evidenced-based treatment of mood disorders (Evans et al., 2005), as do patients with substance use disorders, and patients undergoing known mood-altering medical therapies.

Clinically significant depressive symptoms have been reported in 14–43% of patients with HIV (Cysique et al., 2007; Gibbie et al., 2007), up to 85% of patients with Hepatitis C (Nelligan et al., 2008), 8–18% of patients with diabetes (Gendelman et al., 2009; Li et al., 2008), 20% of patients with COPD (Cleland et al., 2007), 50% of patients with asthma (Van Lieshout et al., 2009), 9–31% of patients after CVA (Brodaty et al., 2007), 14% of patients with CAD (Shanmugasaram et al., 2012), 20% of patients after acute myocardial infarction (Thombs et al., 2006), 20–55% of patients with epilepsy (Kanner 2003), 19–61% of patients after TBI (Kim et al., 2007), 40–60% of patients with multiple sclerosis (Wallin et al., 2006), 30–50% of patients with Alzheimer's disease (Lee and Lyketsos, 2003), 22–29% of patients with cancer (Raison and Miller, 2003), 20–30% of patients with obesity (Stunkard et al., 2003), 30–54% of patients with chronic pain conditions (Campbell et al., 2003), and 4–75% of patients with idiopathic Parkinson's disease (McDonald et al., 2003). Depressive symptoms also feature prominently in patients with endocrine disturbances, including 57–80% of patients with Cushing's syndrome (Haskett, 1985; Kelly, 1996), 30% of patients with hyperthyroidism (Kathol and Delahunty, 1986), and frequently in hypothyroidism (Whybrow et al., 1969). Hyperparathyroidism, hypoparathyroidism, Addison's disease, B vitamin deficiencies, folic acid deficiency, malnutrition, electrolyte imbalances, acid-base disturbances, and uremia have also been associated with clinically significant depressive symptoms, among other neuropsychiatric disturbances (Harrison and Kopelman, 2009, pp. 617–688).

Depressive symptoms in HIV correlate with treatment non-adherence and decreased viral response (Sumari de-Boer et al., 2012; Tsai et al., 2013), and in hepatitis C correlate with treatment non-adherence (Liu et al., 2010). Depressive symptoms in type I diabetes associate with lower therapeutic adherence (Van Tilburg et al., 2001), increased risk of medical complications (de Groot et al., 2001), and increased mortality (Milano and Singer, 2007). Depressive symptoms after CVA correlate with poor functional recovery and higher mortality (Gothe et al., 2012). Depressive symptoms following myocardial infarction predict repeat MI and death (Barth et al., 2004; Glassman et al., 2002). A diagnosis of major depressive disorder in hospitalized elderly patients correlates with increased in-hospital mortality and length of inpatient care (Koenig et al., 1989). Depressive symptoms in cancer patients correlate with greater physical disability (Bukberg, 1984) and increased

mortality (Brown et al., 2003). Furthermore, depressive symptoms in the context of many general medical disorders, such as hepatitis C undergoing interferon treatment (Kraus et al., 2008), HIV (Tsai et al., 2013), CVA (Hackett et al., 2008), and multiple sclerosis (Mohr et al., 2001) are responsive to treatment.

Clinically significant manic symptoms have been reported in 1% of post-CVA patients and 9% of post-TBI patients (Jorge et al., 1993), 2–12% of Huntington's disease patients (Mendez, 1994), 39% of patients with thyrotoxicosis (Brownlie et al., 2000), 27% of patients with Cushing's syndrome (Haskett, 1985), and 3–22% of patients with epilepsy (Robertson, 1992). Clinically significant manic symptoms have also been associated with CNS tumors; multiple sclerosis; complex partial seizures; viral, fungal, and Treponemal meningoencephalitis; Parkinson's disease; Wilson's disease; Cushing's disease; hyperthyroidism; B vitamin deficiencies; and other general medical conditions (Krauthammer and Klerman, 1978; Levenson 2011: p. 227; Mendez, 2000).

In an effort to account for mood disturbances in the context of general medical conditions and substance use disorders: DSM-IV-TR and ICD-10 list diagnostic criteria for mood disorders due to general medical condition, and DSM-IV-TR in particular lists diagnostic criteria for substance-induced mood disorder.

DSM-IV-TR criteria for Mood Disorder due to a General Medical Condition stipulate the presence of prominent and persistent mood symptoms corresponding to the core stem criteria for Major Depressive Episode and/or Manic Episode, in addition to evidence that the disorder is a physiologic consequence of a general medical condition, not better accounted for by another mental disorder, not occurring exclusively during the course of delirium, and causing clinically significant distress or impairment. In contrast to the diagnoses of primary idiopathic mood disorders, the DSM-IV-TR diagnosis of Mood Disorder due to a General Medical Condition does not dictate a threshold number of symptoms; the presence of one stem criterion suffices for the diagnosis. DSM-IV-TR further specifies subtypes, including With Depressive Features, With Manic Features, With Mixed Features, and With Major Depressive-Like Episode. ICD-10 criteria for Mental Disorders due to Brain Damage and Dysfunction and to Physical Disease require objective evidence or history of a medical disorder known to cause cerebral dysfunction, a presumed temporal relationship between development of the medical condition and the mental disorder, recovery or improvement of mental disorder following recovery or improvement from the medical condition, absence of convincing evidence for alternative causation of the mental disorder, and full criteria for one of the primary mood disorders outlined later in ICD-10. The latter criterion makes ICD-10 criteria more stringent than DSM-IV-TR in diagnosing mood disorders due to general medical conditions. ICD-10 further defines subtypes of Organic Manic/Bipolar/Depressive/Mixed Affective Disorder. ICD-10 delineates between provisional and certain diagnoses of organic mood disorders, with certainty dictated by the presence of evidence of recovery or improvement of mental disorder following recovery or improvement from the medical condition.

Similarly, many substance intoxication and withdrawal syndromes include core mood disorder disturbances. For example, euphoria, increased sociability, excitement, inexhaustibility, rambling speech, insomnia, mood lability, agitation, irritability, dysphoria, aggression, heightened sexuality, restlessness, anxiety, depression, interpersonal sensitivity, appetite changes, fatigue, psychomotor retardation, hypersomnia, and hallucinations may occur during intoxication or withdrawal from ethanol, amphetamines, cocaine, caffeine, cannabis, or hallucinogens (American Psychiatric Association, 2000). Furthermore, many drug therapies for general medical conditions have been associated with clinically significant depressive symptoms, including corticosteroids, interferon alpha, interleukin 2, GRH agonists, mefloquine, and propranolol (Patten and Barbui, 2004). Drug therapies for general medical conditions have also been associated with clinically significant manic symptoms, including dopaminergic agents, noradrenergic agents, serotonergic agents, corticosteroids, and anabolic steroids (Krauthammer and Klerman, 1978; Levenson, 2011: p. 227).

DSM-IV-TR criteria for Substance-Induced Mood Disorder require the presence of prominent and persistent mood symptoms, corresponding to core stem criteria for Major Depressive Episode and/or Manic Episode, in addition to evidence that the mood symptoms are temporally (within one month) or etiologically linked to substance use, intoxication, or withdrawal, not better accounted for by another mood disorder, not occurring exclusively during the course of delirium, and causing clinically significant distress or impairment. DSM-IV-TR does not dictate a threshold number of additional mood symptoms for diagnosis. Subtypes include With Depressive Features, With Manic Features, and With Mixed Features. Specifiers include With Onset During Intoxication, and With Onset During Withdrawal. ICD-10 does not define specific criteria for substance-induced mood disorders.

OTHER MOOD DISORDERS

Other mood disorders in DSM-IV-TR are captured by diagnoses of depressive disorder NOS, bipolar disorder NOS, and mood disorder NOS. ICD-10 similarly accounts for several other mood disorders. DSM-IV-TR in particular allows that these diagnoses may be made when the clinician cannot determine whether the mood disorder is primary or due to a general medical condition.

SPECIFIERS

DSM-IV-TR includes prognostically informative specifiers for major depressive, manic, mixed, and recurrent episodes. Episode specifiers include severity, psychotic features, partial or full remission, single or recurrent episodes, melancholic features (for MDE only), atypical features (for MDE and dysthymia only), catatonic features, postpartum onset, and chronicity (for MDE only). Specifiers for recurrent mood episodes include with or without full interepisode recovery, with seasonal pattern, or with rapid cycling. In ICD-10, specifiers for severity, psychotic features, and recurrence apply to depressive episodes singly or as part of bipolar or recurrent depressive

disorders, and are implied for manic, mixed, or hypomanic episodes in the diagnosis of bipolar affective disorder. In the following are presented selected specifiers, with brief descriptions and clinical implications.

SEVERITY

Severity in DSM-IV-TR mood disorders is defined in two ways: total symptom counts above that required for diagnosis, and degree of impairment attributable to the disorder. ICD-10 defines the severity of depressive episodes in terms of total symptom counts, and defines hypomanic versus manic episodes in terms of symptom counts and degree of impairment.

A study by Lux et al. (2010) examined the coherence and validity of the DSM-IV definition of the severity of major depression in a sample of 1,015 Caucasian twins who met criteria for major depressive disorder in the year prior to the study interview. The authors operationalized three measures of severity, including criteria counts (the DSM-IV definition of severity), scaled severity of individual symptoms (which is not present in DSM-IV), and impairment of function in occupational, social, and relational domains (which is not present in the DSM-IV diagnostic criteria, but is reflected to some extent in the separate GAF rating on axis V). Validators of severity in the study included co-morbid psychiatric conditions, personality traits, characteristics of the index episode, prior history of depression, demographic characteristics at index episode, future episodes, and depressive episodes of the co-twin. The authors found that criteria count and severity of individual symptoms were each significantly associated with 14 validators, and that functional impairment was associated with 12 validators. No one measure of severity accounted for all validators, and each measure of severity appeared to tap into different sets of validators. The authors concluded that clinicians should probably use a combination of severity measures, including the severity of individual symptoms.

Severity can be attributed to other aspects of a mood disorder as well, including duration (chronic MDE is shown to respond more poorly to treatment), comorbid symptom severity [several studies have shown severe anxiety correlates with increased time spent in depression over decades, as well as higher risk for suicide], and comorbid substance abuse (predictive of poor long-term outcomes, and suicidal behavior) (Kim et al., 2011; Rush et al., 2012).

Severity in research studies of major mood disorders often takes the form of arbitrarily defined cutoffs on the more common mood disorder rating scales, such as the Hamilton Depression Rating Scale, Montgomery Asberg Depression Rating Scale, Young Mania Rating Scale, and so on.

Severity of depressive and manic episodes among patients with bipolar I and II disorders correlates longitudinally with degree of psychosocial dysfunction (Judd et al., 2005). In addition, severe depressive episodes in both major depressive disorder and bipolar disorder have been associated with treatment resistance (Mendlewicz et al., 2010; Souery et al., 2007). However, antidepressant trials in major depressive disorder tend to show larger effect sizes in more severely depressed populations (Fournier et al., 2010).

PSYCHOTIC FEATURES

DSM-IV-TR defines “with psychotic features” as the presence of delusions or hallucinations concurrent with the mood episode. DSM-IV-TR allows for both mood-congruent and mood-incongruent psychotic features. ICD-10 defines with psychotic features similarly, but excludes those delusions most typical of schizophrenia, such as bizarre delusions or voices with running commentary. In ICD-10, psychotic features in depressive, manic, or mixed episodes may also be mood-congruent or mood-incongruent. Neither DSM-IV-TR nor ICD-10 allows for psychotic features in mild or moderate depressive episodes or hypomania.

Baseline psychotic features in major depressive disorder tend to recur highly in subsequent major depressive episodes (Coryell et al., 1994). Psychotic features in major depressive disorder also appear to portend later onset of mania or hypomania (Fiedorowicz et al., 2011). Furthermore, psychotic features in mood disorders in general associate with worse prognosis. For example, over 10 years of follow-up, psychotic features in major depressive disorder portend longer duration of depressive episodes, shorter intervals between depressive episodes, and greater persistence of subthreshold mood symptoms (Coryell et al., 1996).

PARTIAL OR FULL REMISSION

DSM-IV-TR defines partial remission of a mood episode as having some symptoms of a mood episode, but not meeting full criteria, for at least two months. Full remission is defined as not demonstrating any symptoms of a mood episode for at least two months. ICD-10 defines remission in mood disorders as no longer meeting full criteria for an episode within the disorder, thus grouping together partial and full remission groups. ICD-10 does not define how long mood episode criteria need to be absent for remission.

In general, partial remission carries continued illness-related morbidity and risk of relapse. In major depressive disorder, for example, partial remission and other subthreshold depressive states are associated longitudinally with greater psychosocial impairment than full remission, with the gradient of impairment increasing with increasing numbers of depressive symptoms (Judd et al., 2000). This finding holds true with regard to subthreshold depressive states in bipolar I and II disorders as well (Judd et al., 2005).

SINGLE OR RECURRENT MAJOR DEPRESSIVE DISORDER

DSM-IV-TR defines recurrence in major depressive disorder as two or more major depressive episodes, as does ICD-10. As described in the text of the DSM-IV-TR, within major depressive disorder, a single major depressive episode has about a 60% change of recurrence, a second major depressive episode increases the risk of recurrence to about 70%, and a third major depressive episode increases recurrence risk to 90%. Although DSM-IV-TR and ICD-10 define recurrence in major depressive disorder as two or more major depressive episodes, highly recurrent major depressive disorders begin to behave more akin to bipolar disorder than major depressive disorder (Goodwin and Jamison, 2007). For example, highly

recurrent major depressive disorder probands show family histories enriched with bipolar disorders, convert to frank bipolarity more often than single episode or lowly recurrent major depressive disorder probands, and may respond preferentially to treatments shown to be effective in bipolar disorders. For these reasons, the DSM-IV-TR and ICD-10 definitions of recurrence have been criticized for not delineating definitions for highly recurrent major depressive disorder.

MELANCHOLIC FEATURES

Melancholic features, including dense anhedonia, non-reactive mood, diurnal variation, and neurovegetative signs, are among the oldest described symptoms in psychiatry. DSM-IV-TR defines melancholic features as requiring either loss of pleasure or lack of reactivity to usually pleasurable stimuli, plus three or more additional criteria such as: distinct quality of depressed mood; depression worse in the morning; early morning awakening; marked psychomotor retardation or agitation; and excessive or inappropriate guilt. ICD-10 refers to melancholic features as the somatic syndrome, defined similarly to DSM-IV-TR but without drawing a distinction between core and stem criteria. ICD-10 also notes that many other monikers have accompanied this syndrome in other classification schemes.

Melancholic features in major depressive disorder associate with increased comorbidity of anxiety disorders, greater number of lifetime depressive episodes, more severe impairment, lower levels of neuroticism, and increased risk of major depressive disorder in both mono- and dizygotic co-twins (Kendler, 1997). Melancholic features in major depressive disorder, bipolar I disorder, and bipolar II disorder also correlate with treatment resistance (Mendlewicz et al., 2010; Souery et al., 2007).

ATYPICAL FEATURES

In contrast to the implications of the term, atypical features of depression are not unusual in mood disorders. Historically, the term “atypical depression” stemmed from the striking difference between the clinical appearance of such presentations and that of the more classical endogenous or melancholic depressive syndromes, as well as the differential response of a particular form of atypical depression to MAOI pharmacotherapy as demonstrated by a research group from Columbia University (Davidson, 2007). The DSM-IV-TR criteria for atypical features in depression, derived from the criteria described by the aforementioned Columbia University group, include the stem criterion of mood reactivity, plus at least two of the following additional criteria: increased appetite or weight gain; hypersomnia; leaden paralysis; and a long-standing pattern of extreme sensitivity to perceived interpersonal rejection, occurring most of the time over a two-week period. ICD-10 does not include an atypical features specifier for depressive disorders.

Earlier studies in atypical depression that showed a higher rate of response to MAOI medications than tricyclic antidepressants have been eclipsed by more recent studies showing that SSRI antidepressants such as fluoxetine are equally effective as MAOIs in atypical depression.

CATATONIC FEATURES

The DSM-IV-TR catatonic features specifier is applied when the clinical picture of a mood episode is characterized by marked psychomotor disturbance including two or more of the following: marked motoric immobility such as catalepsy or stupor; excessive motor activity; extreme negativism or mutism; peculiarities of motor movement such as posturing or stereotypies or mannerisms or grimacing; and echolalia or echopraxia. ICD-10 does not have a catatonic features specifier in its section on mood disorders.

A patient with catatonia requires careful supervision to avoid self-harm, or harm to others. Malnutrition, exhaustion, hyperpyrexia, or self-inflicted injury may occur. Catatonic states have been reported in up to 5–9% of psychiatric inpatients. Between 25 and 50% of cases of catatonia occur in mood disorders and 10–15% occur in schizophrenia (American Psychiatric Association, 2000). Catatonia also occurs in postpartum psychosis in 0.1–0.5% of women within weeks of delivery, although it can occur within hours (Strain et al., 2012). However, catatonia is not unique to psychiatric conditions, as it has also been associated with a plethora of general medical conditions. Lastly, as with all catatonic syndromes, catatonic features in mood disorders may respond preferentially to high dose benzodiazepine pharmacotherapy, and may require electroconvulsive therapy (ECT) for definitive treatment.

POSTPARTUM ONSET

The DSM-IV-TR postpartum specifier can be applied to a mood disorder if the onset is within 4 weeks after childbirth. Symptoms may include fluctuations in mood, mood lability, and preoccupation with infant well-being, which may range from overconcern to frank delusions. The presence of severe ruminations or delusional thoughts about the infant is associated with a significantly increased risk of harm to the infant. ICD-10 does not specify postpartum onset. Postpartum depression affects 10–15% of women within six months after delivery. It is important to distinguish postpartum mood episodes from the “baby blues” that affect up to 70% of women within 10 days of delivery (American Psychiatric Association, 2000; Strain, 2012).

CHRONIC MAJOR DEPRESSIVE EPISODE

DSM-IV-TR defines a chronic specifier for major depressive episode, whereas ICD-10 does not. Chronicity in DSM-IV-TR requires that full major depressive episode criteria have been met for at least the past two years. Chronicity in a major depressive episode confers a poorer prognosis. Chronic major depressive disorder in particular has been associated with greater baseline socioeconomic disadvantage, lower baseline quality of life, lower baseline social and occupational functioning, and higher baseline medical disease and anxiety disorder burden. Furthermore, after treatment with antidepressant pharmacotherapy, chronic depression demonstrates continued poorer functioning and greater anxiety, despite an adjusted treatment response rate statistically indistinguishable from non-chronic depression (Sung et al., 2012). Another report, from the STAR*D study, demonstrates that patients with chronic index episodes of major

depressive disorder have lower and slower remission rates, as well as higher relapse rates, than patients with non-chronic index episodes (Rush et al., 2012). In addition, unlike in many studies of non-chronic major depressive disorder, in chronic major depressive disorder the addition of psychotherapy to pharmacotherapy does not appear consistently to provide short-term or long-term treatment benefits above pharmacotherapy alone, with the exception of small add-on effects on quality of life (von Wolff et al., 2012). CBASP (Cognitive Behavioral Analysis System of Psychotherapy) may represent one exception to these latter findings, as this form of psychotherapy has demonstrated add-on effects to pharmacotherapy in chronic major depressive disorder (Keller et al., 2000).

FULL INTEREPISODE RECOVERY

DSM-IV-TR defines full interepisode recovery as full remission attained between the two most recent mood episodes. Similar to partial versus full remission, full interepisode recovery portends better functionality.

SEASONAL PATTERN

In DSM-IV-TR, the seasonal pattern specifier describes a regular temporal occurrence of major depressive episodes in major depressive, bipolar I, or bipolar II disorders. Criteria require that both onset and remission of major depressive episodes occur at characteristic times of the year, that at least two major depressive episodes have occurred with this temporal seasonal pattern over the past two years, and that the number of major depressive episodes occurring during this temporal seasonal pattern outnumber the non-seasonal episodes. ICD-10 does not stipulate a seasonal pattern specifier in its mood disorders chapter. Seasonal major depressive episodes in major depressive disorder may respond to light therapy, although this therapy may also increase the rate of switching to hypomanic or manic episodes when used to treat seasonal depressive episodes in bipolar I or II disorder (American Psychiatric Association, 2000).

WITH RAPID CYCLING

The DSM-IV-TR rapid cycling specifier is applied to either bipolar I or bipolar II disorder diagnoses. The essential feature of the DSM-IV-TR definition of rapid-cycling bipolar disorder is the occurrence of four or more mood episodes during the previous year. ICD-10 does not account for a rapid cycling specifier. Rapid cycling occurs in 10–20% of individuals with bipolar disorder, and is much more commonly found in females, who comprise 70–90% of individuals with a rapid cycling pattern. These episodes are not linked to any particular phase of the menstrual cycle and are seen in both pre- and postmenopausal women (American Psychiatric Association, 2000). Induction of rapid cycling has been reported in association with maintenance tricyclic antidepressant use in five bipolar patients, despite concurrent treatment with lithium (Wehr and Goodwin, 1979). Successful treatment of rapid cycling bipolar disorder has been demonstrated using high dose levothyroxine, carbamazepine, and lamotrigine (Joyce, 1988; Stancer and Persad, 1982; Stromgren and Boller, 1985; Wang et al., 2010).

MOOD DISORDERS IN LATE LIFE

Neither DSM-IV-TR nor ICD-10 outlines criteria for depressive or bipolar disorders in late life (typically defined as older than 60–65 years). However, some important biopsychosocial considerations and phenomenological differences bear mentioning. Normative aging may be associated with altered sleep patterns, diminished sleep quality, diminished energy, decreased cognitive performance, motoric slowing, and interpersonal losses associated with sadness and bereavement. Furthermore, older patients typically manifest more general medical conditions, including conditions themselves linked to clinically significant depressive and/or manic symptoms. Lastly, given the physiologic effects of aging on pharmacokinetics, in combination with frequent pharmacologic treatment of general medical and psychiatric conditions, late life patients may be at particular risk for exposure to mood-altering pharmacotherapy.

Onset of major depressive disorder after age 60 is common, accounting for up to 50% of major depressive disorder diagnoses in late life. Adults with onset of major depressive disorder after age 60 typically evidence a history of less personality dysfunction, and lower burden of psychiatric family history. Patients with major depressive disorder in late life may exhibit more prominent melancholic symptoms, and psychotic symptoms, including prominent delusions of persecution, incurable illness, guilt, and nihilism or non-existence (Blazer and Steffens, 2009: p. 286). Furthermore, patients with depressive disorders in late life may also exhibit cognitive disturbances suggestive of dementia, termed pseudodementia (Snowdon, 2011), which typically demonstrates slowed processing speed, dysexecutive problems, and memory retrieval deficits. With successful treatment of depressive illness, pseudodementia appears reversible in the short term, yet predictive of later onset primary dementia (Saez-Fonseca et al., 2007). Similar to findings that late life patients with major depressive disorder demonstrate less comorbid personality pathology than younger patients with major depressive disorder (Devanand et al., 2002), late life patients with dysthymia also differ from younger patients with dysthymia in that they exhibit less comorbid personality pathology (Devanand et al., 2000). Specifically, late life patients with dysthymia or major depressive disorder appear preferentially to demonstrate cluster C personality pathology, in contradistinction to the cluster B personality pathology preferentially common in younger patients with dysthymia or major depressive disorder.

Bipolar disorder in late life may exhibit less classic euphoric mania, and more mixed depressive and manic symptomatology, with agitated depression and dysphoric mania commonly seen (Shulman and Post, 1980; Spar et al., 1979). Delirious mania may also present in late life bipolar disorder, exhibiting symptoms of mania along with catatonic symptoms and disturbed cognition (Blazer and Steffens, 2009: p. 285).

SEPARATION FROM OTHER CONDITIONS, DIFFERENTIAL DIAGNOSIS, AND COMORBIDITY

As outlined previously, in both DSM-IV-TR and ICD-10, diagnosing a primary idiopathic mood disorder requires

exclusion of other mood disorders, psychotic disorders, and medically induced or substance-induced disorders. Both systems leave it to the clinician's discernment to determine whether the apparent episode or disorder at hand is better accounted for by another condition. This diagnostic task is non-trivial, as many psychiatric disorders, general medical conditions, and substance use syndromes feature signs and symptoms that overlap significantly with mood disorders. For example, hypothyroidism and major depressive disorder both share possible symptoms of anergia, lassitude, impaired concentration and memory, weight gain, depressed mood, and dullness of expression. For the purposes of appropriate treatment planning, however, it remains clinically important to differentiate between primary idiopathic mood disorders, symptomatically overlapping psychiatric conditions, mood disorders due to general medical conditions, substance-induced mood disorders, and co-occurrence of primary and secondary disorders. A differential diagnosis list of possible medically induced and substance-induced mood disorders, as well as symptomatically overlapping psychiatric conditions, is listed in Table 29.2.

TABLE 29.2. General differential diagnosis for mood episodes and mood disorders

Substance-Induced Mood Disorder
Alcohol intoxication, withdrawal, abuse, or dependence
Sedative or hypnotic intoxication, withdrawal, abuse, or dependence
Stimulant intoxication, withdrawal, abuse, or dependence
Opioid intoxication, withdrawal, abuse, or dependence
Cannabis intoxication, withdrawal, abuse, or dependence
Anabolic steroid abuse or therapy
Corticosteroid therapy or withdrawal
Other immunomodulatory therapies
Chemotherapy for oncologic disease
HAART
Interferon therapy, e.g., in hepatitis C
Beta blockers
Malarial prophylaxis, especially with mefloquine
SSRIs, SNRIs, NRIs, TCAs, MAOIs
Stimulant therapy
Mood Disorder due to a General Medical Condition
Obstructive Sleep Apnea
Hyperthyroidism or Hypothyroidism

(Continued)

TABLE 29.2. (Continued)

Hyperparathyroidism or Hypoparathyroidism
Hyperpituitarism or Hypopituitarism
Hypercortisolemia or Hypocortisolemia
Hypotestosteronemia
Diabetes
Electrolyte Disturbances
Acid-Base Disturbances
Malnutrition
Vitamin Deficiency
Renal Failure
Hepatic Failure
Wilson's Disease
Malignancy
Brain Tumor or Metastasis
Systemic Effects of Peripheral Malignancy
Paraneoplastic Syndromes
Paraneoplastic Limbic Encephalitis
Coronary Artery Disease
Other Cardiovascular Disease
Anemia
Arrhythmias
Congestive Heart Failure
Valvular Heart Disease
Respiratory Illness
COPD
Asthma
Obstructive Sleep Apnea
Infectious Disease
HIV / AIDS
Viral Hepatitis
Osteomyelitis
Endocarditis
Mononucleosis
Lyme Disease
Opportunistic Infections

(Continued)

TABLE 29.2. (Continued)

Autoinflammatory Disease
Multiple Sclerosis
Systemic Lupus Erythematosus
Autoimmune Encephalitis
Cerebrovascular Disease
Cerebrovascular Accident
Vascular Dementia
Cerebrovascular Malformation
Parkinsonism
Idiopathic Parkinson's Disease
Antipsychotic-Induced Parkinsonism
Parkinson's Dementia
Dementia with Lewy Bodies
Progressive Supranuclear Palsy
Multisystem Atrophy
Huntington's Disease
Other Dementias
Dementia of Alzheimer's Type
Frontotemporal Dementia
Amyotrophic Lateral Sclerosis
Seizure Disorders
Ictal
Postictal
Interictal
Traumatic Brain Injury
Chronic Pain
Delirium
Catatonia due to General Medical Condition
Brief Psychotic Disorder, Schizophrenia, Schizophreniform Disorder, Schizophrenia, Delusional Disorder, or Psychotic Disorder NOS
Schizoaffective Disorder
Bipolar I or II Disorder
Major Depressive Disorder
Dysthymic or Cyclothymic Disorder
Adjustment Disorder
Bereavement

TABLE 29.2. (Continued)

Demoralization
Attention Deficit Hyperactivity Disorder
Posttraumatic Stress Disorder
Generalized Anxiety Disorder
Eating Disorders
Neurasthenia
Primary Sleep Disorder
Personality Disorders

In keeping with the broad differential diagnosis of mood disorder symptoms, psychiatric standards of care stipulate screening evaluations for general medical conditions and substance use syndromes that may mimic primary idiopathic mood disorders. History of present illness, past medical history, past psychiatric history, substance use history, current medications, family history, social history, developmental history, legal history, review of systems, and focused physical examination are indicated when evaluating patients with mood disorder symptoms. Cognitive screening examinations, such as the MMSE (Folstein et al., 1975) or MOCA (Nasreddine et al., 2005), are also indicated in the routine evaluation of mood disorders, especially so in older patients and patients with a known or suspected cognitive disorder. Routine and inexpensive screening tests in mood disorder diagnosis may include CBC, chemistry panel, liver function tests, TSH, free T4, B12, folic acid, thiamine, *T. pallidum* antibody, HCG, urine drug metabolite screen, and ECG. Further tests indicated by history and physical examination may include an HIV screen, infectious hepatitis panel, ESR, ANA, timed serum or salivary cortisol, free testosterone, prolactin, EEG, polysomnography, and MRI. Medical or neurologic consultation is also warranted, whenever a general medical or neurologic condition is suspected.

Discerning the source of mood symptoms in the face of multiple likely etiologies requires recognition of several logical diagnostic possibilities. Given the presence of two mood-related conditions, A and B, diagnostic possibilities include:

1. An overarching unitary condition AB that has been erroneously, conceptually split
2. A and B represent related conditions arising from a shared root cause
3. Condition A causes condition B
4. Condition B causes condition A
5. Condition A is causally independent from but influences condition B
6. Condition B is causally independent from but influences condition A

7. Condition A and B are causally independent from each other, but mutually influence each other
8. Condition A and B are fully causally independent and do not influence each other.

These logical possibilities underscore the difficulty of diagnostic separation of mood disorders from other conditions, differential diagnosis, and comorbidity assessment. Stemming from these logical possibilities, several approaches obtain to diagnosing mood disorders in the context of known mood-altering medical conditions, substance use, and overlapping psychiatric conditions. These approaches may exist in pure, or combined, forms.

1. Inclusive approach: applies signs and symptoms that satisfy mood disorder diagnostic criteria, or normative cutoffs on depressive symptom screening instruments, without subtracting signs and symptoms that may be related to another condition. Threshold severity and number of total signs and symptoms required for diagnosis remain unchanged from those applied to primary mood disorder diagnosis. This approach maximizes sensitivity and reliability, but minimizes specificity. Examples include the assessment of depressive symptoms in general medical conditions using low cutoff scores on the PHQ-9 (Kroenke et al., 2001; Lamers et al., 2008; Stafford et al., 2007) or CES-D (Jones et al., 2005; Koenig et al., 1998; Weissman et al., 1977).
2. Exclusive approach: applies signs and symptoms that satisfy mood disorder diagnostic criteria, while subtracting signs and symptoms that may be related to other conditions. Threshold severity and number of total signs and symptoms required for diagnosis remain unchanged. An example of this approach may be found in Bukberg et al.'s (1984) assessment of depressive symptoms in hospitalized cancer patients. This approach encourages specificity at the expense of sensitivity.
3. Increased threshold approach: applies signs and symptoms that satisfy mood disorder diagnostic criteria, or signs and symptoms from depressive screening instruments, with or without subtracting signs and symptoms that may be related to other conditions. However, the threshold symptom severity, number of total signs and symptoms, or cutoff score required for diagnosis increase. Examples include the assessment of depressive symptoms in general medical conditions using high cutoff scores on the PHQ-9 (Justice et al., 2004; Williams et al., 2005) or CES-D (Hermanns et al., 2006). This approach also encourages specificity at the expense of sensitivity.
4. Symptom substitution approach: applies signs and symptoms that satisfy mood disorder diagnostic criteria, while subtracting signs and symptoms that may be related to a general medical condition or substance use. These subtracted signs and symptoms are replaced by other signs and symptoms intended to more closely capture mood symptoms, as opposed to general medical condition

or other psychiatric disorder manifestations. Threshold severity and number of total signs and symptoms required for diagnosis may increase or remain the same. This approach, as exemplified in Endicott's (1984) examination of depression in patients with cancer, is also evident in the structure of numerous depressive screening instruments for use in patients with possibly confounding comorbid conditions, including the Hospital Anxiety and Depression Scale (Zigmond and Snaith, 1983), the Geriatric Depression Scale (Yesavage et al., 1982–1983), and the Calgary Scale for Depression in Schizophrenia (Addington et al., 1992). The various versions of the Beck Depression Inventory (Beck et al., 1961, 1996) also exemplify a symptom substitution approach, as they rely more heavily on mood and cognitive symptoms than neurovegetative symptoms. This approach also encourages specificity at the expense of sensitivity.

5. Etiologic approach: attempts to ascribe specific symptoms to their most likely underlying etiology, whether primary idiopathic, medical, or substance-induced, then arrives at a mood disorder diagnosis by applying only those symptoms attributable to the mood disorder. Both DSM-IV-TR and ICD-10 exemplify this approach to mood disorder diagnosis, which also encourages specificity at the expense of sensitivity.

In their classic paper on depression in 460 medically ill older adults, Koenig et al. (1997) outlined the prevalence of major and minor depressive disorders in this population according to inclusive, etiologic, exclusive-inclusive, exclusive-etiological, substitutive-inclusive, or substitutive-etiological approaches. The authors demonstrated that an inclusive approach resulted in the highest prevalence rates for major and minor depression, an exclusive-etiological approach resulted in the lowest prevalence of major depression, and an etiologic approach resulted in the lowest prevalence of minor depression. The exclusive-etiological approach identified the most severe and persistent major depressions. However, the authors also showed that known depression-associated characteristics (predictive validity) and associations with depression scale scores (convergent validity) did not vary remarkably. The authors concluded by suggesting that clinicians or researchers choose from the various diagnostic approaches based on the goals and purpose of the examination. For example, an epidemiologist studying depressive morbidity in a general medical condition may wish to utilize an inclusive approach in order to highlight the problem for public health attention, whereas a clinician working in a resource-limited setting may wish to use an exclusive-etiological approach to identify those patients with the most severe depressive symptoms for treatment.

DIAGNOSTIC VALIDITY

In their landmark paper on diagnostic criteria for psychiatric research, Feighner et al. (1972) outlined five phases for establishing diagnostic validity in psychiatric illness: clinical description, laboratory studies, delimitation from other disorders, follow-up study, and family study.

Certainly, current mood disorder nosologies contain a wealth of clinical descriptors, and take pains to delimit specific mood disorders. Furthermore, family and twin studies have repeatedly demonstrated the heritable nature of all the major mood disorder syndromes, although specific genes appear to explain only small effects in the etiology of mood disorders. Patients with mood disorders also demonstrate a plethora of laboratory abnormalities, although none so sensitive or specific to point to a unified biological etiology. This last fact points to the need further to define mood disorder subtypes, symptom components, and cross-syndromic dimensional constructs, which may serve better to elucidate candidate mechanisms for neurobiologic investigation.

In addition to the preceding problems with genetic and laboratory investigation, follow-up study also points to some weaknesses in the validity of current mood disorder diagnoses. DSM-IV-TR and ICD-10 emphasize cross-sectional diagnosis, causing problems with recall bias and diagnostic instability over time. For example, patients with prior hypomania show demonstrably poor recall of having had hypomania, and a non-trivial portion of patients diagnosed with major depressive disorder turn out rather to have bipolar disorder (Fiedorowicz et al., 2011; Goodwin and Jamison, 2007).

Furthermore, individual symptoms or signs within a given mood disorder diagnosis may vary in their individual validity. For example, a study by Lux et al. (2010) investigated a sample of 1,015 Caucasian twins using logistic regression analyses to compare the associations of individual symptom criteria, and two groups of criteria reflecting cognitive and neurovegetative symptoms, with a wide range of diagnostic validators including demographic factors, risk for future episodes in the co-twin, pattern of comorbidity, and personality traits. Cognitive symptoms included “depressed mood,” “loss of interest,” “worthlessness-guilt,” and “suicidal ideation.” Neurovegetative symptoms included “sleep,” “appetite/weight,” “psychomotor changes,” and “fatigue.” “Trouble concentrating” was excluded as a criterion. Interestingly, the investigators found that individual symptom criteria differed substantially in their associations with specific diagnostic validators, and that the cognitive criteria group generally produced stronger associations with diagnostic validators than did the neurovegetative criteria group. These results challenge the equivalence assumption inherent to the criteria for major depressive disorder, and suggest a degree of covert heterogeneity among these criteria, part of which is captured by the cognitive symptoms being more strongly associated with the most clinically relevant characteristics. They suggest that a detailed evaluation of DSM-IV major depressive episode criteria is overdue.

Recently the construct validity of major depression has been tested with item response theory analysis. Carragher et al. (2011) have shown that the current criteria for major depressive disorder performed well in defining a latent continuum for major depression. In general, the criteria fell along a range of depression severity, with death/suicidal thoughts, worthlessness/guilt, and psychomotor difficulties appearing along the severe end of the range, and concentration difficulties/indecision and sleep disturbance appearing along the middle to mild end of the range.

DIAGNOSTIC ACCURACY

The soft, syndromic, heterogeneous, and cross-sectional nature of current mood disorder diagnoses makes difficult the establishment of a gold standard reference. Structured diagnostic interviews, combined with medical record review and expert reassessment, appear to come closest to a gold standard approach to diagnosis in routine clinical research. Spitzer’s (1983) “LEAD Standard”—L = Longitudinal evaluation of symptomatology, E = Evaluation by expert consensus, AD = All Data from multiple sources—captures the essence of such combined methods. Numerous studies have demonstrated that structured diagnostic interviews outperform routine clinical diagnosis, and that the addition of medical record review brings diagnostic accuracy close to that attained from use of all four LEAD sources (Basco et al., 2000; Miller et al., 2001). However, whereas such methods allow for the calculation of accuracy and reliability data, they do not take advantage of statistical methods such as latent class analysis, which may contribute to improved accuracy in the assessment of such markedly complex phenomena as mood disorder diagnosis (Faraone and Tsuang, 1994).

DIAGNOSTIC RELIABILITY

Field trials of mood disorder diagnoses from DSM-IV and ICD-10 reveal marked variability in interrater reliability. One DSM-IV mood disorders field trial, reported by Keller et al. (1995), included 524 adult patients, comprising approximately 100 patients from each of five US university medical center sites. The study selected patients based on complaint of depressed mood, plus the presence of at least two other DSM-III-R symptoms of major depression or dysthymia, with no minimum duration of symptoms required. The interrater reliability investigation protocol utilized videotaped interviews. In reported results, diagnoses of both major depression and dysthymia demonstrated good to excellent intrasite interrater reliability, and fair to good intersite interrater reliability. Six month test-retest interrater reliability was poor to fair for the diagnosis of major depression, and fair for the diagnosis of dysthymia.

In contrast, the ICD-10 field trial included 11,491 adult patients, unselected by any preconceived symptomatic threshold for inclusion. The ICD-10 field trial reported only intrasite reliability, between pairs of raters from 32 countries. The study reported good to excellent intrasite interrater reliability for overarching categories of manic episode, bipolar affective disorder, depressive episode, recurrent depressive disorder, and schizoaffective disorder. Subtypes of these overarching categories had fair to good intrasite interrater reliability, as had dysthymia and adjustment disorders. Mixed anxiety depressive disorder demonstrated very poor intrasite interrater reliability (Sartorius et al., 1995).

It is important to note that the former field trial included enriched clinical samples, thereby potentially inflating real-world clinical reliability, whereas the latter used unenriched convenience samples, more closely approximating usual clinical practice.

DIAGNOSTIC TESTS

The search for laboratory anomalies associated with the major mood disorders has a long and convoluted history. For example, John Cade's discovery of the mood stabilizing properties of lithium occurred in the context of testing his hypothesis that excess urea in the urine of mentally ill patients signified a general marker of mental illness. In an animal model of this hypothesis, Cade used lithium urate to increase the amount of urea he could administer to his guinea pigs, and observed that lithium protected against the toxic effects of urea. Other lithium salts appeared to tranquilize the animals, and successful trials of lithium for manic agitation soon followed (Cade, 1949).

The era of modern, neohumoral mechanisms as etiologies and diagnostic tests, however, began in earnest with the monoamine and catecholamine hypotheses. Various authors investigated catecholamine metabolites as diagnostic tests for major depression, and later as tests for predicting response to tricyclic antidepressants. However, neither endeavor resulted in evidence supporting a diagnostic or predictive role for these markers.

Other investigators have examined the HPA axis, the hypothalamic-pituitary-thyroid axis, EEG abnormalities, neurotrophic factors, neuroimaging patterns, inflammatory markers, risk conferring genes, and second messenger system components in relation to mood disorders. While such investigations have contributed unquestionably to our understanding of aspects of mood disorder pathophysiology, none have resulted in diagnostic tests able to discern between disordered and non-disordered patients with enough accuracy to warrant clinical use. One recent attempt at compiling various inflammatory, neurotrophic, and neuroendocrine markers in the diagnosis of major depressive disorder, resulted in a reported sensitivity of 91.1%, specificity of 81.3%, positive predictive value of 79%, and negative predictive value of 92% (Papakostas, 2011). This effort represents a significant advance over prior attempts, but if used alone would still result in possibly harmful exposure to unnecessary antidepressant pharmacotherapy or psychotherapy for 21 out of 100 "positive" patients. Note also that the study used DSM-IV criteria, diagnosed via a structured clinical interview, as the comparative gold standard, suggesting that clinicians simply use these clinical procedures for diagnosis in the first place.

LIMITATIONS OF CURRENT CATEGORICAL DIAGNOSES

"With the publication of DSM-III, psychiatrists had an agreed-upon language for naming what they saw, yet this language did not explicitly engage the issue of the nature of the disorders it named."

MITCHELL WILSON (*Wilson, 1993*)

IMPORTANT PROGNOSTIC SPECIFIERS NOT INCLUDED IN DSM

TREATMENT RESISTANCE

Several authors have proposed that treatment resistance in major depressive disorder represents an independent and important

prognostic feature. Systematic methods for assessing treatment resistance include the Maudsley Staging Method (MSM), the Antidepressant Treatment History Form (ATHF), the Massachusetts General Hospital Staging Model (MGH-s), the Thase Rush Staging Model (TRSM), and the European Staging Model (ESM) (Ruhe et al., 2012). In general, these models attempt to assess treatment resistance by scoring the number and adequacy of prior medication trials, the presence of augmentation trials, dose optimizations, and combination strategies, and the use of ECT. The MSM additionally includes measures of index episode duration and severity, which, as demonstrated in the specifiers section, have their own prognostic implications.

A recent review by Ruhe et al. (2012) illustrates the value of the treatment resistant depression concept. In a series of ECT studies, the highest scoring antidepressant trial on baseline ATHF correlated with higher relapse one year status post ECT (Sackeim et al., 1990), lower response to ECT (Prudic et al., 1996), and higher relapse on Li after effective ECT (Shapira et al., 1995). In addition, in outpatient MDD treatment, higher scores on the MGH-s, but not the TRSM, correlated retrospectively with absence of remission (Petersen et al., 2005). Lastly, Fedaku et al. (2009a, 2009b) demonstrated that total MSM score correlated with short-term failure to achieve remission, as well as long-term persistence of a depressive episode, and presence of a depressive episode over 50% of follow-up time. In contrast, total TRSM score correlated more weakly with short-term failure to achieve remission, and did not correlate with long-term outcomes (Fedaku et al., 2009b). Of the preceding treatment resistant depression models, only the ATHF has published interrater reliability data, with a reported intraclass correlation coefficient of 0.94. (Sackeim et al., 1990). Overall, treatment resistance in unipolar depressive disorders appears to have prognostic importance in predicting lack of treatment response, and delineation of treatment resistance may be a helpful diagnostic concept in developing future treatment studies in this therapeutically challenging subgroup.

ANXIETY

A recent review by Goldberg and Fawcett (2012) found that both anxiety diagnoses and anxiety symptoms occur frequently in both unipolar and bipolar depression, and that both anxiety diagnoses and severity of anxiety symptoms in unipolar and bipolar depression also correlate with poor treatment outcomes and higher risk for suicidal behavior and completed suicide.

Fava et al. (2008) reported from the STAR*D study, one of the largest major depressive disorder treatment outcome studies ever conducted, that severity of anxiety symptoms, as extracted from a subscale of the Hamilton Depression Scale, also predicted poor treatment outcomes in this sample.

As Coryell et al. (2012) note, "Many longitudinal studies of depressive disorders have associated comorbid anxiety with poorer outcomes as reflected in a lower likelihood of treatment response, longer times to recovery from index episodes and greater amounts of depressive morbidity over time." (Coryell et al., 2012: p. 210) Drawing from the NIMH Collaborative Depression Study sample, Coryell and colleagues further delineated this relationship by showing that severity of anxiety symptoms during an index depressive episode correlated with duration of future

depressive episodes for both unipolar and bipolar depression (Coryell et al., 2012). Furthermore, baseline anxiety symptom severity predicted duration of future depressive episodes more strongly than did baseline depressive symptom severity, and the predictive power of baseline anxiety symptom severity outlasted that of baseline depressive symptom severity. In addition, the same group also demonstrated that severity of anxiety symptoms during an index bipolar depressive episode correlated with greater percentage of time spent in subsequent depressive episodes versus manic or hypomanic episodes (Coryell et al., 2009). Both of these findings showed dose-response relationships between baseline global anxiety symptom severity and outcomes—relationships that persisted over two decades of follow-up. In neither study did comorbid anxiety disorders at baseline correlate with outcomes at follow-up, indicating that anxiety symptom severity during depressive episodes represents an important prognostic feature inherent to mood disorder diagnosis.

SUBSYNDROMAL MIXED STATES

Cassano et al. (1999) have noted that a failure to recognize subthreshold expressions of mania has contributed to the underdiagnosis of bipolar disorder. More recent studies have shown a frequent occurrence of subthreshold manic symptoms in unipolar mood disorders that correlates with rates of switching to bipolar diagnoses over time. (Fiedorowicz et al., 2011)

TRAUMA HISTORY

Childhood sexual trauma is a risk factor for many mental disorders, including bulimia, alcohol dependence, other drug dependence, and mood disorders. Kendler et al. (2000) found that, of 1,411 adult female twins, 30.4% reported any childhood sexual abuse (CSA), and 8.4% reported childhood sexual intercourse. In turn, any CSA was associated with an increased risk (OR 1.93) for major depressive disorder in adulthood in this sample, and childhood sexual intercourse was associated with an even higher risk (OR 3.24) for major depressive disorder in adulthood. A case control study by Cong et al. (2011) similarly reported that any form of CSA was associated with an increased risk for recurrent major depressive disorder in adulthood, and that incrementally greater severity of CSA heightened this risk. Heim et al. (2010) also reported that a particularly strong link has been found between childhood trauma in general and the mood and anxiety disorders, and Sareen et al. (2012) found in an epidemiological study of Canadian Forces that adverse childhood experiences (ACE) increased the risk of mood and anxiety disorders among active military personnel. Furthermore, it has been reported that childhood abuse dramatically increases the risk for later suicide attempts. Studies of the stress of maternal separation in rats have yielded lasting changes in the HPA axis function, leading to theories that comparable early traumatic events in humans may increase the risk of various disorders, including mood and anxiety disorders, through similar biological mechanisms.

ARBITRARY SELECTION OF CORE CRITERIA

It is worthwhile to note that selection of the core criteria for many of our current psychiatric categorical diagnoses arose

from arbitrary processes. For example, between the Feighner criteria and Research Diagnostic Criteria, researchers dropped the terms “fearful” and “worried” from the list of acceptable dysphoric moods, and elevated the “presence of a pervasive loss of interest or pleasure” as one of the core stem criteria (Spitzer et al., 1978). Spitzer et al. (1978) report that the former change occurred to avoid the inclusion of patients with only anxiety, a reasonable justification. However, given the preceding evidence on the importance of anxiety in depression, evidence whose roots were apparent at the time, why not list “fearful and worried” as an additional criterion? Furthermore, the elevation of anhedonia to a core stem criterion occurred based on “the clinical recognition that many patients with an obvious depressive syndrome do not acknowledge feeling depressed” (Spitzer et al., 1978). Fair enough, yet the authors cited no empirical evidence to support either change.

THRESHOLDS, CASENESS, AND DISCRIMINATIVE ABILITY

ARBITRARINESS OF THRESHOLDS AND FLUIDITY OF CASENESS

In an interesting historical account of the development of the Feighner criteria, Kendler et al. (2010) report that W. L. Cassidy, one of Feighner’s main influences in constructing the diagnostic criteria for major depression, decided on his diagnostic threshold of 6 out of 10 criteria, because: “it sounded about right” (Kendler et al., 2010).

Furthermore, why is the duration of two weeks of symptoms a criterion for a major depressive episode? The early Feighner criteria, precursors of the Research Diagnostic Criteria that were in turn a model for DSM-III in 1980, used a one-month duration criterion. It is difficult to generate the data to justify any particular duration, but the problem of an overlap with “normal reactions of distress to an event” or “demoralization” still exists, as evidenced by current arguments for dropping or keeping the DSM-IV bereavement exclusion for the diagnosis of a major depressive episode. It is worth considering whether to define clinical depression as a binary state, or whether it should be considered on a severity continuum with a certain number of symptoms, severity of individual symptoms, chronicity, and impairment levels defining a spectrum for the syndrome.

RELATED CONDITIONS BLURRING WITH MOOD DISORDERS

Is there a difference between demoralization (learned hopelessness) and depression (Clarke and Kissane, 2002)? When does demoralization become clinical depression? Are these conditions more similar or different when it comes to treatment response? Could descriptive diagnoses be determined that would separate these conditions with respect to specific treatment response, are they on a severity dimension, or are they indistinguishable in terms of mechanism or treatment? Is there a point in the development of learned hopelessness or demoralization when a basic change takes place to establish major depression? Is that point defined by the inability to respond to positive input? Does demoralization become a clinical depression when an individual is no longer capable of responding to

positive stimuli, that is, when the dopaminergic pleasure system is turned off (Treadway and Zald, 2011)? On one hand, maybe there is some other mechanism that leads to a qualitative change. On the other hand, maybe there is no discontinuous mechanism but simply a severity or coping mechanism spectrum that is quantitative, not qualitative. In order to determine this, we need the best possible system for behavioral classification. Even then this may not be a possible discrimination.

Maybe there are risk factors (e.g., negative affect) that can be discriminated behaviorally. Recently, in studying subjects of early abuse (before age 18) that were over 45 (allowing a characterization of their life trajectory), LaNoue et al. (2012) found that patients who scored high on the construct of negative affect (which has been shown to be a lifelong trait) were more likely to see their entire life as “ruined,” in contrast to those who scored low on negative affect on the NEO Personality Inventory (McCrae, 1991). In contrast, patients with low negative affect were less likely to experience lasting impairment and recurrence of symptoms after experiencing early abuse. The patients with low negative affect were more likely to agree that childhood abuse ruined their childhood, but that it did not affect them in adulthood. Responses like “that was then, but this is now” and even “it made me stronger” were volunteered by these subjects, as opposed to “it ruined my childhood and my life” being a characteristic view expressed by high negative affect subjects. High negative affect or “neuroticism” has also been shown to predict recurrence in patients with major depression (Lanoué et al., 2012). Interestingly, despite the concept that neuroticism is a stable trait, SSRI treatment in depression may reduce levels of neuroticism, underscoring a potential mechanism for serotonergic antidepressant action (Tang et al., 2009).

A study by Kendler et al. (2001) showed moderate effects for genetic vulnerability (65% and 50% in females and males, respectively), as well as moderate effects for stress in the origin of depression. Caspi et al.’s (2003) findings demonstrating genetic moderation of life stress on the occurrence of depression point to tantalizing epigenetic methods of understanding vulnerability and resiliency, which may eventually aid in combined genetic-behavioral description of patients who are demoralized versus depressed.

Perhaps our understanding of mood disorder causes and treatments must be tempered not by either-or thinking, but by empirically based pluralism, as discussed by Kendler (2012).

FAILURE OF CURRENT DIAGNOSTIC SYSTEMS TO ELUCIDATE NEUROBIOLOGICAL MECHANISMS OR DEVELOP MORE EFFECTIVE TREATMENTS

The pharmacologic revolution of the 1960s led to a massive increase in neurobiological research starting with the measurement of metabolic and hormonal peripheral changes, to EEG sleep studies, to animal studies of functional brain changes associated with the recently successful antipsychotic and antidepressant medications. Family and twin studies attested to the familial transmission of various major disorders such as schizophrenia, bipolar disorder, and depressive disorders. Technology accelerated and in the late 1980s and

early 1990s molecular biology, genetics, and human brain imaging became possible, offering the promise of more basic understanding of brain function and the pathophysiology of mental disorders.

These technical advances have led to a great increase in knowledge about the complexities of all mental disorders, including mood disorders. As more progress has been attained, the basic understanding of the etiology of mood disorders and other mental disorders has remained elusive, with much work yet to be done.

One reason is the unfolding complexity leading to boxes inside of boxes in the psychobiology of the brain, and the recognition of complex interactions between genetics and environmental inputs, termed epigenetics, which has added a massive layer of complexity to our understanding of the interaction of our brains’ gene expression with environmental circumstances. Another problem that has surfaced is the limitation of our current categorical system of diagnoses in mapping with both genetic and imaging findings.

PROPOSED SOLUTIONS: DIMENSIONAL CONSTRUCTS

SPECTRUM CONCEPTS LINKING SYNDROMES

As Cassano et al. (1999) point out, failure to recognize subthreshold symptoms of mania contributes to frequent underdiagnosis of bipolar disorder. Reasons for the non-recognition of subthreshold bipolar symptoms include the relative lack of suffering compared with depressive symptoms, enhanced productivity, ego-syntonicity, and the assumption by clinicians that such symptoms represent the instability of affect associated with comorbid personality disorders. From the National Comorbidity Survey Replication, Angst et al. (2010) reported that 40% of patients with a diagnosis of major depressive disorder had subthreshold hypomanic symptoms. From the Collaborative Depression Study (CDS) Akiskal et al. (1995) found that, of 559 patients diagnosed with unipolar major depression and followed over 11 years, 8.6% converted to a diagnosis of Bipolar II Disorder, and 3.9% converted to a diagnosis of Bipolar I Disorder. A more recent publication from the CDS found that, of 142 patients diagnosed with Bipolar Disorder I or II, 76% had subsyndromal manic symptoms accompanying their depressive episodes (Judd et al., 2012). Overt irritability and psychomotor agitation were the most prominent symptoms (57% and 39% respectively), and the subsyndromal symptoms were associated with increased severity of depression. These findings show that depression is often on a spectrum with bipolar features. The recent literature showing evidence that response to antidepressants may be diminished in bipolar patients and may lead to more mood instability also stands as a reminder of the importance of distinguishing patients presenting with major depressive episodes that are on a bipolar spectrum (Fountoulakis et al., 2012; Phelps et al., 2008; Sidor and MacQueen, 2011). Given such findings, bipolar spectrum concepts have attempted to unify our understanding of the fluidity between unipolar disorders, bipolar disorders, and monomaniac disorders, and, within each of these disorders, the fluidity between normal symptom

expression, temperamental expression, and full disorder expression (Angst, 2007; Phelps et al., 2008).

BEHAVIORAL CONSTRUCTS DESCRIBING SYNDROME COMPONENTS

In the area of psychopharmacologic treatment, which stimulated our current era of psychobiologic, genetic, and imaging research, it has become clear that, while medications are approved by the Federal Drug Administration as efficacious for various diagnostic categories such as Major Depressive Disorder or Bipolar Disorder, these medications actually seem to address various “behavioral dimensions” that cross diagnostic categories.

Neither the DSM-IV-TR nor the ICD-10 encourages dimensional characterization of manic, mixed, or depressed episodes according to the relative severity of specific symptom components such as depressed mood, motor retardation, anxiety/agitation, insomnia, hostility/interpersonal sensitivity, anhedonia, or suicidality (Bagby et al., 2004; Katz et al., 2004). Katz et al. (2011) have argued for the regular measurement of specific symptom components in treatment studies. Symptom components of depressed mood, motor retardation, and hostility appear to respond differentially to distinct classes of pharmacotherapy. Such differential responses appear to arise early in the course of pharmacotherapy, and these early responses appear to predict later overall and sustained responses. Symptom components that cluster together in factor analytic studies, and show differential responses to treatment, may serve as candidate endophenotypes for further study.

For example, a study by Katz et al. (2004) showed that symptom components of major depression, identified by cluster analysis, not only include symptoms absent from the accepted DSM criteria, but also show different response times when treated with noradrenergic versus serotonergic medications. Another study, by Martinotti et al. (2012), demonstrated differential improvement of anhedonia in major depressive disorder using agomelatine versus venlafaxine XR, in the context of equivalent improvement of the overall syndrome.

Study of other behavioral components of depression such as anticipatory anhedonia, consummatory anhedonia, psychomotor slowing, anxiety-agitation, or angry impulsiveness, may yield specific targets for treatment, or reveal correlations with research domains such as genetic endophenotypes, brain circuit changes, epigenetic events like childhood abuse or adversity, or biomarkers such as HPA axis activation or changes in glucocorticoid receptor function.

The use of theoretically related clinical components, such as decisional anhedonia, anxiety severity, and impulsiveness with affective lability, may also come to prove more useful for understanding the clinical effect of various available or experimental medications (e.g., ketamine, pramipexole) with fairly well understood mechanisms of action. A categorical diagnosis supplemented by severity measures of various behavioral components of mood disorders may prove a valuable advance in clinical utility compared to categorical diagnoses alone. Studies by Katz et al. may prove a starting point for such efforts.

TOWARD FUTURE MODELS: DSM-5 AND RESEARCH DOMAIN CRITERIA

Current categorical diagnoses based on clinical consensus have failed to align with findings emerging from clinical science and genetics, which has slowed the development of new treatments targeted to underlying pathological mechanisms. As mentioned previously, it has been proposed that studying various measurable behavioral traits and dimensions, and looking for correlates with various domains such as genetics, electrical brain functions, or imaging studies, may produce more useful findings than looking for correlates of these domains using categorical diagnoses. Such proposals have led to the development of the Research Domain Criteria (RDoC) by the NIMH (Insel and Cuthbert, 2010).

Behavioral dimensions such as depression, anxiety, psychosis, impulsivity, irritability, agitation, emotional lability, anhedonia, blunting, and negative affect are all “targets” for psychotropic medication, various electronic treatments, and psychotherapies. Many of these symptom complexes occur across categorical diagnoses. For instance, various forms of psychosis occur across schizophrenia, mood disorders, dementias, drug addictions, and even borderline personality disorder. Impulsivity is seen as a behavioral trait across a similar range of disorders. The RDoC hope to leverage such cross-cutting behavioral dimensions in order to better understand the pathogenesis of mental illness, and develop the next generation of treatments.

Currently, DSM-5 is under development for release in 2013. Like DSM-IV-TR, DSM-5 has used literature reviews, results of field trials, review of proposed changes by a scientific review committee, and, where necessary, review of changes by a community public health review committee, as the basis for decisions about changes in diagnostic criteria, or the addition/deletion of diagnoses. In addition, DSM-5 has also used feedback from Internet postings of changes under consideration. DSM-5 has retained most of the diagnostic criteria of DSM-IV-TR, but has added a dimensional perspective to diagnoses in some areas such as mood disorders, psychotic disorders, and personality disorders, in order to address diagnostic overlap and increase the clinical information relevant for treatment planning. Evidence showing the existence of frequent mixed symptoms across mania, hypomania, and depression (depressive symptoms in the manias and manic or hypomanic symptoms in depression) has led to a mixed specifier in DSM-5, allowing the clinician to acknowledge the presence of a mood disorder spectrum in treatment planning. Building evidence for the importance of comorbid anxiety symptoms in the prognosis and treatment mood disorders has also led to the availability of an anxiety severity dimension across all mood disorder diagnoses in DSM-5. Finally, across all DSM-5 diagnoses, clinicians will be asked to record their assessment of the level of concern for suicide in individual patients. The suicide risk assessment will be based off of a list of risk factors for suicide, in combination with the clinician’s own clinical judgment, and will be reflected in the clinician’s treatment plan.

These changes in DSM-5 reflect recognition of the spectrum-like nature of psychiatric diagnoses, and the importance of individual symptom severity in psychiatric disorders, including mood disorders. Such changes may further lead to additional identification of symptom components in major depression, mania, and mixed states relevant to specific medication response prediction, as well as biological correlates and endophenotypes in research paradigms of etiologic mechanisms.

CONCLUSION

What we know today is mood disorders make up an indelible part of the human experience. Since antiquity, the diagnosis of mood disorders has evinced increasing levels of sophistication, in keeping with historical paradigms and scientific influences. Current mood disorder diagnostic classification schemes comprise a collection of atheoretical, prototypal, categorical, operationalized diagnostic criteria, which have modest clinical utility, and have led to intriguing neurobiologic hypotheses. Even so, we have come to expect more clinical and research utility from mood disorder diagnoses, in order to make further progress in understanding mood disorder mechanisms and developing the next generation of mood disorder treatments. After reviewing the development and current state of mood disorder diagnosis, it appears that empirical efforts to elucidate further behavioral components and dimensional constructs salient to mood disorders may help in advancing both treatment and neurobiologic research.

DISCLOSURES

Dr. Hager has no conflicts of interest to disclose.

Dr. Fawcett has not disclosed any conflicts of interest.

DOUGLAS F. LEVINSON

Of the three major psychiatric disorders in adults—schizophrenia, bipolar disorder, and major depressive disorder—major depression has proven to be the most challenging for modern genetic methods. This is perhaps not surprising, given that major depression is the most common and the most influenced by non-genetic factors. Here we will review the progress that has been made with an emphasis on more recent findings, discuss the challenges that remain, and point to possible directions for future research.

DEFINING DEPRESSION FOR GENETIC STUDIES

Genetic researchers face the same problem that has vexed clinicians for centuries: how to classify the sad and painful mood states that are among the most important non-infectious causes of morbidity and disability throughout the world according to World Health Organization statistics. Most people experience periods of sadness in their lives, often in response to painful events. At the other extreme, the most disabling forms of “clinical depression” involve periods ranging from weeks to years or even decades when the individual is consumed by a mental state (“melancholia” in ancient terminology) that seems obviously abnormal even to a casual observer: feelings of sadness, desolation, and guilt; a painful absence of the slightest pleasure; suicidal impulses or acts; an inability to concentrate or make decisions (sometimes reaching a state of complete incapacitation); and a set of characteristic physical symptoms including disturbed sleep, appetite, energy, and movement (either agitated or slowed). Another approach (adopted by some molecular genetic studies) is to define continuous, normally distributed personality traits such as “neuroticism” (more descriptively labeled “negative emotionality”), an index of the degree to which someone experiences unpleasant mood states and anxiety in diverse situations throughout life.

Most modern genetic studies have focused on the category of major depressive disorder, which has remained essentially constant from the introduction of the Washington University or Feighner Criteria in 1972 through the DSM-IV criteria in 1994, as reviewed elsewhere (Maj, 2012). Previous criteria (such as DSM-II) had used categories such as “neurotic” and “reactive” depression, which mixed causal assumptions with vague descriptions of signs and symptoms. *Major depressive episodes*, by contrast, have been defined by a simple checklist of behaviors and experiences that could be readily observed and reported by most people: dysphoric mood state plus at least

four of eight additional criteria (five of eight in the Feighner and RDC versions) for two or more weeks, with impairment of function. *Major depressive disorder* is defined by depressive episodes without certain additional features: the diagnosis is bipolar type I disorder if manic episodes are observed (with or without depression); bipolar type II disorder if there are depressive episodes plus milder hypomanic episodes; and, if psychotic symptoms such as delusions or hallucinations are present well beyond the depressive episode, either schizoaffective disorder or schizophrenia (depending on the relative duration of mood and psychotic symptoms). These criteria for major depressive disorder have proven remarkably robust. The diagnosis can be made reasonably reliably on the basis of self-report or by interviews conducted in-person, by telephone, or with informants such as family members (family history); and it is predictive of increased risk of recurrent depression, response to antidepressant treatments compared with placebo, and increased risk of depression in relatives.

On the other hand, no clinician or researcher believes that these criteria define a single “illness.” A large proportion of the population (12–20%) experiences at least one depressive episode (Hasin et al., 2005; Weissman et al., 1996). It is twice as frequent in females as in males, for reasons that remain unclear. There is great diversity in the severity, acute features, and lifelong course of depression across individuals. No major genetic effects or robust biological markers have been identified. Although clinicians tend to believe that some patients have particularly severe, disabling forms of depression, no objective subtyping method has ever been validated or widely accepted, either for categories or for continuous variables. Similarly, while there are potential “endophenotypes” (variables that may represent biological variation underlying the trait of interest, such as depression), such as imaging and gene expression assays, there is no variable that has been clearly shown to define a more heritable or homogeneous subtype of depression.

GENETIC EPIDEMIOLOGY OF MAJOR DEPRESSIVE DISORDER

Definitions of phenotypes for molecular genetic studies of depression have been informed by genetic epidemiological studies, that is, investigations of relatives (including the special case of twins) that attempt to tease out categories or continuous variables that are both familial and heritable, and to determine the extent to which they are related to each other.

These studies have arrived at a number of consistent conclusions, although there are also important unresolved issues. It is clear that major depression aggregates in families, and (based on twin and adoption studies) that this familial aggregation is likely to be due to genetic factors (Sullivan et al., 2000). These factors do not act in a simple Mendelian fashion (major dominant or recessive effects of single mutations) in any substantial number of cases, based on the pattern of depression in families and the failure to find large single pedigrees in which a mutation could be detected by linkage methods. Thus, major depression is considered a *complex trait*, with multiple DNA sequence variations likely to be combining to influence risk in many cases, with non-genetic factors interacting with genes or perhaps entirely causing depression in some cases.

Two parameters have been of great interest to genetic investigators in planning studies of complex traits: heritability, typically estimated from *twin studies*, and relative risk, based on *family studies*:

1. Heritability is the total proportion of the variance in the trait in a population that is due to genes. For a categorical trait such as a diagnosis, this is based on the proportions of identical (monozygotic, MZ) versus non-identical (dizygotic, DZ) twins of ill probands who are also ill. While in theory a higher MZ concordance could be due to non-genetic, for example, obstetric, factors, in practice this is rarely the case. There would be little point to molecular genetic studies of a trait without substantial heritability. The largest meta-analysis of twin studies of major depression estimated heritability at 0.37 (Sullivan et al., 2000). This estimate is driven by large population-based twin studies in which clinically less severe cases tend to predominate. Higher heritability estimates of 50–70% have been observed in a few small twin studies of more severe cases recruited from clinical settings (Kendler et al., 1995; McGuffin et al., 1996), and from a twin study in which unreliability of self-report was taken into account (by considering depression to be present if it was reported in at least one of two interviews) (Kendler, Neale et al., 1993). A more recent large registry-based study was consistent with the meta-analytic result, but estimated significantly higher heritability in women (0.42) than in men (0.29), a difference that had been considered controversial previously (Kendler et al., 2006). The large sample sizes required for current molecular genetic study designs have been attained in most cases by recruiting all individuals who have major depression criteria during at least one period in their life. But heritability of 37% is modest, which might explain why more significant genetic findings have been obtained for schizophrenia and bipolar disorder, with heritabilities of 70% or more. Ideally, larger twin and family studies of more clinically severe cases might be used to define subtypes with higher heritability, but such studies are difficult to carry out.
2. Relative risk (RR) is an odds ratio computed from the lifetime risks of disease in groups of (usually first-degree)

relatives of ill versus control probands (the latter serving as an estimate for the general population, using the same diagnostic methods in both groups), as an estimate of the true ratio of these risks in the population. (Here, “relative” risk refers to the risk in group A vs. group B, rather than to the fact that “relatives” are being studied.) For major depression, the RR to first-degree relatives across studies is a little under three (Sullivan et al., 2000). Genetic researchers are actually interested in the increase in risk attributable to each specific genetic mutation or variation, because this determines the power to detect the effect with a given study design and sample size. For a complex disorder, it is not known in advance how many genetic loci are interacting to influence risk, or whether mutations with larger effects (which would be easier to find) might be present in some individuals. We now know that there is a close relationship between how harmful a DNA sequence variant is (i.e., its RR for a disease) and its frequency (the proportion of chromosomes in a population on which it is found) (Boyko et al., 2008). Family-based linkage methods are appropriate to search for rare variants with at least moderately large effects on risk (at least 5- or 10-fold increases) in one or a proportion of families (Levinson, 1993), while genome-wide association study (GWAS) methods use very large samples to search for more common variants whose individual effects have generally proven to be quite small (usually up to 10–15% increases in risk) (McCarthy et al., 2008). Our failure to observe clear linkage in single pedigrees suggests that loci with very large effects on depression risk either do not exist or are extremely rare. The absence of significant GWAS findings to date, despite sample sizes similar to those that have been successful in schizophrenia and bipolar disorder, suggests that the effects of individual loci are quite small and/or that etiologic heterogeneity is very high, perhaps with multiple genetic risk mechanisms and diversity in the importance of genetic and non-genetic factors in subsets of cases that cannot currently be differentiated.

PREDICTORS OF FAMILIAL RISK

Given these challenges, it would be helpful to be able to focus genetic studies on cases whose relatives are at the greatest risk of depression, suggesting a greater involvement of genetic factors and perhaps larger locus-specific effects. Substantial efforts have been made to identify characteristics of probands that predict familial risk (as a proxy for involvement of genetic factors), but the results remain controversial. Several proband characteristics have been reported by different investigators to have some predictive value: recurrent episodes (Sullivan et al., 2000), earlier age at onset (AO) (Levinson et al., 2003; Weissman et al., 1984), severity as indexed by the number of MDD criteria endorsed by each subject (Kendler et al., 2007), and depression in both the parental and grandparental generation, with anxiety being an early sign of risk (Grillon et al., 2005). A review of family studies of major depression (Sullivan

et al., 2000) found that recurrent episodes in the proband were most consistently predictive of familial risk.

The present author has interpreted the available evidence as suggesting that the familial nature of depression cases in genetic studies might be increased by requiring at least two episodes (persisting beyond 18 years of age), with age at onset of a full depressive syndrome before the age of 30 and evidence of recurrent depression in a parent or sibling (Levinson et al., 2003), although younger age at onset also might introduce heterogeneity due to greater overlap with bipolar disorder and a greater role for childhood psychological trauma. But no very large epidemiological or family study has provided a reliable estimate of the RR to first-degree relatives of probands with both early onset and recurrence. There is one informative large population-based study of almost 14,000 adult twin pairs from the Swedish National Twin Registry (Kendler et al., 2007). Age at onset, recurrence, and number of endorsed criteria (as an index of severity) each predicted increased familial risk, but more modestly than would have been predicted by previous studies. However, RRs were not computed.

Investigators have also differed in their approaches to the relationship between depression and anxiety. In population-based twin studies, it has become clear that there is a substantial overlap in the genetic factors that predispose to major depression and to anxiety disorders, based on mathematical modeling of their co-occurrence in individuals and in MZ versus DZ twin pairs (Kendler et al., 2003). This close relationship is reflected in the fact that factor-analytic studies of questionnaire-based data on persisting personality traits always identify a major factor similar to what Eysenck termed “neuroticism” (McCrae and John, 1992), which is measured with questions about chronic tendencies to feel dysphoric and anxious, particularly in response to stress. Some genetic investigators have studied neuroticism (or similar dimensional scores) rather than clinical categories, or have defined phenotypes based either on depression-or-anxiety diagnoses or a composite score reflecting both depression and anxiety symptoms (see the following). However, most genetic studies have focused on major depression as a categorical diagnosis, and alternative definitions have not yet succeeded in producing more robust findings.

RELATIONSHIP OF MAJOR DEPRESSION TO BIPOLAR DISORDER AND SCHIZOPHRENIA

The relationship between major depression and bipolar disorder is complex and poorly understood. Clinically, most patients with bipolar-I disorders experience both major depressive and manic episodes (some experience only mania), while bipolar-II disorder is defined by recurrent depressive episodes plus hypomanic episodes. A review of the familial relationships among bipolar and unipolar disorders (Smoller and Finn, 2003) computed summary risks based on family studies (and few additional data have been published since then): the estimated lifetime risk of any bipolar disorder (I or II) was 8.7% in relatives of bipolar probands (mostly bipolar-I), 2.2% in relatives of major depression probands, and 0.7% in

relatives of controls; for major depression in relatives, estimated lifetime risks in the same groups were 14.1%, 17.9%, and 5.2% (although recent studies produced higher estimates for major depression in all groups). In almost all studies, the risk of major depression is similarly increased in relatives of bipolar-I and major depression probands, while the risk of bipolar disorders is increased approximately 10-fold in relatives of bipolar probands, but not significantly in relatives of major depression probands. Because the prevalence of major depression in the population is so much higher than that of bipolar disorders, the relatives of bipolar patients are much more likely to develop major depressive than bipolar disorders. Based on twin data, it has been estimated that bipolar and major depressive (“unipolar”) disorders share some, but not most, of their genetic risk factors (Craddock and Forty, 2006), and this seems consistent with the family study data: genetic factors that underlie bipolar disorders also increase the risk of major depression, but it seems likely that only a minority of individuals with major depression have a substantially increased genetic risk of bipolar disorder.

The situation appears even more complex if one considers the distinction between bipolar-I and -II disorders. While few of the large family studies have considered these disorders separately with adequate groups of control relatives, it appears that in relatives of bipolar-II probands there may be a greater risk of bipolar-II than of bipolar-I disorder, that is, there may be some genetic differences between those two disorders (Smoller and Finn, 2003). This is of interest to major depression researchers, because while the severe manic episodes of bipolar-I disorder are starkly different from anything experienced by major depression patients, there is a continuum of clinical presentations among individuals with predominately depressive disorders ranging from those who have never experienced anything remotely resembling mania, to those who experience brief “subthreshold” periods that resemble hypomania, to those in whom clear-cut hypomania is a recurrent and significant problem (leading to a bipolar-II diagnosis). Those of us who treat patients with severe, recurrent mood disorders see many individuals in whom the degree of subtle “bipolarity” is difficult to judge. By contrast, large population-based depression studies typically use diagnostic methods that are not sensitive to bipolar symptoms (i.e., they are not asked about them at all, or screening is brief, or interviewers are not trained to explore these symptoms), and most of the depression cases observed in these studies seem to be milder and less complex than those in specialized clinical settings.

The issue is illustrated by our experiences in the Genetics of Recurrent Early-onset Depression (GenRED) study (Levinson et al., 2003, 2007; Shi et al., 2011). In the initial planning stages for the first phase of the project that recruited multiply affected families, several collaborators argued that a large proportion of individuals with recurrent, early-onset depression would prove to have bipolar-II disorder. We therefore expanded the hypomania section of the Diagnostic Interview for Genetic Studies, and stressed this area during interviewer training. During recruitment, potential probands with any clear episode of mania or hypomania were excluded, as were individuals with any sibling or parent in whom a bipolar

disorder could not be ruled out with reasonable confidence by either direct interview or indirect family history data. This was not a population-based study—subjects were either volunteers responding to announcements about families with two or more depressed siblings, or were recruited from clinical settings—and severity was typically high. In the 680 families in the final family sample, 4% (47) of the 1,158 directly interviewed affected siblings received diagnoses of bipolar-II disorder, which is higher than the frequency in control relatives in available studies and similar to the frequency among relatives of bipolar-I or bipolar-II probands. Thus, while it was certainly not impossible (as some had feared) to collect a large sample of purely depressed probands and siblings, some degree of overlap with bipolar-II disorder is suggested by the data.

Many efforts have been made to identify clinical features to differentiate “true” major depression from depression that is more closely related to bipolar disorders, despite the absence of manic episodes. Investigators have looked at predictors of subsequent appearance of mania in depression patients (Beesdo et al., 2009; Zimmermann et al., 2009), differences between depressive features in unipolar versus bipolar patients (Blacker et al., 1996; Zimmermann et al., 2009), and subtyping of major depression cases in the families of bipolar probands. (Mitchell et al., 2011) Consistent empirical support is lacking for discrete subtypes. Two recent studies have taken fresh looks at this question. A longitudinal population-based study (Zimmermann et al., 2009) identified individuals with histories of depression with or without subthreshold manic symptoms. Those with such symptoms were more likely to have a family history of bipolar disorder and to develop mania during follow-up (7.2% vs. 1.7% in those with no manic symptoms). The study was unusual in that manic symptoms were carefully explored in subjects from a population-based design, and interestingly, over 40% of depression cases did report what the investigators interpreted as subtle manic symptoms, suggesting that the prevalence of manic symptoms in the population might have been underestimated previously. A study of the relatives of probands with bipolar disorders compared the features of depressive episodes in relatives with either unipolar depressive or bipolar disorders (Mitchell et al., 2011). The major depressive relatives could be clustered into two groups, one of which had features that were also more frequent in the bipolar depression relatives (such as psychomotor retardation and difficulty thinking). Findings like these might prove useful for subtyping subjects in genetic studies of mood disorders, with the caveat that it is difficult to rate subtle clinical features consistently in studies (such as the GWAS described later) in which thousands of subjects are evaluated at multiple sites.

Family studies have also demonstrated that relatives of probands with schizophrenia are at increased risk of major depression (Gershon et al., 1988; Maier et al., 1993). An increased risk of schizophrenia and of schizoaffective-depressed disorder has been reported in the relatives of probands with the psychotic form of major depression (depressive episode with psychotic features—usually delusional beliefs with themes consistent with depressive ideas—that remit with the depression), although not in the relatives of non-psychotic depressive probands (Kendler

et al., 1993; Maier et al., 1993). Thus, molecular genetics investigators are currently using GWAS data to search for genetic associations that cut across diagnostic boundaries among mood and psychotic disorders, as discussed in the following.

ADVERSE LIFE EVENTS INCLUDING CHILDHOOD TRAUMA

It is now well established that individuals who experience more, and more severe, adverse (stressful) life events are at increased risk of depression (Nanni et al., 2012) and other psychiatric disorders (Nelson et al., 2002) during adulthood. Early separation from a parent is also a risk factor (Kendler et al., 2002). More severe abuse (e.g., sexual abuse with penetration) confers greater risk (Kendler et al., 2004). A recent meta-analysis of 16 epidemiological studies reported an odds ratio of 2.27 for increased risk of recurrent and persistent (long duration) major depression after childhood abuse, as well as an increased risk of non-response to depression treatment (OR = 1.43) in 10 studies (Nanni et al., 2012). There is evidence that early psychological trauma may have diverse neurobiological effects on the developing brain, including alterations of hypothalamic-pituitary axis function and structural and functional brain changes, which have been hypothesized to mediate the vulnerability to persistent adult psychopathology (McCrorry et al., 2010). These findings raise the question of whether adverse events are an independent “cause” of depression and other disorders, or whether their effects interact with genotype.

This has been studied indirectly, using family history of depression as a proxy for genetic risk, in the same longitudinal population-based study previously discussed with regard to bipolar disorder (Zimmermann et al., 2008). During a 10-year follow-up period, individuals with histories of early separation or any of seven types of adverse events (including childhood abuse), had an increased risk of major depression (OR = 1.8). However, an interaction between adverse events and genetic liability was demonstrated: adverse events did not increase risk of depression in those with no family history; but in those with a family history, family history alone increased risk (OR = 1.6 vs. those with neither family history or adverse events), and adverse events conferred a further increase (OR = 1.6 vs. those with family history and no adverse events; OR = 2.5 vs. those with neither a family history or adverse events). Thus, it is possible that large genetic studies of depression cases with versus without adverse events such as childhood abuse could detect sequence variants that contribute to this interaction.

MOLECULAR GENETIC STUDIES: OVERVIEW

Three types of studies will be reviewed here.

- (i) **Linkage** analysis was the first approach that permitted searching the genome in an unbiased fashion for genetic factors underlying a disease or trait. Linkage studies use

hundreds or thousands of sequence variants scattered throughout the genome as markers to determine whether ill members in the same family tend to share the same marker alleles in specific locations, suggesting that an etiologic variant might exist somewhere in a broad region (tens of millions of nucleic acids). Several large and a few other small linkage studies of major depression have been reported, with several significant findings that have not yet been linked to specific genes. Linkage methods have been dramatically successful for Mendelian diseases, but usually not for complex diseases as noted previously.

- (ii) The **GWAS** is a more recent, and potentially more powerful, method to search for associations between a disease and specific sequenced variants throughout the genome (McCarthy et al., 2008; Visscher et al., 2012). A GWAS interrogates only the more common single nucleotide polymorphisms (SNPs) in the genome (and other common variants, such as copy number polymorphisms, that might be nearby), taking advantage of the phenomenon of linkage disequilibrium (LD; correlation of SNPs within small chromosomal segments called LD blocks) to permit panels of between 500,000 and several million SNPs to detect associations to most of the common SNPs in the genome. GWAS methods have been extraordinarily successful in detecting associations for many common, complex diseases and traits, including schizophrenia (Ripke et al., 2011) and bipolar disorder (Sklar et al., 2011).
- (iii) Most published molecular genetic studies of major depression have focused on **candidate genes**, and particularly on just a few polymorphisms that are known to have functional effects—for example, changes in expression of genes that influence neurotransmitters that are modulated by antidepressant drugs. Recently, many of these studies have been motivated by a model first suggested by Caspi and colleagues (Caspi et al., 2003), who reported that adverse life events interact with the “short” allele in the promoter region of *SLC6A4*, the gene that encodes the serotonin transporter protein that transports serotonin back into the presynaptic cell from the synapse, and which is blocked by many antidepressant drugs.

A fourth area of research involves study of genome-wide **gene expression** using microarray technology (and in the future, RNA sequencing methods). Both environmental and genetic factors influence gene expression, but if a “signature” of genes with increased or decreased expression could be identified in subsets of depression cases, the basis for the alterations could then be sought. These studies bear directly on the molecular pathology of depression (Chapter 33 of this volume) and will not be reviewed here. They do not yet intersect with research on specific genetic sequence variants as risk factors, but a convergence of these approaches is a goal of both fields of research.

LINKAGE STUDIES

The 10 genome-wide linkage studies of depression that have been reported to date are described in Table 30.1. As shown in the table, only two (Holmans; Breen) focus on the major depression phenotype and have sample sizes that might be considered reasonable for the study of complex traits (more than 500 families, more than 1,000 cases); two were primarily studies of alcohol (Nurnberger, Pergadia) or cocaine dependence (Yang), in which the analysis focused on the phenotype of a major depressive episode and/or dependence; and one (Schol-Gelok) defined depression on the basis of symptom scores or history of antidepressant treatment rather than assessment of major depression. Two of the studies were analyzed twice. Zubenko and colleagues reanalyzed their original linkage data to provide better empirical estimation of significance levels, but the sample, diagnoses, genotypes, and main findings were the same in both analyses. Two separate analyses have been published that used the same set of genotypes for a sample of Utah families ascertained through major depression probands—with many of the nuclear families forming distantly related clusters: once (Abkevich et al., 2003) with bipolar-I and -II relatives included as affected, and then (Camp et al., 2005) with only the recurrent early-onset major depression cases, and also with anxiety disorders considered as a related phenotype (analyses of depression-or-anxiety and of depression-and-anxiety). Overall, the three largest analyses (Camp, Holmans, Breen) required recurrent major depression, two also required early onset (Camp, Holmans), and the third had primarily early-onset probands (Breen).

Two of these larger studies reported findings that were significant after correction for genome-wide testing. The GenRED study (Levinson et al., 2007) reported significant linkage to recurrent early-onset major depression on chromosome 15q25–26, with a Kong-Cox lod score of 4.78 in 631 European-ancestry families after fine-mapping with SNPs (after scanning the genome with microsatellite markers). No other study has reported significant linkage in this region, although two other studies reported that the same region yielded one of their better linkage results (Breen et al., 2011b; Camp et al., 2005). The DENT study (Breen et al., 2011b) reported significant linkage to recurrent major depression on chromosome 3p25–26, with a lod score of 4.0 in 839 families using a dense microsatellite marker set. Significant linkage in the 3p25–26 region was also reported in a second, much smaller study (Pergadia et al., 2011) of 116 families originally selected from a population-based sample for heavy smoking, but which had two or more members with major depression. Another interesting region is on chromosome 8p (interestingly, the same region that has produced the best linkage findings in schizophrenia, although not reaching a genome-wide significant level across studies (Ng et al., 2009), and which has produced among the stronger (but not individually significant) findings in several depression linkage studies and also in studies of neuroticism and related traits (see the following).

The larger question is whether linkage findings will prove useful in elucidating the genetic susceptibility to depression. Investigators (including the present author) applied linkage

TABLE 30.1. Genome-wide linkage scans of depression and related phenotypes

FIRST AUTHOR (YEAR)*	FAMILIES	AFFECTED CASES	PHENOTYPE(S)	SIGNIFICANT OR SUGGESTIVE RESULTS
Nurnberger, 2001	262	839	Alcohol dependence + MD (235); MDD (94); Alcohol dependence (604)	Suggestive (1p31.1, AD, or MD) Suggestive (7q 150 cM, MD)
Zubenko, 2002 Maher, 2010	81	unclear	MDD-RE, MDD-R, "major" mood disorders, "all" mood disorders, "depressive spectrum" disorders. Sex as covariate.	Significant (2q33-35)
Utah study ^a Abkevich, 2003	110	1,107	MDD or BP-I or BP-II (probands MDD)	Significant (12q22-23.2)
Camp, 2005	87 (19–112) ^b	75–718 ^b	MDD-RE; MDD-RE or anxiety disorder; MDD-RE plus anxiety disorder.	Suggestive (MDD-RE or anxiety—3p12-q12, 7p; MDD-RE and anxiety—18q21-22)
Holmans, 2007 Levinson, 2007	656	1,748	MDD-RE	Significant (15q25–26) Suggestive, sex effect (8p22-p21.3, 17p12)
Middeldorp, 2009	133	278	MDD (from samples selected for high depression/anxiety factor scores)	Suggestive (17q, 8p, 2q)
Ayub, 2008	1	63	MDD (mostly recurrent)	None
Schol-Gelok, 2010	45 ^c	115	Elevated depression symptom scores or antidepressant medication	Significant (2p16.1-15) ^d
Breen, 2011	839	2,164	MDD-R; severe MDD-R; very severe MDD-R	Significant (3p25-26)
Yang, 2011	384 (AA) 355 (EA)	unclear	Cocaine dependence; MDD; both (~52%, 25%, and 23% of cases)	Significant (7q36.3 for CD+MDE in AA) Suggestive (multiple)
Pergadia, 2011	116	270	MDD (families selected for heavy smoking)	Significant (3p25-26)

"Significant" (5% probability of false positive result) and "suggestive" (expected < once per genome scan) results are noted, generally based on permutation tests. MDD-RE = recurrent, early-onset mdd (onset < age 25 in Zubenko et al.; <31 in Holmans et al. (<41 for cases other than probands) and in Camp et al. MDD-R = recurrent MDD. MD = major depression ± comorbid alcohol or substance use. BP = bipolar. AA = African American. EA = European ancestry.

- a. Abkevich et al. and Camp et al. drew their pedigrees from the same Utah sample. Abkevich et al. considered all MDD cases plus BP-I and BP-II as affected, and selected families with four or more such cases. Camp et al. considered MDD-RE cases (and/or, in alternative analyses, all DSM-IV anxiety disorders) as affected, excluded BP cases, and selected families with 3 or more MDD-RE cases.
- b. 87 large families studied. P-values were corrected for multiple testing: for each of three diagnostic models, pedigrees were split for analysis by limiting the genealogies to 3, 4, 5, or 6 generations. The N of families and of affected cases varied with diagnostic model and genealogical rule.
- c. Nuclear families that were distantly related within an isolated population (analyses were corrected for this relatedness).
- d. Note that this study used a map of ~6,000 SNPs but did not mention any correction for the inflation of linkage scores that occurs when there is linkage disequilibrium between markers in a region.

*References: (Abkevich et al., 2003; Ayub et al., 2008; Breen et al., 2011b; Camp et al., 2005; Holmans et al., 2007; Levinson et al., 2007; Maher et al., 2010; Middeldorp et al., 2009; Nurnberger et al., 2001; Pergadia et al., 2011; Schol-Gelok et al., 2010; Yang et al., 2011; Zubenko et al., 2002)

methods to depression because they represented the only unbiased, genome-wide scanning method available before the availability of GWAS arrays and whole-genome sequencing. But we have learned a great deal more about the genome since then, and it is now more apparent that linkage studies are successful when the genetic architecture of a trait (the number, frequency, and effect sizes of the causative variants) has features that are not

likely to be met by most complex disorders. Linkage studies of small samples are mostly likely to be successful when one or a very small number of mutations can individually cause a disease in a Mendelian (dominant or recessive) fashion, such that single large pedigrees, or a small sample of nuclear families or sibling pairs, can produce significant results. Such findings have never been observed for depression. Variants with smaller effect sizes

can be detected, but only in much larger samples and only if they are carried by a substantial minority of cases. As an example of a genetic model that would result in reasonable power to detect linkage, if 30% of probands in a study carried a variant whose population frequency was 4%, and if carriers of that variant had a 35% risk of illness compared with 1.38% for non-carriers, then the population frequency of the disease would be 4%, the increase in risk to sibs in those families would be 3.5, and the increase in risk to siblings that would be observed in the population as a whole—due to that specific variant—would be 27%, which is the lower limit of the effect that can be reliably detected in 800–1,000 affected sibling pairs. The ratio of risks (penetrances) to carriers versus non-carriers (25) is comparable to the odds ratio for genotypic risk, but we now know that SNPs with population frequencies as high as 4% virtually never contribute to serious diseases with an OR of 25. Alternatively, there could be one gene in a linkage region (or, more likely, several risk genes in the same region) in which many different families in the population were carrying very rare variants with high penetrances—but one would expect that in this case there would be many large, multiply affected families in which significant linkage could be detected in each family separately, which is not the case.

Nevertheless, linkage studies do have some advantages over current GWAS methods. Whereas GWAS can only detect the (small) effects of common SNPs, linkage analysis in very large samples could detect the aggregate effects of many rare variants in a region, each with moderate effects on risk, thus prioritizing that region for further study. It is quite possible that all depression linkage findings are false positives. But there is another, more complex possibility. It is well known that when statistical effects are analyzed in samples that are underpowered (i.e., too small to reliably detect the actual effect sizes), the measured effect sizes in each sample will vary widely around the true value (Goring et al., 2001). Thus, excessively high estimates will be observed in some samples, and excessively low values in others. This is one version of the “winner’s curse” effect—if one chooses the best test result out of many tests in an underpowered sample, the measured effect is likely to be a large overestimate, and will fail to “replicate” in other underpowered samples. With a sufficiently large sample, the true effect size will be estimated with statistical significance, and will replicate in a second sample of similar size. But if samples of 600–800 families cannot detect true effects reliably, then many thousands of families would be required, and funding for such a study is highly unlikely. Therefore we will not know whether any depression risk variants exist in the best depression linkage regions until whole-genome or targeted sequencing methods are applied to larger samples of cases and controls.

Note that there have also been genome-wide linkage studies of neuroticism as a continuous variable measured in population-based samples, and of harm avoidance, a related measure. A recent rank-based meta-analysis of eight neuroticism linkage scans with and without an additional three scans of anxiety disorders (Webb et al., 2012) reported that in the combined analysis, the top 12 “bins” (in 7 chromosomal regions), in aggregate, contained more highly ranked linkage scores than expected by chance (none of them overlapping with the best major depression findings), but no single region

achieved genome-wide-corrected significance in any of the analyses. Thus, linkage analyses of neuroticism have not been more successful than those of major depression, and the same issues previously discussed for depression would apply to linkage studies of a complex, normally distributed trait like neuroticism. A full discussion of neuroticism and related studies is beyond the scope of this chapter.

GENOME-WIDE ASSOCIATION STUDIES

GWAS DATA FOR MAJOR DEPRESSION

Eight Genome-Wide Association Studies (GWAS) analyses of major depression have been reported (Table 30.2), and others are in progress. The Psychiatric GWAS Consortium carried out a mega-analysis of these datasets (Major Depressive Disorder Working Group of the Psychiatric GWAS Consortium, 2012): in a collaborative effort, a central analysis team was provided with the original genotypes for each study, applied identical quality control procedures to each dataset, identified and eliminated any duplication of samples based on genotypes (i.e., when there was overlap in control samples, or occasionally when the same case was enrolled in more than one study), computed principal component scores reflecting ancestry differences, imputed genotypes for all un-typed SNPs in each sample from the HapMap 3 SNP set for a total of 1.2 million SNPs, and carried out association tests for each SNP with ancestry scores and study site as covariates. Then, additional investigators provided genotypes from 7 independent datasets for 554 SNPs with $p < 0.001$ in the initial (discovery) sample, and a meta-analysis of the discovery and replication data was completed. As shown in Table 30.2, the discovery sample included 9,240 cases and 9,519 controls, and the replication sample included 6,783 cases and 50,695 controls (with most of these latter controls from the Icelandic dataset, and thus only contributing to the analysis of that sample), for a total of 16,023 cases in the final analysis. (Note that for some studies, the dataset in the mega-analysis was different from its own publication, as described in the table legend, usually due either to dividing up the datasets differently based on ancestry and genotyping platform or to partitioning of control samples that were used in more than one study.)

There were no findings in this analysis that met the conventional genome-wide-corrected significance threshold ($P < 5 \times 10^{-8}$). A series of planned secondary analyses was also carried out: separate analysis of females ($N = 6,118$) and males ($N = 3,122$) versus same-sex controls; of all controls versus cases with recurrent major depression ($N = 6,743$), recurrent major depression with onset before age 31 ($N = 4,710$), onset before the age of 13 ($N = 774$); and cases ($N = 3,814$) with high scores on a factor score representing “typical” physiological features of depression (weight loss and insomnia). Age of onset was also analyzed as a continuous trait, within cases. No significant findings were observed (correcting for genome-wide analysis but not for multiple analysis models) in these underpowered subsamples.

A different type of secondary analysis did produce a positive result. This approach tests whether the independent SNPs with the lowest P-values in one dataset (eliminating SNPs in LD with a more significant SNP) have the same direction of

^bThe Bonn/Mannheim sample and the German subsample of the RADIANT published report were combined for analysis in the PGC discovery analysis.

association in a second dataset (OR > 1 or OR < 1 for the same SNP allele), using a simple version of the sign test (one-sided) based on the binomial distribution: if none of the SNPs are associated with the disease, then the ORs in the first dataset are positive by chance, and in the second dataset, half of the directions should be consistent and half inconsistent. The assumption here is that, even if none of the SNPs are significant after genome-wide correction, some of them may in fact be contributing to disease risk in a polygenic fashion. If the true effect sizes are small, then the P-value in the first dataset represents an overestimate of the effect (i.e., winner's curse). So the only prediction one can make in the second dataset is that the ORs

will be in the same direction. In the PGC depression analysis, for female cases and controls, the discovery and replication datasets had ORs in the same direction for the best discovery SNPs significant more than 50% of the time (P < 0.006). The analysis was not significant for the smaller subsample of males (P = 0.17) or for males and females combined (P = 0.05). This result suggests that some of the top SNPs contribute to disease risk, but that the study was underpowered to detect association with these SNPs at a significant level.

The failure to detect significant SNP associations stands in contrast to the PGC mega-analysis and replication analyses, using identical methods, of schizophrenia (Ripke et al.,

2011) and of bipolar disorder (Sklar et al., 2011), both of which detected strongly significant associations; and to the many GWAS analyses of non-psychiatric disorders that detected associations with similar sample sizes (see <http://www.genome.gov/gwastudies/> for an up-to-date catalog of GWAS findings). A recent paper (Wray et al., 2012) discussed several ways to estimate the relative sample sizes needed to explain the same proportion of phenotypic variance in two diseases with different heritabilities and prevalences. The authors point out that GWAS has been most successful for disorders with high heritability and low prevalence (such as schizophrenia and bipolar disorder), rather than low heritability and high prevalence (such as depression). Depending on the method and the assumptions made about genetic architecture of the disease, they estimate that GWAS analysis of depression would require 2.4–5 times as many cases as a schizophrenia analysis to detect the same proportion of total variance; given that the PGC schizophrenia mega-analysis included approximately 10,000 cases, this would mean that 24,000–50,000 cases would be desirable for major depression. Or, if one assumes that hospitalized MDD (or some other definition of a clinical severe subtype) has a higher heritability and lower prevalence, perhaps only 1.8 times as many cases might be needed (18,000), but there were only 4,710 cases in the PGC secondary analysis of recurrent early-onset major depression, which tends to be clinically severe. Collecting such large samples would be very expensive. Some of us who study depression would argue that it would be worthwhile, given the fact that GWAS studies of other diseases have produced many pathophysiological clues and the high worldwide burden of disability from depression. But it is understandable that others in the scientific community might conclude otherwise, particularly during difficult economic times.

Copy number variants (chromosomal deletions and duplications) are also detected from GWAS array data. Three groups have reported on CNV analyses of major depression to date. A significant association was reported between major depression and duplications that spanned *SLIT3*, *CCDC99*, and *DOCK2*, observed in 5 of 1,693 cases (from the GAIN GWAS sample) versus 0 of 34,506 controls (Glessner et al., 2010). The finding has not yet been replicated. Another study reported four nominally significant CNV regions in 604 MDD patients and 1,643 controls, but the findings do not withstand correction for genome-wide testing of CNVs (Degenhardt et al., 2012). A third study, using GWAS data for 3,106 cases of recurrent depression versus 459 screened (for absence of lifetime major depression) and 5,619 unscreened controls, reported that cases had more rare, large deletion CNVs (those with a frequency of less than 1% in controls and length greater than 100,000 bp), with no difference for duplications (Rucker et al., 2011). Interestingly overall frequency of rare CNVs was highest in depression cases, intermediate in unscreened controls, and lowest in screened controls. They did not find any specific CNVs to be associated with depression. Larger CNV analyses of major depression will be needed.

CROSS-DISORDER FINDINGS

Another approach of great current interest is the use of GWAS data to detect associations that cut across current diagnostic

boundaries, and to estimate the overall correlation in the SNP contributions to different disorders or traits. Two papers have investigated association to SNPs in the *CACNA1C* gene (encoding the α -1C subunit of the L-type voltage-gated calcium channel), which had previously been reported to be significantly associated with bipolar disorder in two overlapping datasets (the largest of which was the PGC bipolar mega-analysis). The first analysis, of quite small GWAS samples, reported that the most significant SNP in the bipolar analyses was also nominally associated with major depression ($P = 0.013$) and with schizophrenia ($P = 0.034$), with similar ORs (1.15) as in the larger bipolar studies (Green et al., 2010). A second analysis, using over half of the data used in the PGC bipolar analysis plus the GAIN major depression dataset, reported significant association to a combined bipolar-major depression phenotype (Liu et al., 2011).

A second finding was reported in a combined analysis of the PGC major depression and bipolar disorder (BP-I) discovery datasets after eliminating any sample overlap (16,236 cases and 15,814 controls, Table 30.2), treating both disorders as a single phenotype. One significant finding was observed for multiple SNPs on chromosome 3p21.1 in a region containing many genes. Significant associations in this region were previously reported in a combined analysis of PGC bipolar and schizophrenia data (Sklar et al., 2011) and in a previous combined analysis of some of the same bipolar and major depression datasets included in the larger PGC analysis (McMahon et al., 2010). The PGC depression group suggested caution in interpreting this as a cross-disorder finding, given that the bipolar cases provided most of the evidence for association, with the depression replications samples not supporting the finding. The same point was made in a comment (Breen et al., 2011a) on the McMahon et al. combined analysis.

The sign test approach, discussed earlier for evaluating consistency between PGC depression discovery and replication samples, was also applied to the depression-bipolar analysis. There were 176 independent SNPs in this analysis (drawn from both the depression and bipolar analyses). Of the 100 SNPs that were the best bipolar findings, 65 had the same direction of effect in the depression analysis ($P = 0.0018$), whereas of the 76 best independent SNPs from the depression analysis, 46 had the same direction of effect in the bipolar analysis ($P = 0.042$). This suggests that at least some of the common SNPs that confer risk of bipolar disorder also confer some degree of risk to major depression.

The PGC Cross-Disorder Group is currently completing a comprehensive combined mega-analysis of GWAS data for depression, schizophrenia, bipolar disorder, autism, and attention deficit hyperactivity disorder, which should shed further light onto possible cross-disorder associations.

NEUROTICISM

GWAS analyses have also been carried out for personality questionnaires from population-based samples. In a meta-analysis of 15 samples (10 discovery and 5 replication) totaling 20,669 individuals with data for the NEO Five-Factor Inventory, which includes neuroticism (de Moor et al., 2012) no significant associations were detected for neuroticism.

Another approach to cross-dataset analysis did produce positive findings regarding the relationship between depression and neuroticism scores. Polygenic profile (score) analysis (Purcell et al., 2009) is based on the hypothesis that for many complex diseases, there are large numbers of risk-modifying SNPs, most with such small effect sizes that they will not produce statistically significant results with feasible sample sizes. To test this hypothesis, a genome-wide set of independent SNPs (i.e., pruned to eliminate LD among SNPs) is selected from a first (“training”) dataset. For each SNP, the association test result (e.g., log of the OR for a specified test allele) in that dataset is adopted as a weighting factor. Then, for each SNP in the second (“test”) dataset, the number of observed test alleles is multiplied by the weight, and the resulting scores are summed across all SNPs. If the polygenic risk factors in the two datasets are similar, then cases and controls will have significantly different scores. The test is generally repeated using larger and larger proportions of the SNPs, rank ordered by their P-values in the training dataset (e.g., the SNPs with the best 10%, 20%, 30%, etc., of P-values in the training dataset). The test has produced robustly significant results, for example, across virtually all pairs or combinations of schizophrenia GWAS datasets (Purcell et al., 2009; Ripke et al., 2011). In an analysis of a training dataset of GWAS data for personality traits in 13,835 subjects and separate test datasets for depression (3,839 GAIN subjects and 5,082 MD2000 subjects) and bipolar disorder (3,375 cases and 3,370 controls from the STEP-BD and Wellcome Trust samples), weights from the results for neuroticism scores in the training dataset differentiated depression cases and controls in analyses of five different “bins” of SNPs at $P < 0.05$. Weights based on the analysis of extraversion scores were significant at $P < 0.05$ for differentiating bipolar cases and controls. This is an intriguing result although the significance level is modest.

STUDIES OF CANDIDATE GENES AND POLYMORPHISMS

Historically, the term “candidate genes” has referred to genes that were selected for study because their biological function was considered potentially relevant to the pathophysiology of a disease. Because the biological mechanisms that contribute to depression risk are not known, most depression “candidate genes” have been nominated because of their potential relevance to the mechanisms of action of antidepressant drugs, particularly polymorphisms (SNPs but also insertion-deletion and variable-number-of-tandem-repeats [VNTRs]) with putative functional effects on gene expression. The vast majority of published studies of genetic factors in depression have analyzed one or a small number of such polymorphisms, usually in samples that are now considered vastly underpowered given the small effect sizes that were being reported.

ASSOCIATION TO MAJOR DEPRESSION

A comprehensive meta-analysis of these studies (Lopez-Leon et al., 2008) analyzed data from 129 studies of 20 polymorphisms

in 18 genes that had been studied at least three times, and showed results for previous meta-analysis of polymorphisms in two genes for which no additional studies had appeared in the interim. Fifteen of these 20 genes were related to neurotransmitters or receptors involved in antidepressant actions. Fixed and random effects meta-analyses were carried out of counts for two alleles, of heterozygotes versus homozygotes, and contrasting the two homozygotes (although no correction was provided for these multiple tests). Nominally significant results (the 95% confidence interval for the OR did not include 1.0) were observed in one or more of these analyses for single polymorphisms in each of six genes: DRD4 (dopamine-4 receptor; 319 cases vs. 808 controls; allelic OR = 1.73; $P < 0.01$), APOE (apolipoprotein $\epsilon 2,3,4$ alleles; 827 cases vs. 1,616 controls; allelic OR = 0.51 for $\epsilon 2$ vs. $\epsilon 3$, n.s. for $\epsilon 4$ vs. $\epsilon 3$; $P < 0.001$); GNB3 (guanine nucleotide binding protein 3; 375 cases vs. 492 controls; allelic OR = 1.38, homozygote OR = 2.13; $P < 0.01$ for both effects); MTHFR (methylene-tetrahydrofolate reductase; 875 cases vs. 3,859 controls; allelic OR = 1.20; $P < 0.01$); SCL6A3 (dopamine transporter; 151 cases vs. 272 controls; heterozygote test OR = 2.06; $P < 0.01$); and SLC6A4 (the 44 bp insertion/deletion polymorphism referred to as 5-HTTLPR, in the promoter of the serotonin transporter gene; 3,752 cases vs. 5,707 controls; allelic OR = 1.11; $P < 0.01$).

A larger meta-analysis was published in 2010 for the short and long alleles of the 5-HTTLPR indel, including 46 samples with at least 7,769 cases vs. 16,107 controls (this is the present author’s count from the main table in the paper, but certain counts were not clear, so the totals are probably larger) (Clarke et al., 2009). This is by far the most frequently studied single polymorphism in psychiatric and psychological research. The OR estimate for allele counts (the number of s alleles) was 1.076 ($P = 0.001$), with the dominant model not significant (s/s or $s/l > l/l$) and the recessive model ($s/s > s/l$ or l/l) yielding an OR = 1.16 ($P < 0.001$). In an unusually thoughtful discussion, these authors comment on many of the methodological issues that have plagued these candidate gene studies, including small sample sizes, variable and often unreliable genotyping methods, and diversity of many other aspects of study design as well as ancestral backgrounds. For this particular well-known polymorphism, the authors list several caveats that suggest the possibility of technical artifacts that might also explain the positive results: (1) the polymorphism is notoriously difficult to assay, and authors have usually not commented on what quality control procedures were implemented to ensure accuracy; (2) no association (OR = 0.96) was observed in the 5 studies that genotyped the third allele (a SNP in the long allele that was reported to make it functionally similar to a short allele, see the following); (3) in the 33 studies of European-ancestry samples, the evidence for association was marginal (OR = 1.06, confidence interval = 1.01–1.10, $P = 0.019$), thus the association was primarily driven by 7 East Asian samples; and the P-value for association was correlated with the short allele frequency in controls, which could suggest genotyping problems.

ADVERSE EVENTS AND 5-HTTLPR GENOTYPE

In 2003 Caspi and colleagues introduced what has become an influential approach for studying genotype-environment

interactions (Caspi et al., 2003). The 5-HTTLPR (5-HTT [serotonin]-linked polymorphic region) insertion-deletion polymorphism just 5' to the promoter region of the serotonin transporter gene (now called SLC6A4) had been identified in 1996 (Heils et al., 1996). Within a region of GC-rich 21–23 bp repeat sequences, there was a common variant allele that contained a 44 bp deletion, thus designated as the “short” allele versus the more common “long” or intact allele. Several lines of evidence suggested that the short allele reduced transcription of the gene product. Because the serotonin transporter is the site of action of the commonly used type of antidepressant drugs (serotonin-specific reuptake inhibitors, which block the transporter site), the effect of genotypic variation at this polymorphic site had already been studied many times. Caspi and colleagues measured the number of short and long alleles carried by each of 847 individuals whose health and psychological development had been studied longitudinally from childhood to age 26. The data permitted rating of the subjects for two measures of life stress: number of stressful life events between age 21 and 26, and childhood maltreatment between the ages of 3 and 11. The outcome measures were major depressive symptoms (or alternatively, major depression diagnosis) in the year before the 26th birthday (for the analysis of life events), and occurrence of a major depressive diagnosis between 21 and 26 (for the child maltreatment analysis). Genotype did not significantly predict the overall outcome of depression, or either type of stress. However, the number of *s* alleles predicted (1) the slope of the increase in depression outcomes (symptoms or diagnosis) as the number of stressful life events increased; and (2) the increase in the probability of a major depressive episode in those with probable or severe maltreatment versus no maltreatment.

This finding has been controversial since its initial publication, but it has been an attractive model for many investigators, and has been applied to the study of many different groups of subjects in relation to diverse stressors. More has also been learned about the polymorphism itself. As noted previously, an SNP inside the long allele has been described (rs25531) whose rare G allele alters an AP2 transcription factor binding site and thus reportedly makes the resulting allele (termed L_c) functionally equivalent to the short allele (Hu et al., 2005). However, only a small minority of behavioral studies have genotyped this SNP. Additional SNPs in the region have also been studied, and it has been reported that other SNPs are associated with greater changes in transcription than the short/long variant (Martin et al., 2007), but these have also not been studied further. It has been noted that the most commonly used assay for the short-long alleles is prone to error due to bias toward calling of short alleles (Martin et al., 2007; Wray et al., 2009). Most behavioral studies have genotyped only the short/long polymorphism.

Because there have been both positive and negative findings in a diverse set of studies, meta-analyses are of particular interest. Here, too, the evidence is contradictory, with two recent analyses taking very different approaches and arriving at opposite conclusions. The first meta-analysis (Risch et al., 2009) selected 14 studies (with 14,250 participants, of whom 1,769 developed major depression) for a narrow test of one

version of the primary Caspi et al. finding: that the recent onset of categorical major depression could be predicted by an interaction between *s/s*, *s/l* and *l/l* genotype status and the number of recent life events (0, 1, 2, ≥ 3). They found that the number of events was predictive (as has been repeatedly shown including by Caspi et al.), but that neither genotype nor the interaction of genotype and life events predicted major depression onset. The main advantage of these authors' approach was in rigorously defining the requirements for inclusion of studies, so that the predictor and outcome measures were consistent with the original finding. The authors' more general interpretation of the result was that gene-environment interactions are rarely true findings in the absence of a main effect for genotype.

However, the analysis was criticized for excluding so many of the positive studies for various methodological differences. A second meta-analysis was thus carried out (Karg et al., 2011) that included 54 studies with 40,749 participants. They opted for an inclusive approach, considering diverse types of stressful events, with most studies being categorized for secondary analyses into three groups based on the type of stress: number of all stressful life events ($N = 26,921$), childhood trauma ($N = 6,936$), and specific medical conditions ($N = 6,592$). Thus, these authors opted for inclusiveness, tolerating differences in predictive measures and study design as long as the outcome could be analyzed in terms of consistency with the hypothesis that increased numbers of short alleles would be predictive of increased vulnerability to development of depression by either continuous or categorical outcome measures. The analysis of all studies strongly supported the hypothesis ($P = 0.00002$). Interestingly, the secondary analyses supported the hypothesis for childhood maltreatment ($P = 0.00007$) and specific medication conditions ($P = 0.0004$), but not for number of stressful life events ($P = 0.03$ without correcting for multiple tests), and the latter analysis was also sensitive to removal of many individual studies and to the use of self-report scales. So in one sense the two analyses were consistent (number of stressful events does not robustly interact with genotype in predicting depression), but the positive result in the larger meta-analysis for definable stressors like specific medical conditions suggests that the more general hypothesis could be true.

A CRITIQUE OF CANDIDATE GENE STUDIES

Psychiatric candidate gene studies have been fraught with problems from the perspective of investigators in the field of modern genomics (the study of all genes and their relationships to each other and to the environment):

1. Given the number of sequence variants in the genome and the lack of prior knowledge to formulate strong pathophysiological hypotheses about psychiatric disorders (until recently), the a priori probability of any one candidate polymorphism being associated with a given disorder is essentially zero, and thus false positives are likely to be very common (Sullivan et al., 2001). Combined with the typical practice of requiring only a nominal significance level for each separate study of a single polymorphism ($P < 0.05$), rather than correcting

for all tests performed for a particular outcome (as is done in genome-wide linkage and association studies), there is ample room for skepticism about the results of these studies.

2. Virtually all psychiatric candidate gene studies have investigated common polymorphisms which, as noted previously, are unlikely to have large effects (ORs for association). Yet, psychiatric and psychological researchers have persisted in studying them with samples that are vastly underpowered for detecting small effects.
3. Many of the initial positive findings for the “popular” candidate genes were reported at a time when genotyping assays had much higher error rates, and with much greater variability across labs in accuracy of genotyping, than is the case with current high-throughput genotyping arrays. Sen and Burmeister (2008) demonstrated empirically that psychiatric candidate gene studies have been prone to genotyping errors: they found that in 325 studies of 17 polymorphisms, deviation from Hardy–Weinberg equilibrium (the expected distribution of homozygous and heterozygous genotypes based on the frequencies of the alleles) was significantly correlated with the sample size. Genotyping error is by far the most likely explanation for this. This effect was observed separately for the many studies of 5-HTTLPR. This might not be critical if all investigators routinely balanced the order in which cases and controls were genotyped in each batch of assays, but frequently, case and control DNA specimens are obtained, stored, or even genotyped separately so that systematic differences can result from variation in error rates across batches of sample or across labs. For many years, genetics investigators were very resistant to performing duplicate assays to evaluate test genotyping error rates, although it is now routine.
4. Almost all published “candidate gene” studies are really studies of one or a few polymorphisms and ignore the gene as a unit of study. (The term “polymorphism” simply refers to a specific position in the genome where different chromosomes in a population have different DNA sequences. It arose when sequence variants were genotyped by methods that required the migration of processed DNA on gels, resulting in pictures of two or more horizontal bands that were due to radioactive or other labels attached to the variant sequences. Thus the “shapes” of the variants were different, hence “polymorphic.”) The most widely studied polymorphisms in psychiatric genetics were selected because there was evidence that they resulted in different levels of expression of the gene. But the polymorphisms that have been frequently studied do not represent the only genetic determinants of expression levels of their genes, and comprehensive studies of variation in each gene have rarely been carried out. In one such example, it was shown that several SNPs in the serotonin transporter gene (SLC6A4, 5-HTT) were significantly associated with expression, some of them more strongly than 5-HTTLPR (Martin et al., 2007). Yet,

no other behavioral study of this gene has ever considered these other variants. Instead, behavioral researchers commonly refer to a study of, for example, the 5-HTTLPR polymorphism as a study of the “serotonin transporter gene,” as if the genotype at this polymorphism is all one needs to know about the gene. Similarly, investigators write that “we studied the X, Y, and Z genes” when they studied one polymorphism in each gene.

We may be turning a corner in this area of research. Unbiased genome-wide studies are beginning to produce robust evidence for association of genes to disorders such as schizophrenia and bipolar disorder. Subsequent studies of gene expression, gene-gene, or gene-environment interactions, and biological and clinical effects of genotype can be carried out on the basis of a strong prior hypothesis, and study results are more likely to have biological relevance to pathophysiology. Also, with the advent of high-throughput sequencing methods, it is gradually becoming easier and cheaper (but still not routine in 2012) to carry out comprehensive studies of sequence variants in targeted regions or throughout the genome. It is to be hoped that the next generation of candidate gene studies will avoid the pitfalls that have been so common in the past.

CONCLUSIONS AND FUTURE DIRECTIONS

It has proven difficult to detect specific genetic associations for depression-related phenotypes. It is likely that this is due to modest heritability, high prevalence, and substantial heterogeneity of genetic and non-genetic factors without known clinical or biological markers to permit analysis of more homogeneous subgroups. Linkage studies have produced some promising findings, but common SNPs do not have sufficiently large effects on risk to explain these findings (and significant common SNP associations have not been observed in the best linkage regions), so large targeted or whole-genome sequencing studies will be needed to determine whether there are rare risk variants in these regions, or whether they are false positive results. GWAS analyses have not yet yielded significant results for single SNPs after genome-wide correction, and it seems likely that much larger GWAS samples would be required to accomplish this. There are additional studies in progress, most notably a study of 5,000 cases and 5,000 controls in China (Flint et al., 2012), but it is unclear whether a several-fold increase in total worldwide sample size will be available in the near future. There have been some promising results suggesting overlapping findings in major depression and bipolar disorder (i.e., that bipolar risk genes might increase risk of major depression in some individuals), and larger-scale cross-disorder analyses that will be available soon from the Psychiatric Genomics Consortium should provide new information about the degree of genetic overlap and about specific cross-disorder associations. Gene expression studies of postmortem brain specimens have produced promising results, but small samples and confounding factors remain problematic. Finally, in the present author’s judgment, “candidate gene” studies of single polymorphisms have not been productive in elucidating the genetic basis of risk for depressive disorders, and have been prone to

methodological and technical problems; and the much-studied hypothesis of gene-environment interactions involving stress and the 5-HTTLPR polymorphism remains controversial.

What can we expect in the near future? Advances in studies of depression have always been driven by new genetic technologies but also by improvements in clinical methods and study designs, and we will consider both here.

Larger GWAS analyses (i.e., association of common SNPs) will be forthcoming as large-scale genetic projects are completed, such as (to give examples from the United States) the Kaiser Permanente Research Program on Genes, Environment, and Health (Hoffmann et al., 2011) and the Million Veteran Program (<http://www.research.va.gov/MVP/>). One dilemma inherent to such projects is that they must rely on brief assessments and/or information from medical records, so that detailed clinical characterization is usually impossible. It is not yet known whether very large sample sizes will overcome the high degree of heterogeneity that is likely to result from this type of strategy. But it is clear that epidemiologists are beginning to think in creative new ways about studying larger population-based and clinical samples, and new sampling and data collection methods would be useful for depression research. Larger analyses of rare CNVs in depression samples will also emerge. Emerging findings of genetic associations that cut across current diagnostic boundaries could begin to shed light on genetic mechanisms in depression.

All of the developing technologies of modern genomics will be applied to depressive disorders as costs decline: genome-wide sequencing; targeted high-throughput sequencing (including exome sequencing, although regulatory sequences might be particularly critical in common complex disorders); RNA sequencing; and epigenetic assays. The first genome-wide epigenetic study of major depression was recently published (Sabunciyan et al., 2012). DNA methylation was studied in postmortem prefrontal cortex samples from 39 individuals with major depression histories and 26 controls, with a small follow-up sample. No replicable results were reported. Nevertheless, larger-scale studies using diverse epigenetic designs are likely to be attempted because of substantial evidence suggesting that epigenetic factors could be relevant to depression (Sun et al., 2012).

Because depression is such a common and modestly heritable disorder, it is possible that virtually all genetic risk factors have individually small effects. In this case, more powerful methods for analyzing the aggregate role of genetic pathways should provide useful, and it is to be expected that increasing knowledge about the functions of genes, coupled with advances in proteomic research, will lead to substantial progress. Research on animal models and pharmacological mechanisms could also provide critical clues. Studies of gene-environment interactions may also prove to be critical; this may depend on further improvement in epidemiological technologies for identifying and recruiting large relevant samples, for example, individuals with severe childhood abuse in whom genetic factors might be interacting in specific ways with the effects of trauma.

Studies of neurons generated from individuals with depression (and other disorders) using cell reprogramming technologies (Brennand and Gage, 2011; Pang et al., 2011) are likely to permit studying genetic, structural, and physiological changes

in brain tissue in much larger samples, while circumventing the problems inherent in the use of postmortem tissue. The potential disadvantage is that these cells may not be entirely representative of cells in specific tissues that have fully developed functional connections with other brain regions. Further advances in the use of sequencing technologies to study immunological variation could also prove useful, given the putative role of inflammatory responses in depression.

Not to be overlooked is the continued importance of genetic epidemiological research. During a time of increasing criticism of categorical definitions of psychiatric disorders and of emerging genetic findings that cut across those boundaries, it may be useful to remember that the first breakthroughs in etiological research into the major adult disorders—namely, robust SNP association findings for schizophrenia (Ripke et al., 2011) and for bipolar disorder (Sklar et al., 2011), and high-penetrance CNV associations for schizophrenia (Levinson et al., 2011)—were discovered in cases that met criteria developed on the basis of careful dissection of twin and family study data. For depression, there is an even larger genetic epidemiological dataset, but there are many holes in our knowledge. Much of the existing data are from large-scale twin studies that necessarily have used abbreviated clinical assessments to achieve large sample size; they shed little light on such issues as differences between the mild forms of depression that are often observed in population-based studies and the disabling disorders observed in the clinic; the relationships among depressive, mild manic, and severe manic symptoms in the population; the extent to which clinically severe depressive and/or anxiety disorders might define less common and more heritable traits; and so on. New cross-disorder genetic findings will raise additional questions that might best be answered by careful genetic epidemiological studies of the distribution and co-occurrence of symptoms and syndromes that share genetic risk factors. Ultimately, technologies will be needed that permit more detailed phenotypic assessment of very large samples.

31 | ANIMAL MODELS OF MOOD DISORDERS

GEORGIA E. HODES AND SCOTT J. RUSSO

WHY USE ANIMAL MODELS?

One of the first questions that arises when planning a research project is what approach to use. How do we accurately model a disease in a rodent to understand the human pathophysiology and gain insight into new treatments? This is increasingly challenging for psychiatric disorders where the human diagnosis is based largely on self-report. Nevertheless, ongoing efforts in neuroscience to develop valid rodent models focus on key behavioral domains that are conserved across species that accurately model symptoms of depressive disorders. While other animal models, including non-human primates, dogs, and even fish, are used to model depression-like behavior, the majority of research is currently being done in the rodent model, which will therefore be the primary focus of this chapter.

Given advances in technology one might question why we still need to model behavior in an animal. Aren't there computer programs available to model drug or genetic manipulations? The reality is that animal models are currently the key to understanding a multitude of diseases. While there are computer-generated programs such as "Sniffy the virtual rat" (http://www.wadsworth.com/psychology_d/special_features/sniffy.html) that model some aspects of operant conditioning, there is currently no substitute for *in vivo* research. At this point there is still too much that is unknown about how the brain and body work to accurately model drug action *in silico*, and thus, rodent studies are critical to determine drug safety before human trials. Adding additional complexity, even when animal models have been used for drug screening purposes, sometimes the findings do not translate to humans. For example a cortisol releasing factor-1 antagonist Pexacerfont recently underwent clinical trials for generalized anxiety disorder. Although the drug was effective in animal models of anxiety, in human trials, the drug was completely ineffective, underscoring the difficulty in treating human behavioral disorders (Coric et al., 2010). Until we have a better understanding of the underlying biology driving mood disorders, we need to depend on animal models to develop safe and effective treatments.

This chapter will focus on animal models of depression, although there is significant overlap between rodent models of mood and anxiety disorder making our discussion relevant to both disorders. We will discuss the behavioral domains tested to explore depression and discuss the benefits and drawbacks of each approach. We will examine models stemming from two basic approaches. The first uses behavioral manipulations (i.e., chronic stress) to induce depression-associated behavior in normal mice. The second uses breeding strategies to try

and understand how naturalistic genetic variation can lead to a depression-like phenotype. These approaches and the symptoms of depression in humans that they model are presented in Table 31.1 and discussed throughout the chapter. Both of these approaches are valid and can inform us about the mechanisms of mood disorders and identify new compounds to treat them.

WHAT CONSTITUTES AN ANIMAL MODEL?

A relevant animal model is capable of reproducing one or more core symptoms of the disorder and should have face, construct, and predictive validity (Dalla et al., 2010). Face validity is the ability of the model to mimic the symptoms of the disorder. An example would be a model, like chronic mild stress (CMS) that results in decreased preference for a natural reward (i.e., sucrose water) (Willner, 2005). In this model, animals are exposed to alternating minor stressors for approximately two to four weeks. These stressors can include forced circadian shifts, tilted cages, physical restraint, or wet bedding (Willner, 2005), the main point being that the animal's environment is constantly changing in uncomfortable ways with no predictable pattern. This model has face validity because it induces anhedonia or the inability to experience pleasure, which is a core symptom of depression. Exposure to CMS reduces sucrose preference as well as decreasing the rewarding properties of intracranial self-stimulation (Dalla et al., 2010). Any model that measurably decreases the animal's engagement in these types of reward-related behaviors would have good face validity and be considered to model a core symptom of the disorder.

Construct validity evaluates the plausibility or rationale of the model to explain the human disorder. Construct validity is basically addressing the question, does the basis of the model make sense in light of what we know about the human disorder? An example of a model with good construct validity is the early life stress model (Plotsky et al., 2005), though it should be noted that all stress models have a degree of construct validity, since stress is a major precipitating factor in human depression. In this model, animals are separated from their mothers for three hours at a time from postnatal day (PND) 2 to PND 14. During that time they are kept warm but not held or stimulated. In adulthood, they display a number of measures of depression including altered hypothalamic-pituitary-adrenal axis (HPA) activity, increased addiction liability (Moffett et al., 2007), and decreased coping behavior when faced with a stressor (Gardner et al., 2005). Animals that are

TABLE 31.1. Diagnostic symptoms of depression and the behavioral measures used to model them in animals

DSM IV DEPRESSION SYMPTOM	BEHAVIORAL DOMAIN	ANIMAL MODEL
Depressed mood for majority of the day	Not measurable	No available model
Diminished interest or pleasure in most activities for majority of the day including social withdrawal	Decreased sucrose preference (Cryan and Mombereau, 2004) Shift in sensitivity to intracranial self stimulation (Cryan and Mombereau, 2004) Novelty-induced hypophagia (Dulawa and Hen, 2005) Social Interaction test (Krishnan et al., 2008)	CMS (Dalla et al., 2010; Krishnan et al., 2008) Olfactory bulbectomy (Cryan and Mombereau, 2004) Learned helplessness (Anisman and Matheson, 2005) Social defeat stress (Krishnan et al., 2007) Prenatal stress (Goel and Bale, 2009) FSL rats (Overstreet, 2012) WKY rats (Malkesman and Weller, 2009) Rouen helpless mice (El Yacoubi and Vaugeois, 2007)
Weight loss (when not dieting) or weight gain consisting of a change in more than 5% of body weight within a month, or decrease or increase in appetite nearly every day	Measure food intake (Dulawa and Hen, 2005) Weight (Neumann et al., 2011) Novelty-suppressed feeding (Dulawa and Hen, 2005)	CMS (Dallman et al., 2000), Social defeat (Krishnan et al., 2007) FSL rats (Neumann et al., 2011) WKY rats (Pare and Redei, 1993)
Increased or decreased sleeping every day	Shift in REM sleep patterns (Steiger and Kimura, 2010) Theta activity in hippocampus and amygdala (Kronfeld-Schor and Einat, 2012) Changes in body temperature or activity during sleep/wake cycle (Kronfeld-Schor and Einat, 2012)	CMS (Dalla et al., 2010; Kronfeld-Schor and Einat, 2012) Olfactory bulbectomy (Song and Leonard, 2005) Prenatal stress (Maccari et al., 2003; Steiger and Kimura, 2010) Social defeat stress (Kronfeld-Schor and Einat, 2012) FSL rats (Overstreet et al., 2005) WKY rats (Steiger and Kimura, 2010) Rouen helpless mice (Steiger and Kimura, 2010)
Observable psychomotor agitation or retardation. Psychomotor retardation includes decrease in ability to perform “self care,” difficulties with day-to-day physical activities. Psychomotor agitation includes unintentional purposeless movements including activities resulting in self harm.	Exploration of a novel environment in the open field test (Cryan and Mombereau, 2004) Motor coordination using a Roto-rod test (Cryan and Mombereau, 2004) Grooming activity in the splash test Active or avoidance (Cryan and Mombereau, 2004) Social interaction test (Cryan and Mombereau, 2004)	CMS (Krishnan et al., 2008), Olfactory bulbectomy (Song and Leonard, 2005) Learned helplessness (Seligman et al., 1975) Early life stress (Gardner et al., 2005) Social defeat stress (Krishnan et al., 2007) WKY rats (Pare and Redei, 1993)
Fatigue or loss of energy	Swimming activity in forced swim test (Cryan and Mombereau, 2004) Immobility in the tail suspension test (Cryan and Mombereau, 2004) Running wheel activity (Cryan and Mombereau, 2004) Active avoidance	Learned helplessness (Seligman et al., 1975) Early life stress (Gardner et al., 2005) Prenatal stress (Weinstock, 2008) FSL rats (Dalla et al., 2010) WKY rats (Pare and Redei, 1993) Rouen helpless mice (El Yacoubi and Vaugeois, 2007)
Feelings of worthlessness, excessive or inappropriate guilt for the majority of the time period	Not measureable	No available model
Cognitive difficulties including indecisiveness	Eye blink conditioning Barnes maze (Mueller and Bale, 2007) Radial arm maze (Song and Leonard, 2005) Morris water maze (Song and Leonard, 2005)	Olfactory bulbectomy (Song and Leonard, 2005) Prenatal stress (Mueller and Bale, 2007; Weinstock, 2008)
Suicidal ideation and recurrent thoughts of death	Not measurable	No available model

only separated from their mothers for 15-minute intervals during the same time period show resiliency to stress on all of these domains (Plotsky et al., 2005). From the human literature, studies of orphans in Romania in the 1980s, showed that children who are not held or stimulated during early postnatal life can develop

biological and emotional changes including depression, and cognitive deficits (Chugani et al., 2001). These studies support that the early life model of stress has good construct validity. From what we know about human depression, it makes sense that early life adversity can contribute to susceptibility to depression.

Predictive validity is the ability of known treatments to reverse the symptoms induced by the model. An example of a model of depression with good predictive validity is the repeated social defeat model (Krishnan et al., 2007). In this model the experimental mice are exposed each day to a novel aggressor and allowed to physically interact for 10 minutes. Animals are then separated with a perforated Plexiglas barrier that allows for sensory contact but no physical interaction. On the following day, animals are given a social interaction test that measures the time spent in the vicinity of a novel object and a novel animal. Animals that show susceptibility to the stressor will avoid the novel animal, a phenotype that is essentially permanent and only reversed by chronic, but not acute, treatment with antidepressants, including imipramine and fluoxetine (Berton et al., 2006). Importantly, these antidepressant treatments in humans also require chronic administration, thus providing excellent predictive validity. It should be noted that some models fulfill one or more of these criteria, however, ideally a model of depression will fulfill all three criteria. All of the models discussed in this section, chronic unpredictable stress, early life stress, and social defeat stress, have face, construct, and predictive validity.

Another set of criteria that have been used for determining the validity of a model are those proposed by McKinney and Bunney in the late 1960s (McKinney and Bunney, 1969). They proposed that a model should show similarity of symptoms or traits to the disorder being modeled, much like face validity. The model should also have an observable and objectively measurable behavioral change. Like predictive validity, the behavioral change should be sensitive to or reversible with known antidepressant agents, although as these known antidepressants have limited efficacy at best, they may not be the best determinants of a valid animal model for novel drug development. Finally, the model should be reproducible between investigators and laboratories. This is a key issue with some animal models of depression. For example some researchers have had difficulties in replicating the effects of chronic mild stress across laboratories (Cryan and Mombereau, 2004). A number of factors can contribute to difficulties in replicating behavioral effects, including strain of animal, age, sex, temperature differences, health of the animal colony, and so forth.

Lastly, a particularly important form of validity, not often used, involves the degree to which an animal model recapitulates the biological causes of depression in humans. This criterion has been termed pathological validity (Krishnan and Nestler, 2011) and is critical to future drug development efforts. To date, a number of peripheral biomarkers such as changes in release and feedback of cortisol, alterations in cytokine profiles, postmortem brain molecular changes, and structural and functional brain imaging changes have been identified in humans, some of which have also been found in validated animal models. These are summarized in Table 31.2 and referred to throughout the chapter in the context of each model. At this time there is still too much unknown about the etiology of depression to develop bona fide models using clinically accepted diagnostic criteria to establish the pathological validity. However, it a good criterion to keep in mind as the field moves forward.

WHAT IS DEPRESSION AND HOW DO WE MODEL SYMPTOMS?

Depression is a debilitating disorder that currently affects 16.5% of people in United States within their lifetime and can affect up to 6.7% of the population in any given year (Kessler et al., 1993). Women are twice as likely as men to experience an episode of depression within their lifetime (Kessler et al., 1993). Depression is diagnosed based on a heterogeneous cluster of symptoms listed from the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)*. To meet criteria for depression a patient must report depressed mood or lack of interest plus four additional symptoms for two or more weeks. As shown in Table 31.1, the other symptoms include decreased interest and pleasure, weight or appetite change, changes in sleep patterns including either sleeping too much or too little, psychomotor agitation or retardation, fatigue, feelings of worthlessness or guilt, cognitive difficulties including decreases in ability to concentrate or feelings of indecisiveness, and recurrent thoughts of suicide or death (American Psychiatric Association, 2000). Because diagnosis of depression is dependent on expression of a group of symptoms rather than a biomarker-based test it leads to issues in modeling. Two individuals can exhibit very different clusters of symptoms and yet both are diagnosed with the same disorder. For example, patient A reports feelings of sadness accompanied by loss of appetite, insomnia, psychomotor agitation, and suicidal ideation. Patient B reports a lack of interest along with increased appetite and weight gain, hypersomnia, psychomotor retardation, and feelings of indecisiveness. While both patients would receive a diagnosis of major depression, their symptomology is completely different. Given this, animal models tend to focus on endophenotypes or behavioral domains that model these core symptoms rather than trying to fulfill the full criteria for depression diagnosis. In this way, animal models allow us to understand the brain circuits that control the endophenotypes, which may allow us to develop more selective therapeutics that treat the domain rather than the diverse cluster of symptoms that define depression. The next section will include a discussion of common measures used to examine the validity of these models for each depression-like phenotype.

ENDOPHENOTYPES OF DEPRESSION

Behavioral screens used to discern a depressive phenotype can be sorted into three core domains: appetitive tasks, measures of behavioral despair, and ethologically relevant behaviors, such as grooming and social interaction. In addition, researchers use physiological measures that are consistently altered in human subjects with depression, or have otherwise been validated in animal models of depression. These include, but are not limited to, peripheral endocrine, metabolic, and immune markers, along with cellular and structural changes identified through brain imaging. Each of these pathological markers will be discussed throughout the following sections in the context of animal models that exhibit pathological validity (summarized in Table 31.2).

TABLE 31.2. Behavioral and pathological validity of animal models of depression

ANIMAL MODEL	BEHAVIORAL DOMAIN	RODENT PERIPHERAL ALTERATIONS	RODENT STRUCTURAL ALTERATIONS
Olfactory bulbectomy	Increased open field exploration (Song and Leonard, 2005) Increased anhedonia (Cryan and Mombereau, 2004) Decreased spatial learning (Song and Leonard, 2005) Decreased avoidance learning (Song and Leonard, 2005)	Elevated basal CORT (Song and Leonard, 2005) Increased pro-inflammatory cytokines (Song and Leonard, 2005)	Increased cell death (Song and Leonard, 2005) Decreased volume of hippocampus (Song and Leonard, 2005) Decreased dendritic spines and synapses (Song and Leonard, 2005)
Chronic mild stress	Increased anhedonia (Dalla et al., 2010) Decreased grooming (Willner, 2005) Increased immobility in FST (Willner, 2005) Potentiation of learned helplessness (Willner, 2005)	Increased basal CORT (Dallman et al., 2000) Increased pro-inflammatory cytokines (Grippo et al., 2005) Development of metabolic disorder (Dallman et al., 2000)	Decreased neurogenesis (Kubera et al., 2011) Decreased dendritic spine density and shift in spine type (Michelsen et al., 2007)
Learned helplessness	Decreased active avoidance (Seligman et al., 1975)	Alterations in brain region specific cytokine protein levels (Lee et al., 2008)	Decreased neurogenesis (Malberg and Duman, 2003) Decreased synaptic proteins (Reines et al., 2008)
Prenatal stress	Increased immobility in FST and TST (Alonso et al., 1991; Goel and Bale, 2009) Increased anhedonia (Goel and Bale, 2009) Decreased spatial learning (Weinstock, 2008) and alterations in spatial navigation strategies (Mueller and Bale, 2007)	Increased basal CORT and alterations in negative feedback (Goel and Bale, 2009)	Decreased neurogenesis (Weinstock, 2008) Decreased dendritic spine density (Weinstock, 2008)
Early life stress	Increased immobility (Krishnan and Nestler, 2011) Increase in submissive postures during social defeat (Gardner et al., 2005) Decreased spatial learning (Krishnan and Nestler, 2011)	Exaggerated CORT response to stress (Plotsky et al., 2005) Down regulation of cytokine gene expression within the brain (Dimatelis et al., 2012)	Decreased neurogenesis (Mirescu et al., 2004)
Repeated social defeat stress	Increased social avoidance (Krishnan et al., 2007) Increased anhedonia (Krishnan et al., 2007) Increased anxiety behaviors (Krishnan et al., 2007)	Exaggerated CORT response to a second stressor (Krishnan et al., 2007) Increase in pro-inflammatory cytokines (Gomez-Lazaro et al., 2011) Altered metabolism (Krishnan et al., 2007)	Decreased neurogenesis (Lagace et al., 2010) Decreased dendritic spine density and shift in spine type (Christoffel et al., 2011)
FSL rats	Increased time immobile in FST (Overstreet, 2012) Decreased social interaction (Overstreet, 2012) Increased anhedonia (Overstreet et al., 2005)	Decreased CRF and ACTH (Overstreet et al., 2005) Low body weight (Overstreet et al., 2005) Basal reductions in pro-inflammatory cytokines (Overstreet et al., 2005) More prone to infection (Overstreet et al., 2005)	Increased neurogenesis (Husum et al., 2006)
Wistar Kyoto rats	Increased time immobile in FST (Pare and Redei, 1993) Decreased active avoidance (Pare and Redei, 1993) Increased anhedonia (Malkesman and Weller, 2009) Increased anxiety (Malkesman and Weller, 2009)	Increased basal CORT and CORT response to stress (Malkesman and Weller, 2009) Decreased HPA negative feedback to stress (Malkesman and Weller, 2009) More severe stress-induced ulcers (Pare and Redei, 1993) Low body weight (Malkesman and Weller, 2009)	Possible reduction in neurogenesis (Kronenberg et al., 2007) Possible decreased dendritic length (Falowski et al., 2011)
Rouen helpless mice	Increased immobility in FST and TST (Cryan and Mombereau, 2004) Increased anhedonia (El Yacoubi and Vaugeois, 2007)	Elevated basal levels of CORT (El Yacoubi and Vaugeois, 2007)	Not examined

BEHAVIORAL DOMAINS

APPETITIVE TASKS

Appetitive tasks generally measure the core symptom of depression, anhedonia, although some are also negatively affected by anxiety or cognitive deficits. A first-pass screen for anhedonia is done using sucrose preference tests, which consists of giving an animal a choice between a 1% sucrose solution and water. Although many derivations of the procedures have been published, access to a two-bottle choice for sucrose or water is given for an acute period of time (1–2 hours) (Dalla et al., 2010) or overnight (Krishnan et al., 2007). The researcher then measures how much sucrose is consumed versus the total amount of fluid consumed (both sucrose and water) and the percent sucrose preference is reported. While most animals greatly prefer the sucrose over water, a variety of stressors and genetic manipulations result in decreased sucrose preference (Cryan and Mombereau, 2004) while chronic treatment with classic antidepressants can reverse the effects of some chronic stressors on sucrose preference (Willner, 2005). One issue that arises when using this test to compare effects between the sexes is that females show a greater sucrose preference as baseline than males (Dalla et al., 2010). While sucrose preference tests are the most widely published measures of anhedonia, there are many other appetitive tasks that operate on similar principles. For example, sexual activity and the preference a male exhibits toward a sexually receptive female is considered to be a measure of natural reward preference (Willner, 2005). This measure also has validity given that depressed humans exhibit similar sexual dysfunction. The “gold standard” to measure reward function is intracranial self-stimulation (Carlezon and Chartoff, 2007). In this test, an electrode is implanted directly into the medial forebrain bundle, containing dense dopaminergic fibers emanating in the VTA, and the animals are allowed to press a lever to stimulate dopamine release. The more current necessary to invoke an operant response is thought to reflect reward thresholds and are significantly increased in stress disorders, meaning that they need greater activation of the circuitry to find things reinforcing.

Other appetitive tasks make use of food restriction or food rewards to measure a depression-like behavior. Novelty-suppressed feeding (NSF) is a task that measures the latency of an animal to eat in a novel environment. In this task, animals are food-restricted over night and then placed in a new environment the following day. One pellet of food is placed in the center of the novel space and the latency to approach and feed is measured (Dulawa and Hen, 2005). This was originally considered an anxiety test, however, evidence that latency to eat could be reversed or shortened by giving the animals chronic antidepressants led people to use the test as a measure of depression (Santarelli et al., 2003). In addition, a biological process in the hippocampus called neurogenesis, thought to control antidepressant efficacy, was shown to be necessary for the antidepressant effects on latency to feed in this task (Santarelli et al., 2003). A variation of this test is called novelty-induced hypophagia (NIH). The NIH test does not require food restriction. Instead animals are trained to eat a novel palatable substance in the home cage (Dulawa and Hen, 2005). Once the animal is reliably eating the substance, the latency to feed is measured

in a novel environment (Dulawa and Hen, 2005). While this again taps into aspects of anxiety/exploratory-based behavior, chronic, but not acute, treatment with antidepressants shortens the latency to eat in the novel environment.

BEHAVIORAL DESPAIR

A number of depression tests are considered measures of behavioral despair. These include the forced swim test (FST) (Fig. 31.1 A, B), tail suspension test (TST) (Fig. 31.1 C, D), and active avoidance tests. Behavioral despair tests can be thought to model feelings of sadness, psychomotor retardation, and fatigue. However, they are all confounded if the animal has a motor deficit and the active avoidance tasks are additionally confounded by cognitive deficits, since the animal has to learn how to escape or avoid a shock.

The FST was developed by Porsolt in the late 1970s. In this test, rats are placed in a cylinder containing 15 cm of room temperature water for 15 minutes. Twenty-four hours later they are again placed in the same cylinder and the amount of time the animal spends floating (immobile) is measured (Porsolt et al., 1978). The concept behind the test is that animals with higher levels of emotional despair would give up struggling sooner and remain immobile, thereby forgoing an attempt to escape the aversive environment. Importantly, the FST was the first animal model of depression that could be used as a rapid screening device for antidepressants, since tricyclics, MAOIs, and atypical antidepressants all decrease immobility on this test (Detke and Lucki, 1996). Variations of this test were later used to differentiate between different types of antidepressants. Drugs that engaged the norepinephrine (NE) system, such as tricyclic antidepressants, resulted in decreased immobility and increased climbing behavior. Drugs such as selective serotonin reuptake inhibitors (SSRIs) decreased immobility but also increased their swimming behavior (Detke and Lucki, 1996). An additional modification shortening the test to one day was then validated for use in mice and since has been used in a number of genetic mutant mice to screen for potential depression phenotypes (Krishnan and Nestler, 2011). The TST is essentially a variation of FST developed so that despair could be measured without the use of water. Removing the water element was thought to prevent hypothermia and increase repeatability (Steru et al., 1985) because water level and temperature can alter behavioral outcome. In this test mice are suspended by their tails for six minutes and the amount of time spent immobile is recorded as a behavioral measure of despair (Steru et al., 1985). The benefit of these types of tests is that they are rapid and allow for high throughput screening of new compounds. In addition, they are fairly accurate at detecting the efficacy of current antidepressants. However, they lack predictive validity in that acute antidepressants effectively decrease the time spent immobile in both the FST and TST even though chronic treatment is necessary to alleviate depression symptoms in humans. In general, these types of tests work well for determining antidepressant efficacy and screening potential new drugs based on the monoamine hypothesis, but their validity as a model for depression or use in testing novel mechanisms of action is highly questionable.

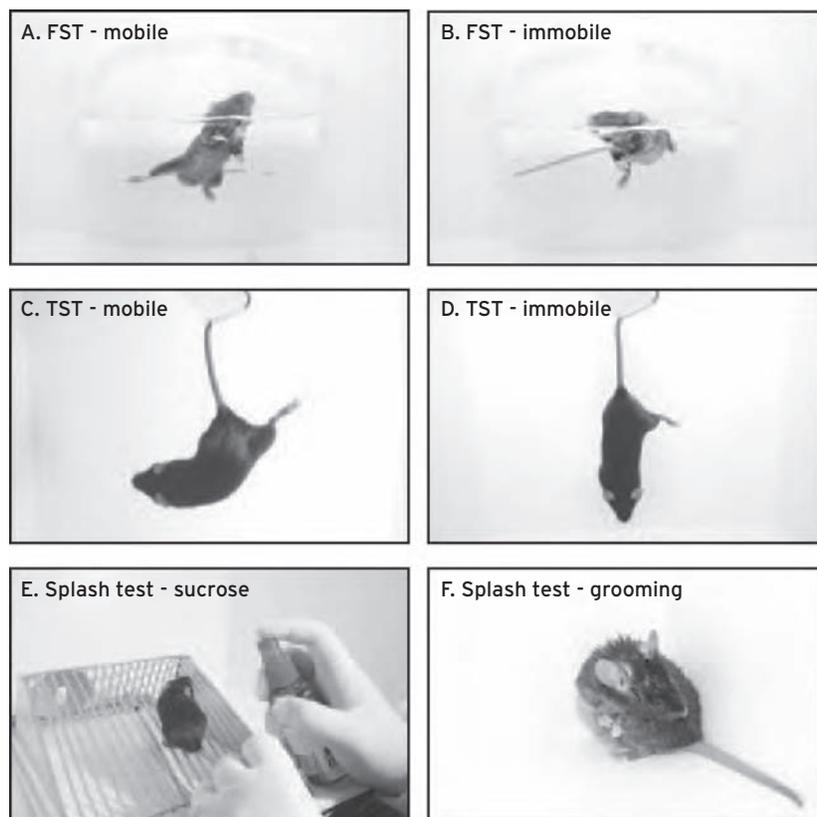

Figure 31.1 Behavioral assays of depression-like behavior in mice. Common behavioral tests used to assay depression-associated behavior. (A) Time spent swimming in the forced swim test (FST) is considered an antidepressant measure, as SSRIs will increase engagement in this type of behavior. (B) The time spent floating or in an immobile posture is considered prodepressant, as stress manipulations increase this behavior. (C) Struggling behavior in the tail suspension test (TST) is considered an antidepressant measure, as antidepressants increase engagement in this activity. (D) The amount of time the animal spends immobile is considered a depression-like response, as stress based manipulations increase the amount of time spent immobile. (E) In the splash test, an animal is sprayed with a 10% sucrose solution to make their coats sticky. (F) The amount of time spent grooming is measured as an indicator of a depression-like state; animals that are stressed spend less time grooming and this can be reversed by chronic antidepressant treatment. (Photography credit: Christopher Wood.)

Active escape avoidance is another commonly used measure of behavioral despair. In an active avoidance task animals are required to perform an operant behavior allowing them to escape an aversive environment. The operant response requirement can vary from simple (i.e., running through a doorway from one side of a cage to another) to complex (i.e., pushing a lever, turning a wheel, or poking their nose into a hole). Usually the stimulus that makes the environment aversive is a mild foot shock. A subset of animals that are stressed will fail to engage in active avoidance behavior (Krishnan and Nestler, 2011). This task has face validity and it is often used to test learned helplessness behavior, since animals experiencing repeated stress learn that they have no control over their environment and therefore don't attempt escape (Overmier and Seligman, 1967). Chronic treatment with antidepressants can reverse active avoidance deficits induced by the learned helplessness paradigm (Malberg and Duman, 2003), therefore the model has good predictive validity.

ETHOLOGICALLY RELEVANT BEHAVIORS

A number of behavioral tests for depression measure the degree to which ethologically relevant behaviors are altered. These are

behaviors that the animal would normally engage in within their natural environment. Two examples of this type of test include social avoidance behavior (Fig. 31.3) and the splash test (Fig. 31.1 E, F). Social avoidance behavior is defined as the amount of time an animal spends in the presence of a novel animal versus a novel object. This test is used to model two core symptoms of depression: lack of interest or pleasure, since rodents are social organisms and find these interactions to be naturally rewarding, and psychomotor retardation, as we can measure the total distance traveled within the environment as well as the time spent near the target or in the corners. While a version of this test, often referred to as sociability test, is also used extensively to test features of autism and memory, in depression, it is commonly used as a behavioral endpoint following repeated social defeat stress (Fig. 31.2). During testing the experimental animal is placed in a novel environment with a novel object, consisting of a small wire mesh cage. The amount of time the animal spends within the interaction zone with a novel animal placed inside the mesh cage is measured. A ratio of the time spent in the interaction zone with the novel animal divided by the time spent in the same area without the novel mouse can be used to determine if an animal exhibits social avoidance. Under control conditions, most animals prefer the

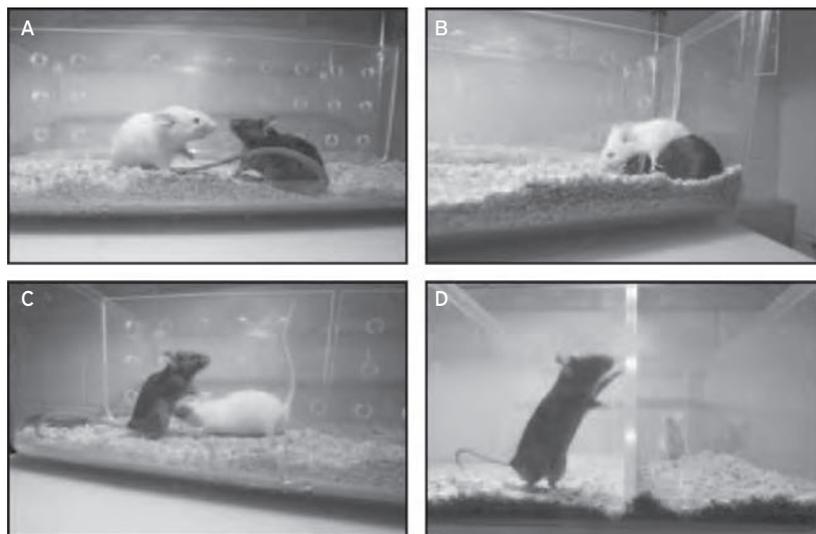

Figure 31.2 Repeated Social Defeat Stress and Social Interaction Testing. Repeated social defeat stress is an animal model of depression with strong face, construct, and predictive validity. The experimental mouse is housed with a new aggressor every day for 10 days. (A) The smaller C57BL/6J mouse is given a 10-minute physical interaction with a larger CD-1 mouse that is screened to show aggression within his home cage. (B) CD-1 aggressor mouse is pinning the C57BL/6J mouse, one type of aggressive behavior. (C) The C57BL/6J mouse is displaying a submissive posture to the CD-1 mouse. (D) After the physical interaction, the C57BL/6J mouse is separated by a divider that allows for sensory, but not physical, stimulation for the next 24 hours. (Photography credit: Christopher Wood.)

social target and increase their interaction time when the novel mouse is placed in the mesh cage. Conversely, susceptible mice avoid the novel animal and typically hide within the corners of the arena. This model has predictive, construct, and face validity, since chronic, but not acute, antidepressant treatment can reverse avoidance behavior in mice (Berton et al., 2006) and there is an extensive literature showing the contribution of repeated social subordination in the development of depressive disorders in humans (Gilbert, 2006). The model also has pathological validity; a number of biological targets have been identified in this model that are similarly changed in postmortem brain from humans with depression (Krishnan et al., 2007; Wilkinson et al., 2011).

Another ethologically relevant measure of a depressed state is a decrease in grooming behavior. All organisms including humans and rodents tend to decrease grooming when they are sick or stressed (Isingrini et al., 2010). These types of tests can be used to model lack of interest in normal activities of daily life, another core symptom of depression. Rodent studies such as the splash test score grooming intensity as a behavioral measure of an animal's psychological state. In this test animals are sprayed with a 10% sucrose solution that makes their coat sticky. The amount of time the animal spends grooming is then measured as an indicator of a depression-like state. This test has predictive and face validity since animals experiencing chronic stress will spend less time grooming, like depressed humans, and chronic, but not acute, antidepressants have been shown to reverse this effect (Isingrini et al., 2010). Together these endophenotypes give us multiple functional behavioral outputs that are relevant to depressive-like states in humans. It should be noted however, that each test focuses on aspects of core symptoms of depression and are most effective when used

as part of a larger test battery providing a powerful set of tools to explore the underlying biology of depression.

ANIMAL MODELS OF DEPRESSION

While there are no clinically accepted genetic or biological causes of depression in humans, it is clear that stress exposure increases depression onset and severity. Therefore, most models of depression utilize various environmental stressors to induce a depression-like behavioral phenotype and then study the underlying biological consequences of such stress on the key behavioral domains described earlier. Environmental models use “normal” animals and manipulate their environment through physical or psychological stress, surgical manipulation, or other methods to produce a depression-like phenotype. Examples of this type of stressor include early life stress, CMS, and olfactory bulbectomy. Genetic models make use of naturally occurring or trait-based selective breeding or gene knockout/transgenic technology to produce a depressive state. These studies can vary from examining natural strain differences in depression-associated behavior to conditional removal or overexpression of genes of interest, although the latter is beyond the scope of the current chapter and is discussed in detail in subsequent chapters. Recently, there has been increasing interest in epigenetic models of depression. These models examine the impact of environmental stressors on parent-offspring heritability of traits that are outside of genetic sequence differences. Alternatively they consider differences in the stress response not driven by genetic sequence differences. While epigenetics is clearly an important area of research, it is discussed in detail in subsequent chapters and is

beyond the scope of the current discussion. The following section will discuss examples of a variety of these animal models of depression and discuss their validity within the context of the behavioral domains previously described.

OLFACTORY BULBECTOMY

The majority of these studies have been performed in rats, with only a small subset in mice (Cryan and Mombereau, 2004). In this model the olfactory bulbs are removed resulting in a variety of behavioral, cellular, neuroendocrine, and immune changes consistent with depression (Cryan and Mombereau, 2004). Animals that undergo olfactory bulbectomy are highly aggressive and hyperactive, including increased investigation of novel environments and increased nocturnal activity (Song and Leonard, 2005). They also show cognitive impairment similar to patients with depression. These cognitive impairments include decreased abilities to perform spatial learning tasks that engage the hippocampus, such as the radial arm maze and Morris water maze, along with deficits in active avoidance tasks (Song and Leonard, 2005). Olfactory bulbectomy results in anhedonia measured by decreased sucrose preference (Cryan and Mombereau, 2004) and reduced sexual activity (Song and Leonard, 2005). These deficits are due to the removal of the olfactory bulbs, as inducing anosmia by flushing zinc through the nasal cavities does not cause any significant depression phenotype (Song and Leonard, 2005). The removal of the olfactory bulbs also leads to cell death and degeneration in a number of areas implicated in depression in humans, including the hippocampus, amygdala, dorsal raphe, cortex, and locus coeruleus. Within the hippocampus there is a reduction in volume along with a decrease in the number of dendritic spines. These changes have also been reported in the piriform cortex (Song and Leonard, 2005) and the amygdala (Cryan and Mombereau, 2004). Chronic antidepressant treatment can reverse behavioral and structural changes (Song and Leonard, 2005). In addition, removal of the olfactory bulbs also induces changes similar to those seen in depressed humans within the immune system. These include increases in serum concentrations of the pro-inflammatory cytokine interleukin (IL)-1 β and prostaglandin E₂ along with a decrease in circulating levels of the anti-inflammatory cytokine IL-10 (Song and Leonard, 2005). Olfactory bulbectomized animals also have elevated basal corticosterone (CORT) levels, the rodent homolog for the stress hormone cortisol in humans. While this model does not have good construct validity and only moderate face validity, it does have excellent predictive validity, as chronic antidepressant treatments consistently reverse the behavioral effects of olfactory bulbectomy (Cryan and Mombereau, 2004). The paradigm also has excellent reproducibility across labs. Interestingly, olfactory bulbectomy is one of the few models of depression that does not show sex differences in the behavioral measures. Both males and females show behavioral effects of olfactory bulbectomy in tests of locomotor activity, exploration of a novel environment, anxiety, and sucrose preference (Song and Leonard, 2005) making it a test of interest for those studying depression in females.

CHRONIC MILD STRESS

In the chronic mild stress (CMS) paradigm, sometimes referred to as chronic variable or unpredictable stress (CVS or CUS), animals are exposed to variable stressors for a length of time extending between 6 (LaPlant et al., 2009) and 28 days (Willner, 2005). The stressors are typically minimally invasive but are given in a varied and unpredictable order. Animals can be exposed to more than one stressor in a day and the stressors are administered during all phases of their light:dark cycle. Stressors include restraint, tail suspension, disruption of the light/dark cycle, cage tilt, food and/or water restriction, changing of cage mates, temperature reductions, exposure to soiled or wet bedding, and random foot-shocks (Willner, 2005). Animals exposed to CMS generally show anhedonic behaviors, such as decreased sucrose consumption, impairments in natural reward associations, and changes in responsiveness to intracranial self-stimulation (Dalla et al., 2010). Animals exposed to CMS display increased immobility in the FST (Willner, 2005) and are more likely to show decreased active avoidance if they are subsequently exposed to the learned helplessness paradigm described in the following section in this chapter (Willner, 2005). They also show deficits in grooming, sexual behavior, and immune function (Willner, 2005). Biological profiling shows that CMS can induce increases in circulating levels of the pro-inflammatory cytokines tumor necrosis factor (TNF) α and IL1 β (Grippe et al., 2005) both in the brain and the body. Four weeks of CMS exposure also results in increased basal levels of CORT (Grippe et al., 2005) along with disruptions in circadian release of CORT leading to reduced peak levels and an elongation of the trough of the cycle (Dallman et al., 2000). This dysregulation of normal HPA feedback results in changes in the storage of calories and fat leading to the development of a metabolic syndrome (Dallman et al., 2000). CMS can reduce neurogenesis in rodents although this may be due to effects on cell survival rather than cell proliferation (Kubera et al., 2011). CMS can also alter spine density in the prefrontal cortex and hippocampus of rodents consistent with work in humans showing reduced volume of these structures by magnetic resonance imaging (MRI) (Michelsen et al., 2007). Importantly, many of these effects can be reversed with chronic, but not acute, antidepressant exposure, giving this model good predictive validity. Also, an abbreviated six-day variation of this model can induce depression-like behaviors in females, but not males, making it an ideal model for understanding biological differences in stress responses between males and females (LaPlant et al., 2009). The utility of CMS to understand the neurobiology of depression in both males and females makes it a very useful tool to test new compounds for the treatment of depression and possibly identify targets for individualized approaches to treatment in men and woman.

LEARNED HELPLESSNESS

The learned helplessness paradigm was developed in the late 1960s. In the original experiments, dogs were given a single

session of multiple inescapable shocks and then presented with an active avoidance task (Overmier and Seligman, 1967). They were allowed to escape the shock by jumping over a barrier in a shuttle box. In control animals that were not exposed to a previous bout of inescapable shock, the animals quickly learned to escape the aversive environment. Dogs that had experienced a prior uncontrollable shock failed to learn to escape the shuttle box and would exhibit helpless behavior (i.e., dogs would lie down and whimper) (Seligman, 1972). This test was later adapted for use in rodents and is now considered to be a primary depression test. Adaptations of the protocol have included yoked controls, allowing the researcher to directly compare behavioral and biological effects of having control over shock termination. Here, both groups of animals are exposed to the shock before avoidance training but only one group can control the termination of the shock (Seligman et al., 1975). Animals that can terminate the stressor, usually by performing an operant task, learn to escape in a subsequent active avoidance task, whereas yoked animals receiving the same shock without control over termination show a much greater degree of helplessness behavior. Interestingly, there are individual differences in susceptibility to inescapable stress; a third of the animals exposed to inescapable shock display susceptibility and engage in helplessness behavior, whereas a majority of animals are resilient to the stress and still learn to escape (Russo et al., 2012). This suggests that there may be an epigenetic component, since many of these studies are performed in genetically identical inbred animals, though further studies are needed. The difference in susceptibility also highlights a degree of face validity to the model, since most humans are resilient in the face of stress and don't develop significant depression symptoms. The model also has good construct validity, as loss of control over one's environment is highly stressful and can contribute to onset of a depressive episode (Gilbert, 2006) and all classes of antidepressants reverse learned helplessness in adult male rats (Zazpe et al., 2007). The model has some pathological validity, since helpless rodents have decreased hippocampal synaptic proteins such as PSD 95 and synaptophysin, and decreased neurogenesis (Malberg and Duman, 2003), which are consistent with some of the structural changes observed by MRI in humans. Both behavioral and structural deficits can be reversed by chronic, but not acute, treatment with antidepressants (Malberg and Duman, 2003), indicating that the model has good predictive validity (Malberg and Duman, 2003; Reines et al., 2008). Helpless animals also show reductions in IL-2 levels in brain regions implicated in depression including the hippocampus and prefrontal cortex (Lee et al., 2008). In the periphery IL-2 is involved with T-cell development and the recognition of "self" within the immune system (Lee et al., 2008) and within the brain it has been demonstrated to control emotion associated behaviors (Lee et al., 2008). However, females do not have the same stress-related behavioral deficits in LH (Shors et al., 2007), nor do they exhibit any chronic stress-related decrease in neural plasticity (Shors et al., 2007). Therefore the utility of the test is limited, especially when studying females. Regardless, LH models important aspects of mood disorders, and therefore, warrants further mechanistic

studies to determine pathological validity across a wider array of biomarker targets.

DEVELOPMENTAL STRESSORS

Stress exposure during critical periods of development has been shown to produce long-lasting changes in depression and anxiety-like behavior (Russo et al., 2012). Prenatal stress paradigms involve exposing pregnant females to stress and examining the effects of this stress exposure on the adult offspring. The effects of prenatal stress depends in part on the critical prenatal period when the mother is exposed to the stressor (Goel and Bale, 2009; Weinstock, 2008). Any number of prenatal stressors, including CMS (Goel and Bale, 2009), restraint stress, foot shock, and swim stress have been used (Weinstock, 2008). Stress during the early prenatal period (PND 1–7) results in a depression-like phenotype in male but not female mice (Goel and Bale, 2009), as measured by increased immobility in the FST and TST. Male mice exposed to gestational stress at this time point also displayed decreased sucrose preference (Goel and Bale, 2009). Interestingly, during this period, stress leads to dysmasculinization, causing males to engage in female-like behavioral strategies in their exploration of the Barnes maze (Mueller and Bale, 2007). Physiological changes in HPA-axis sensitivity to stress have been shown. Male mice exhibit larger stress-induced increases in CORT along with alterations of gene expression involved with negative feedback of the HPA (Goel and Bale, 2009). Later gestational stress can lead to a more pronounced depression-like phenotype in females than males, although this depends heavily on the behavioral domain being studied (Weinstock, 2008). Restraint stress (PND 15- parturition) leads to greater immobility in the FST in females than males (Alonso et al., 1991). However, other studies have reported that late gestational restraint stress (PND 14–20) impacts cognitive abilities in males but not females (Weinstock, 2008). Both restraint stress and foot shock starting at PND 8 have been reported to decrease spatial learning in males (Weinstock, 2008). These mice also had reductions in dendritic spine densities within the hippocampus that were thought to be associated with the cognitive deficit (Weinstock, 2008). Other studies performed only in males have found late gestational restraint stress also leads to adult reductions in cell proliferation within the hippocampus (Weinstock, 2008). Like early gestational stress, late gestational stress leads to hypercortisolemia in adults along with dysregulation of HPA negative feedback (Weinstock, 2008). Late gestational restraint stress also leads to alterations in circadian rhythm and changes in REM sleep (Maccari et al., 2003). These alterations include increases in paradoxical and fragmented sleep along with a decrease in deep slow wave sleep (Maccari et al., 2003). This model has good predictive validity, since treatment of offspring exposed to late gestational stress with chronic antidepressants in adulthood can reverse behavioral effects in the FST and alter glucocorticoid receptor expression (Maccari et al., 2003).

Early life stress can also produce significant depression-like phenotypes (Russo et al., 2012). Most studies have used

maternal separation during the early postnatal period followed by behavioral, hormonal, and molecular analysis of the separated offspring during adulthood (Plotsky and Meaney, 1993). Studies typically separate pups for either 15 or 180 minutes a day during the postnatal period. Offspring separated for 15 minutes a day did not differ from normal facility reared controls or else showed resilience to stress exposure later in life (Plotsky et al., 2005). This phenomenon is referred to as stress tolerance and may promote active coping strategies (Russo et al., 2012). Conversely, animals exposed to early life stress have displayed greater immobility, and decreased spatial learning (Krishnan and Nestler, 2011). Rats exposed to maternal separation and then put through a repeated social defeat paradigm in adulthood used a passive coping mechanism to the stressor and engaged in more submissive postures and behavior (Gardner et al., 2005). Other studies have demonstrated that early life stress can make animals more prone to self-administer alcohol and cocaine (Moffett et al., 2007). They also exhibit greatly exaggerated HPA responses to stress (Plotsky et al., 2005) and have decreased cell proliferation in hippocampus leading to a smaller overall volume (Mirescu et al., 2004). Interestingly, studies in rodents have demonstrated that most early life stress affects male, but not female, rodents in adulthood (Diehl et al., 2007). In general it is currently thought that male animals are more susceptible to most forms of early life stress than females (Goel and Bale, 2009), whereas females are more susceptible to stress after puberty (Dalla et al., 2010). More research is clearly needed to understand how stress susceptibility changes across

the life span in both sexes. In sum, early life stress models are excellent for understanding a host of biological and behavioral changes important in depression. They exhibit excellent face, construct, and predictive validity as well as a growing body of evidence that suggests the model has pathological validity.

REPEATED SOCIAL DEFEAT STRESS

Repeated social defeat stress (Fig. 31.2) can unmask behavioral differences in vulnerability to stress across a wide spectrum of behavioral domains. In this model, experimental mice are placed into the home cage of a novel larger aggressive mouse each day for 10 days (Krishnan et al., 2007). The larger mouse quickly establishes dominance through physical interaction for a brief five to ten minute period, and then a perforated Plexiglas divider is placed in the cage to physically separate the two animals, allowing them to experience continued sensory cues. At the end of 10 days, experimental mice are separated into resilient and susceptible populations based on their social interaction score (Fig. 31.3), described earlier in the behavioral domains section of this chapter. Susceptibility and resilience scores are calculated as a ratio of the time spent near the novel animal divided by the time spent near the novel object. Animals that prefer the novel animal are considered resilient and behave like control animals that have not been exposed to stress. Animals that avoid the novel animal and spend more time near the novel object are considered susceptible. Approximately two-thirds

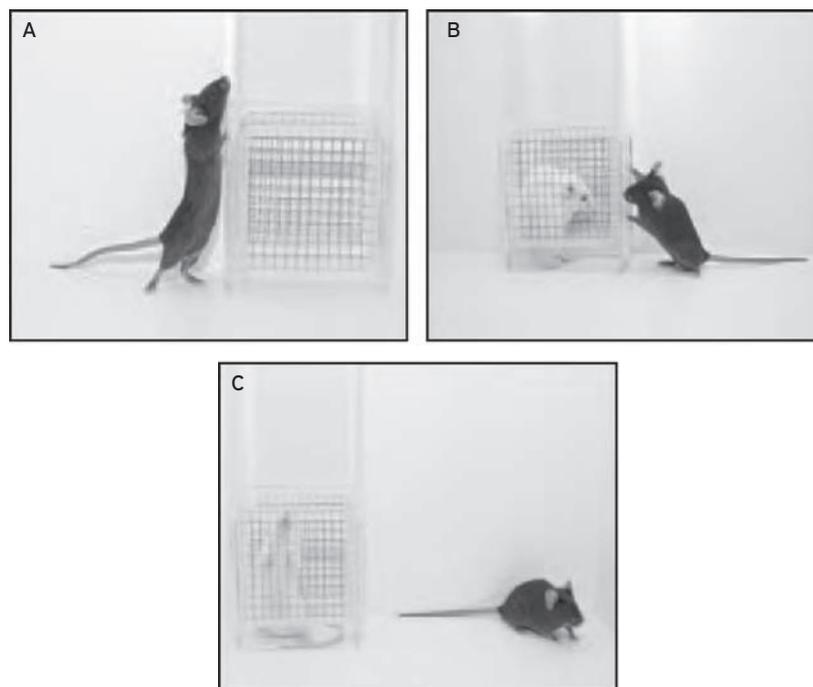

Figure 31.3 Social interaction testing. The social interaction test is used as a behavioral endpoint for stress-based manipulations such as repeated social defeat stress. In this test an animal is placed in a novel environment and allowed to interact with a novel object or a novel animal. (A) The time the mouse spends near a novel object is measured. (B) The amount of time spent interacting with the novel animal is measured. Control and resilient mice spend more time with the novel animal than the novel object. (C) The amount of time spent avoiding the novel animal is measured. Stress-susceptible mice will spend more time with the novel object than the novel animal. (Photography credit: Christopher Wood.)

of the mice exhibit social avoidance behavior and are considered susceptible, while the remaining one third do not show avoidance behavior and are considered resilient (Krishnan et al., 2007). Interestingly, both susceptible and resilient mice exhibit significant anxiety phenotypes, yet only susceptible mice show depression-like phenotypes measured by social avoidance, anhedonia, disruptions of the circadian system, and metabolic changes, including weight gain (Krishnan et al., 2007). The fact that only a subset of animals shows vulnerability to the effects of stress is again consistent with human responses to stress and provides construct validity. Some of the behavioral effects, including social avoidance and metabolic syndrome, can be reversed with chronic, but not acute, antidepressant treatment (Berton et al., 2006). Mechanistically, social defeat stress leads to a transient decrease in cell proliferation in both susceptible and resilient mice (Lagace et al., 2010), though reduced neurogenesis has been functionally implicated in resiliency, which may be somewhat counter to the reduced hippocampal volume identified in depression in humans (Lagace et al., 2010). Susceptibility to social defeat stress increases dendritic spine density on medium spiny neurons in the nucleus accumbens, a region critical for emotion and reward (Christoffel et al., 2011). These changes in spine profiles correlated with social avoidance behavior. Social defeat stress also increases circulating levels of pro-inflammatory cytokines in susceptible mice (Gomez-Lazaro et al., 2011). While social defeat is clearly a powerful model of depression exhibiting face, construct, and predictive validity, one of the major limitations of this type of stress is that it is difficult to test in female mice. Female mice do not normally attack each other, making it difficult to establish antagonistic interactions based on these dominance hierarchies. A few recent studies using a female rodent that is monogamous and territorial (California mouse; *Peromyscus californicus*) (Trainor et al., 2011) or nursing dams have effectively established social dominance in females (Shimamoto et al., 2011). Importantly, these studies have shown similar effects as males in measures such as anhedonia, drug addiction, and metabolic effects. However, more research is clearly necessary to determine whether the same molecular cascades and neural circuitry are affected in both sexes.

SELECTIVE BREEDING MODELS

While there are no known genetic causes of depression, there is clearly a strong familial linkage (Gilbert, 2006), suggesting that certain heritable complex genetic traits may predispose one to depression. For years, researchers have utilized selective breeding strategies to uncover the genetic basis of disease and, not surprisingly, there are a few lines, including the Flinder's sensitive line (FSL) and the Wistar-Kyoto (WKY) line, that show increased depression-associated phenotypes. Although the FSL was not originally investigated as a model of depression, it became clear that some of the neurochemical changes recapitulated alterations in humans with depression. The FSL rats were derived from Sprague-Dawley rats by selecting animals that were sensitive to cholinergic and anticholinergic compounds (Overstreet, 2012). It was later determined

that FSL rats show increased time spent immobile in the FST and decreased social interaction behavior (Overstreet, 2012). In addition, FSL rats are less motivated to work for a natural reward and have lower body weight and alteration in REM sleep (Overstreet et al., 2005). Interestingly, male FSL rats show greater behavioral deficits than females; females only show reductions in latency to immobility but not in time spent immobile (Dalla et al., 2011). The male response in the FST has been used to screen novel antidepressant compounds because they can be tested in concert with the Flinder's resistant line (FRL), which do not show the same behavioral deficits and are not responsive to acute antidepressant treatment. Interestingly, FSL rats are only responsive to chronic, antidepressant treatment, making this line particularly useful for its predictive validity. Pathological changes are also shown in the FSL rats. They have reductions in CRF and ACTH, similar to the subset of depressed subjects with hypocortisolemia and psychomotor retardation (Overstreet et al., 2005). The FSL rats also show abnormalities in immune function. There is a reduction in the number of natural killer cells in FSL rats, and they are more vulnerable to infection. However, FSL rats show basal reductions in pro-inflammatory cytokines such as IL-6 (Overstreet et al., 2005) that are normally elevated in the blood of subjects with depression (Dowlati et al., 2010). While FSL rats have increased cell proliferation in the dorsal hippocampus compared to the FRL line, during aging, they have a sharp decline in cell proliferation concurrent with a decrease in serotonergic innervation of the hippocampus thought to increase depression associated behavior (Husum et al., 2006). These findings warrant future investigation in that they may provide insight into the mechanisms of increased depression prevalence during aging. In general, the model shows good predictive validity in male animals. The face and pathological validity is mixed, as some symptoms do overlap with those of depression, whereas a number of biological measures do not. There is also a degree of construct validity, as humans with depression have abnormal sensitivity to cholinergic agents (Overstreet, 2012). Importantly, the model shows good reproducibility, at least in male rats, as multiple labs have found similar effects of antidepressants on the FST response (Dalla et al., 2011; Overstreet, 2012). However the fact that females show less depression behavior than males offers an important caveat, since females of most other rodent strains and women exhibit greater stress-induced depression-like behavior and higher depression prevalence, respectively (Dalla et al., 2010).

As mentioned previously, the WKY rats are also predisposed to greater depression behavior as a result of selective breeding. WKY rats were originally bred as a control for a hypertensive line (Mallesman and Weller, 2009). WKY rats compared to other strains show greater stress susceptibility, including increased immobility in the FST, decreased active avoidance when exposed to the learned helplessness paradigm, and increased vulnerability to stress-induced ulcers (Pare and Redei, 1993). Females show greater immobility than males in their response in the FST and also develop more severe ulcers, although this varies across the estrous cycle (Pare and Redei, 1993). In addition, WKY rats show greater anhedonia, anxiety-like behavior, and stress-induced weight loss compared with other strains

(Malkesman and Weller, 2009). This cluster of behavioral symptoms have led researchers to classify this as a model of comorbid depression and anxiety disorder (Malkesman and Weller, 2009). Mechanistically, WKY rats display dysregulation of the HPA axis including increased levels of CORT and ACTH along with an elongation of the elevation in CORT and a decrease in ACTH levels following an acute swim stress (Malkesman and Weller, 2009). Little is known about differences in brain plasticity, as most studies have compared the WKY rats to the spontaneously hypertensive strain, but these studies have shown that WKY rats have lower rates of cell proliferation and survival (Kronenberg et al., 2007). This strain has recently been used to explore the antidepressant and anxiolytic effects of novel antidepressant drugs acting on the kappa-opioid system (Carr et al., 2010). The model has good face and predictive validity, but lacks construct validity, as the basis for the susceptibility of WKY rats to stress is not yet understood. Reproducibility between laboratories is mixed because differences in breeding strategies by commercial breeders can lead to significant genetic drift (Overstreet, 2012).

In addition to selective breeding models in rat, Rouen helpless or “depressed” mice have been heavily used to study the mechanisms of depression and for novel antidepressant discovery. These mice were originally generated in 1995 by breeding CD-1 mice with high and low immobility scores in the TST (Cryan and Mombereau, 2004). Fourteen generations later these mice were shown to display increased immobility in the FST and TST, alterations in REM sleep, anhedonia, and elevated basal levels of CORT (El Yacoubi and Vaugeois, 2007). The helpless phenotype appears more often in females than males, making it a valid line for studying sex differences (Yacoubi et al., 2011). The model has good predictive validity as a number of classic antidepressants are able to reverse the behavioral effects in both sexes (El Yacoubi and Vaugeois, 2007). Reproducibility is also good, as multiple labs have identified similar behavioral phenotypes (Svenningsson et al., 2006). This model was used to first identify a functional role for P11 (Svenningsson et al., 2006), a protein that interacts with serotonin 1B receptors. P11 is decreased in helpless male and female mice, as well as in postmortem tissue from subjects with depression (El Yacoubi and Vaugeois, 2007; Svenningsson et al., 2006) and is proposed to be a potential novel target for the development of new antidepressants. The selective breeding strategy is one method of developing animal models of depression with pathological validity for discovering complex genetic variations that may underlie depression. However, there are some major drawbacks to selective breeding models. The generation of animals is time consuming and expensive, multiple overlapping genetic factors make it impossible to understand contributions of specific genes, and genetic drift occurring over time can affect the reproducibility of phenotypes (Overstreet, 2012; Yacoubi et al., 2011). Despite these factors, selective breeding may help to understand how these complex psychiatric phenotypes are maintained in a population and eventually, through the use of high-throughput genetic sequencing, we may even determine the complex genetic contributions driving depression susceptibility.

SUMMARY AND CONCLUSIONS

In this chapter we have discussed the validity of each major animal model of mood disorders currently being used to uncover novel mechanisms of psychiatric illness and to develop new therapeutics. These models range from those based on stress exposure to induce a depression-like phenotype in genetically identical mice to models that use selective breeding to examine the complex genetic contributions to depression between strains. Some of the models make use of acute or short-term stress exposure such as learned helplessness, whereas others depend on exposure to chronic stress, such as CMS and social defeat stress. All of the models discussed at least partially fulfill the criterion for face, construct, and predictive validity, which is critical to establishing animal models that accurately mimic the disease. However, as we have discussed throughout this chapter, we need to judge the validity of these animal models with greater stringency and incorporate new criteria, such as reproducibility across labs and pathological validity. Pathological validity is especially important and will lead to a greater understanding of the underlying biology of depression. Over time, this may help clinicians to develop diagnostic criteria based on these biological changes and move drug discovery efforts beyond monoamine-based antidepressants, which only lead to successful remission in approximately 40% of the population (Krishnan and Nestler, 2008). New, rapid onset treatments such as ketamine (Berman et al., 2000) are undergoing clinical trials and show promise, however, all currently approved antidepressants are based on serendipitous discovery and do not directly target the underlying pathology of mood disorders. Additionally, diagnosis is based largely on non-overlapping clusters of behavioral symptoms that are often shared across disorders, making it difficult to achieve specificity in diagnosis. Thus, we need to develop biomarkers and diagnostic tests for the core symptoms of depression, and diagnose and treat based on these factors. For this, the use of valid animal models is critical and we need to continually develop and expand on our models to cover an even greater range of behavioral deficits. Moreover, few basic drug discovery studies use female animals as experimental subjects (Beery and Zucker, 2010), despite the fact that in humans, there are twice as many women that suffer from depression as men (Kessler et al., 1993). While there are a few models that accurately reflect this sex difference in depression prevalence, many do not. Thus, we need to be cognizant of this limitation in validity and understand that there may be individual- or sex-based differences in our models that will impact our results. In summary, the field has made tremendous progress in developing animal models of mood disorders that, in some cases, have a high degree of validity in modeling human depression. By using a battery of tests to understand distinct behavioral domains we can gain a greater insight into the biology of depression behavior. Over time, we can use these animal models that mimic the pathophysiology of depression to develop biomarker diagnostic tests and eventually more effective treatments with fewer negative side effects.

32 | MOLECULAR AND CELLULAR PATHOGENESIS OF DEPRESSION AND MECHANISMS FOR TREATMENT RESPONSE

RONALD S. DUMAN

INTRODUCTION

Major depressive disorder (MDD) is a debilitating illness that affects approximately 17% of the US population at some point in life, causing enormous economic burden and devastating personal suffering (Kessler, 2005). MDD is a heterogeneous illness characterized by impaired mood, low self-esteem, inability to experience pleasure (i.e., anhedonia), cognitive deficits, and altered eating and sleeping patterns. The available medications are only effective in approximately two-thirds of depressed patients, but can take months to years and still leaves one-third of patients untreated (Trivedi, 2006). The low rates of efficacy and lag time for treatment response are particularly problematic for a patient population at high risk for suicide.

Our inability to rapidly and successfully treat and ultimately cure MDD is due in large part to the lack of information on the underlying causes of this disorder. Early theories of depression and treatment response were centered on disruption of monoamine neurotransmitter systems, 5-hydroxytryptamine (5-HT) and norepinephrine (NE), but more recent studies have focused on dysregulation of the major amino acid neurotransmitters glutamate and γ -aminobutyric acid (GABA), and the role of disrupted neuroplasticity in depression. A delicate balance of glutamate and GABA, the major excitatory and inhibitory neurotransmitters, in key limbic and cortical circuits is required for control of emotion and mood. This balance is also critical for the function and health of neurons, which are controlled in part via activity dependent regulation of neurotrophic factors. Altered activity levels, either increases or decreases, over sustained periods of time can result in neuronal damage, atrophy and loss, contributing to cellular and behavioral abnormalities in depression.

Clinical brain imaging and postmortem studies provide evidence that MDD is associated with structural abnormalities, and preclinical work in rodent models of depression also demonstrate alterations of neurons and glia at the cellular level. Stress and other environmental factors, combined with genetic polymorphisms are thought to contribute to an individual's vulnerability or resilience to depression. This could also explain the heterogeneity of depressive disorders, as the combination of life exposure to stress/trauma and genetic makeup determine whether a particular person will develop MDD. Another limiting factor is that there are no validated biomarkers of depression or treatment response.

The recent discovery of a rapid-acting antidepressant ketamine that is effective in patients who have failed to respond to typical antidepressants represents a major advance for the treatment of depression. Research on the mechanisms underlying the actions of ketamine further highlight the importance of altered synaptic connections in depression and provide targets for development of a new generation of antidepressants. This chapter will discuss the neurotransmitter systems, cellular and structural changes, and the role of neurotrophic factors and inflammatory cytokines in the pathophysiology and treatment of depression. Work on the synaptogenic and behavioral actions of ketamine, as well as novel antidepressant targets will also be presented.

ALTERED NEUROTRANSMISSION AND NEUROPLASTICITY IN DEPRESSION

Many theories of depression have involved alterations of neurotransmitter systems in limbic and cortical brain regions that control emotion, mood, and cognition. Most notable are the early hypotheses that involved the monoamines 5-HT and NE, and more recently the amino acid neurotransmitters glutamate and GABA. A brief review of the role of these monoamines and amino acid neurotransmitter systems is provided in this review. Also discussed is one of the key processes for regulation of neurotransmission, neuroplasticity, which has been implicated in psychiatric illnesses including depression. There have been a number of neuropeptide systems implicated in the pathophysiology and/or treatment of depression, including corticotrophin releasing factor, neuropeptide Y, neurokinin/substance P, galanin, and others that will not be discussed here due to space limitations.

ALTERED MONOAMINE NEUROTRANSMITTER SYSTEMS

The first evidence-based neurobiological theories of MDD focused on dysregulation of the monoamine neurotransmitter systems. This included evidence that early drugs with antidepressant efficacy increased monoamine levels by blocking the reuptake or breakdown of these neurotransmitters. Agents that produced these kinds of effects included the tricyclic

antidepressants, such as imipramine, a nonselective inhibitor of the 5-HT and NE transporters, as well as iproniazid and tranylcypromine, drugs that inhibit monoamine oxidase, the enzyme responsible for monoamine metabolism (Heninger, 1996; Jacobsen, 2012). There was also early evidence that compounds that caused depletion of monoamines, like reserpine, which disrupts monoamine vesicle storage, could cause depression, although subsequent studies failed to consistently replicate this finding (Heninger, 1996). Later studies provided evidence that 5-HT and NE were required for sustained therapeutic responses to drug treatments, as selective depletion of either monoamine caused relapse in patients being treated with the corresponding selective reuptake inhibitor (Heninger, 1996).

Evidence based on direct analysis of monoamine levels has also been mixed, with some reports of reduced levels of 5-HT, NE, and/or their metabolites in blood, cerebral spinal fluid, or postmortem brain tissue, although there are also negative reports (Heninger, 1996; Jacobsen, 2012). The data with regard to 5-HT, metabolites, and other functional markers appear to be more consistent when considering severe depression and/or suicide (Jacobsen, 2012). Together these studies indicate that reductions in levels of monoamines are not a generalized trait marker of depression, which is not unexpected given the heterogeneity of depressive illnesses.

The heterogeneity of MDD could have multiple origins, including genetic polymorphisms based on findings from association studies. There is evidence that polymorphisms of the gene for tryptophan hydroxylase, the rate-limiting enzyme for 5-HT synthesis, are associated with depression in a subpopulation of patients (Jacobsen, 2012). Variants of the 5-HT transporter gene, specifically the short, low expressing variant, are associated with anxiety-related traits and increased risk of depression in individuals exposed to early life stress or trauma (Caspi, 2010). This type of gene x environment interaction is thought to play a prominent role in depression as well as other psychiatric illnesses, as the effects of susceptibility genes are expressed when combined with precipitating stressors and/or other comorbid illnesses (see Chapter 37).

Based on this heterogeneity it is not surprising that drugs that act on monoamine systems, including 5-HT selective reuptake inhibitor (SSRI) antidepressants, have limited efficacy with approximately one in three depressed patients responding to the first antidepressant prescribed (Trivedi, 2006). Nevertheless, there is still interest in developing drugs that act on the monoamine systems, with increased emphasis on dual or triple (i.e., 5-HT, NE, and/or dopamine) reuptake inhibitors. While such agents may have fewer side effects than earlier reuptake inhibitors, it is reasonable to question whether such drugs will be more efficacious than currently available antidepressants. The limited efficacy could be due to disease heterogeneity and the restricted role of monoamine depletion in the symptoms of depression, as discussed. In addition, the monoamines are considered to be modulatory neurotransmitter systems (Fig. 32.1), influencing the activity and function of other systems, in contrast to fast-acting glutamate and GABA. This could explain in part the limited efficacy and therapeutic time lag for the actions of antidepressants that work via the monoamine systems. This possibility is supported by recent

studies demonstrating that novel antidepressants that act on glutamate neurotransmission (i.e., ketamine) produce rapid antidepressant actions in hard-to-treat depressed patients (Zarate, 2006) (see the following for further discussion of rapid-acting antidepressants and glutamate).

ALTERATIONS OF GLUTAMATE AND GABA IN DEPRESSION

In recent years the focus of depression research has shifted from the monoamine systems to the amino acid neurotransmitters glutamate and GABA. Although the glutamate and GABA systems are often discussed separately, it is useful to consider how they work in concert, as reciprocal interactions are critical for fine control of neuronal circuits and brain function. Notably, tonic firing of GABAergic neurons constrains glutamate transmission and allows for high fidelity point-to-point activation of glutamate activity (Fig. 32.1). The tonic firing of GABA neurons is in turn controlled in part by glutamate receptors on these neurons. The delicate balance of glutamate and GABA transmission is necessary for normal brain function, and disruption of this homeostasis contributes to depression as well as other psychiatric illnesses. Unbalanced signaling can also lead to sustained elevation of glutamate, which can produce excitotoxic neuronal damage and even cell loss.

With this in mind, there is substantial evidence that levels of glutamate and GABA are dysregulated in mood disorders. However, as is often the case with clinical studies of a heterogeneous illness such as depression, there are inconsistencies that could also be related to methodological differences, brain regions examined, medication status, and other variables. With regard to GABA, the prevailing evidence is in favor of a reduction of this neurotransmitter. This includes initial studies of blood plasma and cerebral spinal fluid and later with the development of proton magnetic resonance spectroscopy (MRS) direct evidence for *in vivo* reductions of GABA content in cortical (occipital and frontal) brain regions in depressed patients (Sanacora and Saricicek, 2007). Further studies demonstrated that the GABA deficits measured by MRS are reversed by antidepressant treatments. Postmortem studies also report a loss of GABAergic interneurons in the dorsal lateral PFC (dlPFC) of depressed subjects (Maciag, 2009) and decreased levels of the primary GABA synthesizing enzyme, glutamic acid decarboxylase (Karolewicz, 2010). Imaging studies also demonstrate functional deficits of cortical GABA inhibition (Levinson, 2010).

The evidence for alterations of glutamate transmission is more mixed. Studies of glutamate in blood, CSF, or brain show increases, or no change (reviewed by Yüksel, 2010). Studies using proton MRS have been more consistent. Proton MRS measures levels of Glx, a composite containing mostly glutamate and glutamine (an intermediary metabolite of glutamate) but also some GABA and other metabolites. These studies report decreased levels of Glx in most cortical brain regions of depressed patients, including the anterior cingulate, dlPFC, dorsal medial PFC, ventral medial PFC, amygdala, and hippocampus (Yüksel, 2010). One exception is the occipital cortex, where an increase was reported (Sanacora, 2004). There are also several reports that antidepressant treatments reverse the

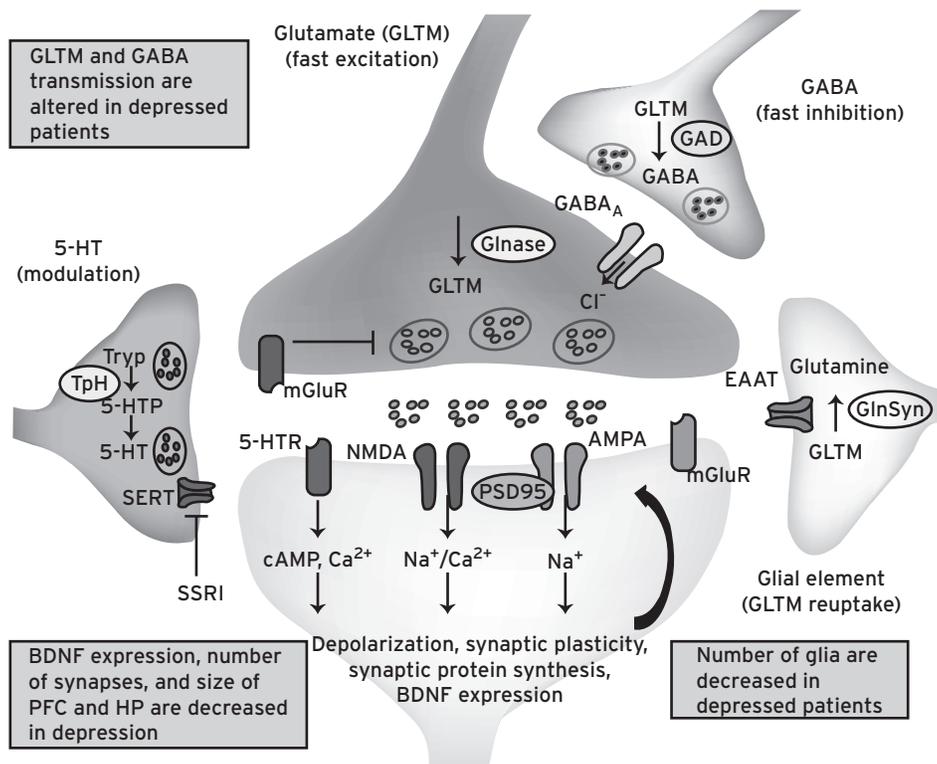

Figure 32.1 Diagram of glutamate transmission and the influence of GABA and 5-HT neurotransmitters, as well as glia. The glutamate, GABA, and 5-HT neurotransmitter systems are coded in dark gray, light shaded gray, and medium gray, respectively; a glial element is also shown on the right. Glutamate transmission is tightly controlled by GABA as well as other synaptic inputs. Glutamine is converted by glutaminase (Glnase) to glutamate, which is then packaged into presynaptic vesicles and released in an activity dependent manner. Glutamate acts on postsynaptic receptors, including ionotropic (i.e., AMPA and NMDA) and metabotropic (e.g., mGluR2/3) subtypes. Activation of AMPA and NMDA receptors, which interact with postsynaptic density proteins (PSD) such as PSD95, leads to influx of Na^+ and Ca^{2+} , causing excitatory postsynaptic currents (EPSCs) and eventually depolarization. These pathways also mediate synaptic plasticity, including the insertion of AMPA receptors into the synaptic membrane, which enhances the maturation, stabilization, and function of synapses. Glutamate is cleared from the extracellular space by excitatory amino acid transporters (EAAT) located primarily on glia, where glutamate is converted to glutamine by glutamine synthetase (GlnSyn). Glia cells are also a major source of glutamine for the presynaptic glutamate terminal. GABA and tonic firing of GABAergic neurons provides negative control over glutamate. Glutamate is converted to GABA by glutamic acid decarboxylase (GAD). GABA binds to ionotropic GABA_A receptors, which when activated allow influx of Cl^- , resulting in inhibitory postsynaptic currents (IPSCs) and hyperpolarization. 5-HT is a modulatory neurotransmitter that is derived from tryptophan (Tryp), which is converted to 5-hydroxytryptophan (5-HTP) by the rate-limiting enzyme tryptophan hydroxylase (TpH). 5-HT released into the synapse is inactivated by reuptake into the presynaptic terminal by the 5-HT transporter (SERT), which is the target of SSRI antidepressants. Activation of 5-HT receptors (5-HTR) and coupling with G proteins leads to regulation of second messenger systems, including the cAMP cascade and intracellular Ca^{2+} . Alterations in depression include imbalance of glutamate and GABA transmission, decreased expression of BDNF, decreased number of synapses, reduced size of the PFC and hippocampus (HP), and decreased number of glia as indicated.

deficit in levels of Glx. In addition, levels of Glx are increased in patients with bipolar disorder.

Together, the evidence points to a decrease in GABA and glutamate neurotransmission, which could indicate an overall reduction in neuronal function and circuit level control in the brains of MDD patients. This could also be related to the atrophy of neurons and loss of glia in the same cortical and limbic brain regions where neurotransmission is disrupted (see following). The mechanisms that result in decreased neurotransmission, atrophy of neurons, and loss of glia are not known but could be due to an imbalance of glutamate and GABA signaling, resulting in over- or underactivation of neurons. This may occur via loss of the proper balance of activity dependent neurotrophic factor support, and/or increased glutamate excitotoxicity. The need for proper balance of glutamate and GABA signaling is further highlighted by evidence that the therapeutic action of novel rapid antidepressants is dependent on a transient burst of glutamate transmission. These possibilities are discussed in the following sections.

DISRUPTION OF NEUROPLASTICITY IN DEPRESSION: REVERSAL BY ANTIDEPRESSANT TREATMENT

The loss of glutamate/GABA balance also supports the hypothesis that alterations of neuroplasticity contribute to depression and other stress-related illnesses. Cellular models of neuroplasticity, such as long-term potentiation (LTP) are used to study the mechanisms underlying learning and memory. However, neuroplasticity is a critical process that is involved in many aspects of neuronal adaptation and function. Neuroplasticity refers to the sensing and summation of neurotransmitter signals under a specific set of conditions, resulting in adaptations of synaptic function and architecture, which lead to altered responding upon exposure to the same or related signals. This includes activation of ionotropic glutamate receptors, AMPA (α -amino-3-hydroxy-5-methyl-isoxazole-4-propionic acid) and NMDA (*N*-methyl-D-aspartate), increased intracellular calcium

signaling, insertion of glutamate receptors into the synaptic membrane, and stabilization of spine synapses (Fig. 32.1) (the exact mechanisms for synaptic plasticity are reviewed in detail in Chapter 5).

The ability to make the appropriate adaptive response, for example upon exposure to stress or trauma, is critical for proper function of neural circuits that allows for adaptation and resilience to change. Studies in rodent models demonstrate that exposure to chronic stress decreases synaptic plasticity in the PFC and hippocampus (Duman and Aghajanian, 2012). The synaptic plasticity deficits are caused by chronic stress exposure, as a single acute stressor enhances glutamate transmission in the PFC (Yuen, 2012). Conversely, chronic administration of typical antidepressants, such as the highly prescribed SSRIs, increases cellular neuroplasticity determined by studies of hippocampal LTP (Duman and Aghajanian, 2012). Additional evidence is provided by work demonstrating that chronic fluoxetine reinstates ocular dominance plasticity in the adult mouse visual cortex and enhances the extinction of conditioned fear, an active learning process (Karpova, 2011; Maya Vetencourt, 2008). Moreover, SSRI-induced neuroplasticity requires BDNF. These studies are consistent with evidence that glutamate signaling and neurotransmission are altered in depression and in animal models of chronic stress exposure.

STRUCTURAL ABNORMALITIES IN DEPRESSION

In addition to alterations of neurotransmission and plasticity, there is now clear evidence of structural alterations in depression, including changes in the size or volume of cortical and limbic brain regions, as well as ultrastructural changes of the neuronal processes/connections and numbers of neurons and glia. These findings are provided by human brain imaging and postmortem studies as well as animal models of stress and depression.

HUMAN BRAIN IMAGING OF DEPRESSION

There is now consistent evidence from magnetic resonance imaging studies that depression is associated with alterations of the volume or size of several brain regions, notably the PFC and hippocampus (Drevets, 2008; MacQueen, 2011). These brain regions are known to control memory and cognition, which are severely compromised in depressed patients, and are also part of a neural circuit that includes other brain regions that control emotion, anxiety, fear, vegetative, and endocrine responses that are dysregulated in depression (i.e., limbic-cortical-striatal-pallidal-thalamic, with connections to amygdala, hypothalamus, and brainstem structures) (see Chapter 34 on depression circuitry).

Hippocampus, a highly stress-sensitive structure, has been one of the most studied brain regions in MDD patients and in preclinical models of stress. A recent review of imaging studies of over a thousand depressed patients and the same number of controls, demonstrates a consistent reduction in hippocampal size associated with depression (MacQueen, 2011). The smaller

volume of hippocampus in depressed patients has been associated with severity and duration of illness and non-response to antidepressant treatment; and conversely there is evidence that treatment response can reverse hippocampal volume deficits. Early life stress and trauma, which are risk factors for depression (see Chapter 44 on early life stress), are also associated with smaller hippocampal volumes. There is evidence that smaller hippocampal volume is observed before the onset of illness in a population of high-risk adolescents.

Prefrontal cortex subregions, including the subgenual PFC, infralimbic, and anterior cingulate cortex, are also altered in depression. Neuroimaging studies demonstrate that decreased volume of these PFC cortical regions occurs at an early stage in depressive illness, and are observed in high-risk young adults, and that the volume deficits progress with length of illness in psychotic depressed patients (Price, 2010). The reductions in subgenual PFC are reported to persist after successful treatment of depressed subjects, but are reversed toward control levels by lithium treatment.

Together these studies demonstrate structural alterations of hippocampus and PFC subregions that are associated with depression. Importantly atrophy of these regions can be attenuated or even reversed with antidepressant treatment. This reversibility is a key feature that distinguishes depression from more permanent structural changes often observed in patients with neurodegenerative disorders. This is also supported by studies in rodent models demonstrating that neuronal atrophy caused by stress is reversible.

Nucleus accumbens and amygdala: In contrast to atrophy of hippocampus and PFC, there is evidence for hypertrophy or increased arbor of neuronal processes in the nucleus accumbens and amygdala in rodent models of depression (Duman and Aghajanian, 2012; Roozendaal, 2009). The nucleus accumbens is part of the mesolimbic dopamine system that controls motivation and reward, and the amygdala regulates emotion and fear. Alterations of these structures in depressed patients have also been identified (Price, 2010). In addition to structural changes, there is evidence for altered metabolic activity and connectivity between the nucleus accumbens, amygdala, PFC, hippocampus, and other cortical and limbic regions implicated in depression. This is consistent with preclinical studies that provide strong evidence for a role of the amygdala and mesolimbic dopamine system in anxiety and mood related behaviors (see Chapter 31).

HUMAN POSTMORTEM STUDIES OF DEPRESSION

The exact cellular changes underlying the volumetric decreases in depression have been difficult to identify and must rely solely on morphometric analysis of neurons in postmortem brain tissue of depressed subjects. These studies have begun to identify changes that are consistent with the brain imaging studies, showing a reduction in the size of neuronal cell bodies, decreased density of neurons, and decreased number of GABAergic interneurons in the dlPFC (Price, 2010; Rajkowska, 2007). The numbers of glia are also decreased in the dlPFC, as well as other cortical structures (Rajkowska, 2007). Postmortem studies of hippocampus

report an increased packing density, implying that the neuronal body size is increased in depression. Preclinical studies also demonstrate that stress decreases adult hippocampal neurogenesis (Samuels, 2011). Although decreased neurogenesis has not been observed in postmortem tissue from depressed subjects, there are reports of increased cell birth in subjects treated with antidepressant medications at the time of death (Boldrini, 2012).

The reductions in PFC and hippocampal volume, combined with postmortem evidence for reduced size of neuronal cell bodies suggest that the processes and connections between neurons are also decreased in depression. However, the analysis of synaptic number has been hampered by poor fixation and tissue conditions. The first study to address this question recently reported that the number of synapses, determined by electron microscopy, is decreased in the dlPFC of MDD subjects (Kang, 2012). Supporting evidence for loss of spine synapses is provided by studies reporting decreased levels of synaptic signaling proteins in depressed subjects, including AMPA and NMDA receptor subtypes, presynaptic neurotransmitter vesicle-associated proteins, and postsynaptic structural and functional proteins in the dlPFC, hippocampus, and other forebrain structures (Duman and Aghajanian, 2012). These studies provide strong evidence of disrupted synaptic integrity and function in cortical and limbic brain regions of depressed subjects.

EVIDENCE FOR CELLULAR AND STRUCTURAL ALTERATIONS FROM RODENT STUDIES

The hypothesis that the pathophysiology of depression and stress-related psychiatric illnesses is related to structural alterations has gained significant support from preclinical studies of chronic stress models of depression. There are a number of chronic models that have been developed, including chronic unpredictable stress (CUS), which leads to behavioral anhedonia, a core symptom of depression that is reversed by chronic antidepressant administration, consistent with the therapeutic time lag seen in depressed patients. Chronic social defeat is another well-established model that is characterized by social interaction deficits, as well as anhedonia and vegetative differences, that are also reversed by chronic, but not acute antidepressant treatments (see Chapter 31 on preclinical models). These models contrast with acute helplessness paradigms, such as the forced swim test, in which animals respond rapidly after just a single antidepressant dose, and which are best known for their utility as drug screening paradigms.

Neuronal atrophy: Studies of the hippocampus were the first to demonstrate that chronic immobilization stress causes atrophy of neurons, notably a reduction in the number and length of the apical dendrites of CA3 pyramidal neurons (McEwen, 2012). Subsequent studies of chronic immobilization or CUS also demonstrate atrophy of the apical dendrites of pyramidal neurons in layers II/III and V of medial PFC (Fig. 32.2) (Duman and Aghajanian, 2012; Morrison, 2012). In addition, chronic stress causes a reduction in the number of spine synapses, the primary connection points between neurons, as well as a corresponding decrease in

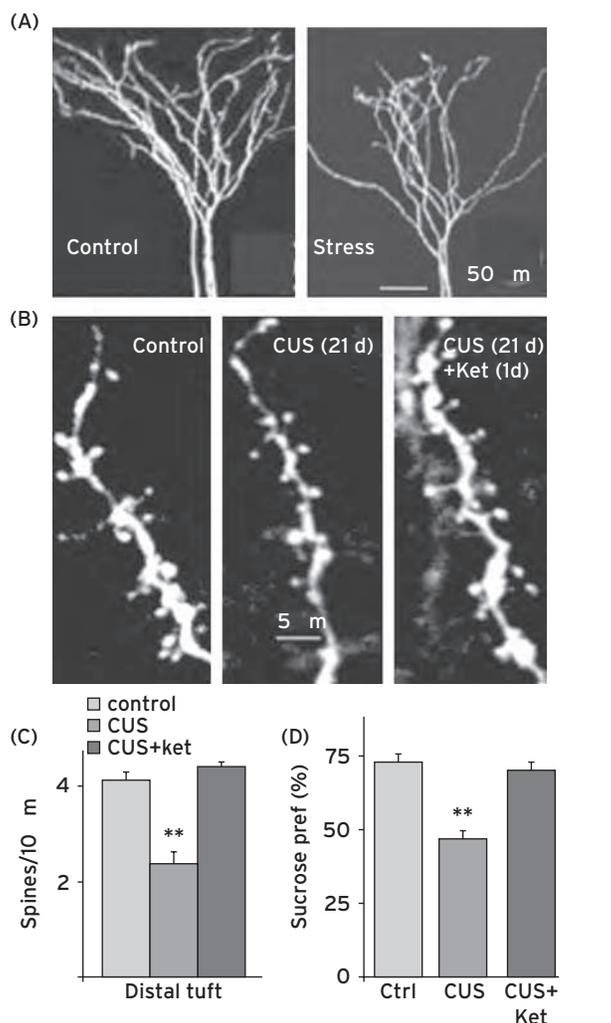

Figure 32.2 Chronic stress causes atrophy of neurons in the PFC. (A) Shown are representative confocal photomicrographs of layer V pyramidal neurons in the medial PFC labeled with neurobiotin. Chronic immobilization stress (~30 min per day, 7 days) causes a reduction in the number and length of apical dendrites in PFC neurons. (B) CUS (21 days) decreases synaptic connections and produces depressive-like behavior that is rapidly reversed by a single dose of ketamine. Representative confocal images of single dendrites of labeled layer V pyramidal neurons in the medial PFC. CUS decreases the number of dendrites, and a single dose of ketamine rapidly reverses the deficit caused by CUS. (C) Quantitation of the numbers of spines on distal tufts of layer V neurons, further demonstrating the reversal of the CUS spine deficit by ketamine. (D) Influence of CUS ± ketamine on behavior in the sucrose preference test (measured by percent preference for a sucrose solution). The sucrose preference test provides a measure of anhedonia, a core symptom of depression that is rapidly reversed by a single dose of ketamine, compared to long-term administration (three weeks) needed for a typical antidepressant, such as a SSRI.

neuronal function, demonstrated by a reduction in 5-HT and hypocretin-induced excitatory postsynaptic potentials (EPSPs) (Liu, 2008; Morrison, 2012). These changes are accompanied by altered synaptic glutamate transmission (Popoli, 2011). The atrophy of pyramidal neurons in the PFC is particularly sensitive to stress, with reductions of apical dendrites observed after as little as 30 to 45 minutes of immobilization stress per day for 7 days. Neuronal atrophy caused by stress exposure is reversible, either by removal of stress or with antidepressant

treatment, consistent with clinical studies demonstrating that volumetric changes of PFC and hippocampus are reversible with treatment.

As previously discussed, pyramidal neurons of the basolateral amygdala undergo hypertrophy in response to chronic stress exposure (Roozendaal, 2009). This could represent an effect independent of other limbic and cortical structures or could be related to, and influenced by, connections with these regions. Notably, there are reciprocal connections between the PFC and amygdala, with the PFC exerting negative control of amygdala neuronal activity; reduction of the negative feedback from the PFC could account for hypertrophy of amygdala neurons and decreased control of emotion and mood.

Decreased neurogenesis: In addition to neuronal atrophy, stress exposure decreases the birth of new neurons in the adult hippocampus, one of the few neurogenic zones found in the adult brain (the other is the subventricular zone, which gives rise to new neurons in the olfactory bulb) (Samuels, 2011). Neural progenitor cells in the subgranular zone give rise to immature neurons that migrate into the granule cell layer and develop into mature, functional neurons over the course of four to six weeks. Acute or repeated stress exposure decreases the birth of new neurons, and recent studies demonstrate that this stress-induced decrement causes depression-related behaviors in rodents (Snyder, 2011). In contrast, chronic, but not acute administration of all classes of antidepressant treatment increases the birth of new neurons and blocks the effects of stress (Samuels, 2011). Antidepressant treatment is also associated with the birth of new neurons in postmortem hippocampus of MDD subjects (Boldrini, 2012). Moreover, the induction of new neurons in the hippocampus is required for some but not all antidepressant behaviors, linking this cellular process to antidepressant actions. These studies support a role for adult hippocampal neurogenesis in stress, depression, and antidepressant responses.

Glial loss: Decreased number of glia represents one of the most consistently reported postmortem findings in depression, and evidence from rodent stress models is compatible with these findings. This includes studies demonstrating that chronic stress decreases the proliferation of newborn oligodendrocytes in the PFC and astrocytes that express the marker glial fibrillary acidic protein (GFAP) in the PFC and hippocampus (Banasr, 2012). Astrocytes play an important role in the reuptake and termination of glutamate neurotransmitter signaling, as well as metabolism of amino acid neurotransmitters (Fig. 32.1). GFAP+ astrocytes, while capable of proliferation when activated by excitotoxic or mechanical injury, do not typically undergo proliferation under non-activated conditions. Oligodendrocytes are best known for myelination of neurons, but there are also subtypes that have morphological and functional characteristics similar to astrocytes. Oligodendrocyte precursors, labeled with the NG2 proteoglycan, continue to proliferate in the adult brain, and stress decreases the birth of these cells, an effect that could contribute to the decrease observed in depressed subjects. In contrast, chronic antidepressant treatment produces the opposite effect, increasing the number of NG2+ oligodendrocytes (Banasr, 2012).

STRESS-MEDIATED PATHWAYS IN DEPRESSION: THE HYPOTHALAMIC-PITUITARY-ADRENAL AXIS

The mechanisms underlying neuronal atrophy, reduced neurogenesis, and loss of glia are still being characterized, but are related to stress activation of the hypothalamic-pituitary-adrenal (HPA) axis and excess glucocorticoid levels, as well as activation of inflammatory cytokines. These systems then regulate a variety of other pathways that control all aspects of neuronal and glial function and survival, including regulation of growth factors and intracellular signaling cascades. Here we discuss the evidence demonstrating the role of these systems in stress, depression, and treatment response.

ELEVATION OF ADRENAL GLUCOCORTICOIDS IN STRESS AND DEPRESSION

One of the best-studied stress-activated systems is the HPA axis (Holsboer, 2010). Corticotrophin releasing factor (CRF), expressed in neurons in the paraventricular nucleus of the hypothalamus that project to the pituitary and, together with vasopressin, causes release of adrenocorticotrophin hormone (ACTH) into the circulatory system. ACTH then stimulates the biosynthesis and release of glucocorticoids in the adrenal cortex. Clinical studies have provided evidence that HPA activity is elevated in depressed subjects, with reports of increased levels of cortisol, the primary glucocorticoid in humans, and reduced responsiveness to administration of a synthetic glucocorticoid (i.e., dexamethasone suppression test). In fact, a recent extensive review of the literature (354 studies with 18,374 subjects) found that 73% of depressed patients had elevated cortisol levels compared to non-depressed controls (Stetler, 2011).

Glucocorticoids bind to two major types of receptors termed glucocorticoid (GR) and mineralcorticoid (MR), intracellular cytoplasmic receptors that when activated function as transcription factors and regulate expression of a wide range of target genes. MR has a higher affinity for glucocorticoids and mineralcorticoids and serves as the primary signaling receptor under normal, non-stressed physiological conditions, while GR has lower affinity and is only activated by higher, stress-induced levels of glucocorticoids. Both receptors are expressed throughout the brain, but levels of GR are particularly high in the hippocampus, as well as PFC and some other cortical regions. The hippocampus, hypothalamus, and pituitary also respond to glucocorticoids, which provides negative feedback control of HPA-axis release of glucocorticoids. Reductions of this important feedback system, measured in the dexamethasone suppression test, are often reported in depressed subjects, further demonstrating that this key stress response neuroendocrine system is overactivated in MDD (Holsboer, 2010). There is also evidence that levels of CRF are elevated in depressed subjects. In addition to signaling in the HPA axis, CRF and its receptor are expressed in other brain regions, including the amygdala, and have been implicated in the regulation of fear and anxiety, as well as depressive behaviors.

Preclinical studies demonstrate that high levels of glucocorticoids can account for many actions of chronic stress exposure on neurons and glia. Chronic exposure to corticosterone, the active glucocorticoid in rodents, causes atrophy of neurons in the PFC and hippocampus, similar to the effects of chronic stress (McEwen, 2012; Morrison, 2012). Chronic corticosterone exposure, also decreases neurogenesis in the adult hippocampus, and causes reduction of oligodendrocyte proliferation in the PFC (Banasr, 2012; Samuels, 2011). There is also evidence that chronic corticosterone administration decreases the expression of the astrocytic marker, GFAP. Together these findings indicate that elevated glucocorticoid levels could account for the neuronal and glial atrophy caused by chronic stress exposure, and for the atrophy of cortical and limbic brain regions observed in depressed patients.

The findings that stress and glucocorticoids can cause atrophy of neurons and loss of glia are unexpected, as it is difficult to understand the evolutionary advantage of this deleterious effect. However, in nature the stress response is designed to be active only for a transient, brief period of time, during the fight or flight response, and then rapidly return to baseline levels. Acute activation of the stress response systems is required for mobilizing energy and resources to the appropriate organs and tissues to provide a maximum response to danger conditions. However, problems occur when the stress is sustained over long periods of time, as is the case in modern daily human lives filled with stress related to social interactions, work demands, and other environmental conditions, which then results in deleterious effects on brain and many other organ systems.

INFLAMMATORY CYTOKINES AND DEPRESSION

EVIDENCE OF ELEVATED CYTOKINES IN DEPRESSION AND UNDERLYING MECHANISMS

Clinical studies have provided evidence that inflammatory cytokines play a role in the pathophysiology of depression and other mood disorders. Levels of several pro-inflammatory cytokines, including interleukin-1 β (IL-1 β) and IL-6, as well as tumor necrosis factor- α (TNF α), are increased in the blood of depressed patients compared to control subjects (Miller, 2009). These cytokines cause sickness behavior in rodents, characterized by suppressed locomotor activity, decreased social exploration, decreased food intake, lethargy, and anhedonia, many of which are also observed in depression. Treatment with interferon (IFN), a cytokine that strongly activates the immune system, causes high levels of depressive symptoms (i.e., ~50% of patients) when used as a treatment of certain cancers and viral infections (Raison, 2006). In addition, many illnesses, including diabetes, cancer, and cardiac disease, that have high rates of comorbidity with depression (~20–30%), are characterized by chronic inflammation (see Chapter 37). The inflammatory system can also be activated by psychological stressors, which may account in part for elevation of cytokines in depressed patients (Miller, 2009).

Inflammatory cytokines are released in the peripheral blood system by circulating macrophages, a primary cellular response

element of the innate as well as the adaptive immune system. In addition, inflammatory cytokines are released in the brain from microglial cells, which, like macrophages, are derived from monocytes. Typically, activation of macrophages and microglia occurs via a two-step process: first, via binding of danger substances (e.g., viral, bacterial, etc.) to a toll-like receptor (TLR) that couples to signaling pathways that increase pro-IL-1 β gene transcription; and second by substances released during cell damage such as ATP, which activates the inflammasome system resulting in the processing and release of IL-1 β . The importance of the latter is highlighted by the ability of IL-1 β to act as a primary regulatory of the immune response, as it also leads to increased release of other cytokines such as IL-6 and TNF α .

The mechanisms underlying the release of inflammatory cytokines by psychological stress are less clear, but may involve increased glutamate transmission followed by release of ATP that stimulates microglia in the brain. Another unanswered question is how the peripheral and central inflammatory cytokine systems communicate. Cytokines are large peptides that cannot cross the blood-brain barrier under most conditions, although there may be active uptake, porous regions of the barrier, or conditions that make the barrier leaky and allow cytokines to cross into the brain. It is also notable that inflammatory cytokines are one of the most potent activators of the HPA axis and could contribute to elevated glucocorticoid levels in depression. However, glucocorticoids also suppress the immune system and cytokines, adding another layer of complexity and unanswered questions regarding the interaction and regulation of these related systems in depression.

CONSEQUENCES OF ELEVATED CYTOKINES

Inflammatory cytokines influence a wide range of cellular and neuronal signaling pathways. As is often the case they produce biphasic effects on neuronal systems, characterized by normal physiological responses at low levels but deleterious actions at higher levels caused by stress. For example, both IL-1 β and TNF α have been implicated in cellular and behavioral models of learning and memory, but at high doses are known to cause sickness, anxiety, and depressive behaviors in rodent models (Yirmiya, 2011). IL-1 β also decreases the birth of new neurons in the adult hippocampus, and blockade of IL-1 β signaling with the endogenous antagonist IL-1Ra blocks the antineurogenic, as well as behavioral effects of stress exposure (Koo, 2009).

Inflammatory cytokines such as IL-1 β activate the I κ B-nuclear factor-kappaB (NF- κ B) signaling pathway, resulting in regulation of many aspects of neuronal function. This includes regulation of gene transcription, such as indoleamine 2,3-dioxygenase (IDO), an enzyme that degrades tryptophan to kynurenine. Earlier studies suggested that this could lead to decreased levels of 5-HT, a product of tryptophan metabolism, but kynurenine is also a precursor of quinolinic acid, an NMDA receptor agonist that could cause neurotoxic damage. In addition, I κ B-NF κ B signaling in the nucleus accumbens is upregulated by social defeat stress and underlies the morphological alterations caused by stress in this brain region (Christoffel, 2011). Further studies are needed to characterize the mechanisms underlying the behavioral actions of IL-1 β , TNF α , and

other inflammatory cytokines, as well as the role of these factors in neuronal atrophy and glial loss caused by stress.

INFLAMMATORY CYTOKINE TARGETS FOR ANTIDEPRESSANT THERAPEUTICS

The possibility that inflammatory cytokines can be targeted for the treatment of depression is supported by clinical studies demonstrating that blockade of TNF α , by administration of a neutralizing antibody (i.e., Etanercept), produces an antidepressant response in patients receiving treatment for psoriasis (Miller, 2009) (see Chapter 35). Further studies are needed to replicate this finding and to determine whether blockade of other inflammatory cytokines, such as IL-1 β or IL-6 could be useful for the treatment of depression. There is also preclinical evidence that blockade of the ATP-purinergic receptor that activates IL-1 β processing and release has antidepressant efficacy in rodent behavioral models. Combined with advanced biomarker testing, these strategies may hold promise for treating depressed patients that present with elevated levels of a specific inflammatory cytokine that could be directly corrected with appropriate antagonist or neutralizing agent.

ROLE OF NEUROTROPHIC FACTOR SUPPORT IN DEPRESSION AND TREATMENT RESPONSE

Activation of the HPA axis and elevation of adrenal glucocorticoids, as well as induction of inflammatory cytokines by stress, results in altered regulation of many neuronal systems that have been implicated in depression. Alterations of neurotrophic factors, particularly BDNF and related signaling pathways have been of particular interest because of the important role that these factors play in the formation and regulation of synapses, as well as the survival and function of neurons. Here we discuss evidence for the role of several key neurotrophic factors in the pathophysiology and treatment of depression. Long-lasting changes in the expression of neurotrophic factors, as well as other signaling molecules, due to epigenetic alterations have also been implicated in depression and treatment response and have been discussed in several excellent reviews (Krishnan, 2008; Sun, 2012).

STRESS DECREASES BDNF EXPRESSION AND SIGNALING: OPPOSING ACTIONS OF ANTIDEPRESSANTS

BDNF is a member of the nerve growth factor family, which also includes neurotrophin 3 and 4. These factors were originally discovered because of the important functions they serve during brain development, guiding the migration and maturation, as well as survival and function of neurons. However, these factors are also expressed in the adult brain, are regulated by neuronal activity, and are involved in synaptic plasticity, and neuronal function and survival (Martinowich, 2007). Initial studies demonstrated that chronic stress exposure decreases the expression of BDNF in the hippocampus and PFC, while

chronic antidepressant administration produces the opposite effect and blocks the decreased expression caused by stress (Duman, 2006; Krishnan, 2008). The relevance of these findings is supported by postmortem studies demonstrating that levels of BDNF are decreased in the cerebral cortex of MDD subjects (Duman, 2006). Surprisingly, serum and plasma levels of BDNF are also decreased in depressed patients, and this deficit is reversed with antidepressant treatments (Duman, 2006; Dwivedi, 2010).

The actions of BDNF are mediated by a tyrosine kinase receptor, TrkB, that when stimulated leads to activation of several intracellular pathways including Ras-microtubule-associated protein kinase (MAPK) and phosphatidylinositol-3 kinase (PI3K)/serine threonine kinase (Akt) (Duman and Voleti, 2012; Martinowich, 2007). These pathways positively influence synaptic maturation and stability via regulation of synaptic protein synthesis and glutamate receptor cycling (Collinridge, 2010; Hoeffler, 2010). Studies of rodent stress models and human postmortem tissue also demonstrate disruption of BDNF-TrkB receptor signaling, including reductions of ERK and Akt pathways in the hippocampus and PFC (Duman and Voleti, 2012; Duric, 2010). Stress and depression also influence BDNF-TrkB signaling by induction of a negative regulator, MAP kinase phosphatase 1, that is sufficient to cause depressive behaviors when expressed in rodent hippocampus (Duric, 2010). Chronic stress also decreases Akt signaling in the mesolimbic dopamine system. Another study has reported that chronic stress inhibits glutamate transmission via ubiquitin/proteasome-mediated degradation of glutamate receptors in the PFC, and that this effect is correlated with cognitive function (Duman and Aghajanian, 2012).

STUDIES OF BDNF MUTANT MICE AND A LOSS OF FUNCTIONAL HUMAN BDNF

GENE POLYMORPHISM

These findings, combined with brain imaging and postmortem studies, have contributed to a neurotrophic hypothesis of depression, which proposes that the neuronal and behavioral deficits caused by stress and depression result from decreased BDNF, and conversely that the actions of antidepressant treatment occur via induction of BDNF. The latter hypothesis is supported by studies demonstrating that the behavioral actions of antidepressants are blocked in BDNF deletion mutant mice, and that BDNF infusion into the hippocampus produces antidepressant responses (Autry, 2012; Duman, 2006).

The hypothesis that loss of BDNF underlies depressive behavior has been more complicated. Studies of mutant mice, including constitutive heterozygous deletion (homozygous mutants are lethal), as well as conditional forebrain deletion mutants have not reported evidence of a depressive phenotype with the exception that female conditional deletion mice show behavioral despair (Autry, 2012; Duman, 2006). However, BDNF deletion mutants are more vulnerable to stress, providing support for a gene x environment interaction, and targeted deletion of BDNF in the hippocampus is sufficient to cause depressive behaviors (Duman and Aghajanian, 2012). In contrast to the PFC and hippocampus, BDNF activity in the

mesolimbic dopamine system produces prodepressive effects, demonstrating region-specific actions of this plasticity-related factor (Krishnan and Nestler, 2008). This could also account for the lack of overt behavioral phenotype in constitutive and forebrain deletion mutant mice, in which BDNF deletion in multiple different regions at the same time may have offsetting behavioral consequences.

There is also evidence that BDNF is involved in neuronal deficits caused by stress. In heterozygous deletion mutant mice there is a reduction in number and length of apical dendrites of CA3 pyramidal neurons of the hippocampus, and the effects of chronic stress are occluded, suggesting that BDNF reduction underlies the atrophy of dendrites (Duman and Aghajanian, 2012). There have also been studies of mice with a knockin of a loss of function variant of the BDNF gene, Val66Met, that is found in approximately 30% of humans (Dincheva, 2012). The Met allele decreases the transport of BDNF transcripts to dendrite compartments, where local protein synthesis occurs to support synaptogenesis and neuroplasticity. BDNF Met knockin mice display a reduction of dendrite length and branching, and decreased spine-synapse density, maturity, and function in the hippocampus and/or PFC (Duman and Aghajanian, 2012). Studies in humans demonstrate that carriers of the Met polymorphism have decreased hippocampal volume and reduced executive function and if exposed to early life stress are more vulnerable to depressive symptoms (Duman and Aghajanian, 2012).

OTHER TROPHIC FACTORS IMPLICATED IN STRESS, DEPRESSION AND ANTIDEPRESSANT TREATMENT

There are several other neurotrophic/growth factors that have been implicated in depression, including vascular endothelial growth factor (VEGF), fibroblast growth factor 2 (FGF2), and insulin-like growth factor 1 (IGF1). Altered regulation and function of these factors is not surprising given that, like BDNF, they are regulated by neuronal activity, neuroendocrine, and inflammatory factors that are dysregulated by stress and depression. Chronic exposure to stress decreases the expression of VEGF in rodent hippocampus, and levels of FGF2 are decreased in postmortem cerebral cortex of depressed subjects; conversely, antidepressant treatment increases the expression of VEGF and FGF2 in cortical and/or hippocampal brain regions (Duman and Voleti, 2012). In addition, central infusions of VEGF, FGF2, or IGF1 produce antidepressant actions in behavioral models of depression, and blockade of VEGF or FGF2 signaling blocks the response to antidepressant treatments (Duman and Voleti, 2012). These studies demonstrate a complex interaction between these trophic factors and their intracellular signaling pathways, all of which include activation of intracellular tyrosine kinase domains and Ras-MAPK and PI3K-Akt signaling pathways. This overlap may suggest convergence of growth factor receptor signaling on neurons and glia, but it is also possible that different populations of neurons and glia are differentially regulated by these factors. This represents a small number of the growth factors and cytokines that control brain function, and it is likely that there

are other factors and signaling pathways involved in depression and treatment response yet to be discovered.

RAPID-ACTING ANTIDEPRESSANTS INCREASE SYNAPTOGENESIS

Currently available antidepressants that influence monoamine levels require weeks to months to produce a therapeutic response and are only effective in about one-third of patients, and up to two-thirds with multiple trials that can take years. This underscores a major unmet need, particularly for depressed patients at high risk for suicide. In this context, one of the most important findings in the field of depression is the discovery that a single dose of ketamine, an NMDA receptor antagonist, produces rapid antidepressant actions (clinical improvement within two hours) in treatment-resistant depressed patients (Machado-Vieira, 2011). These treatment-resistant patients have failed to respond to two or more typical antidepressants, and the antidepressant response to single-dose ketamine is sustained for 7 to 10 days. Ketamine also produces a rapid antidepressant effect in bipolar depressed patients and decreases suicide ideation. The fast, efficacious actions of ketamine by a completely different mechanism than typical monoamine reuptake inhibitors, NMDA receptor blockade, make this arguably the most exciting advance for depression therapeutics in 50 years. Preclinical studies have demonstrated that ketamine rapidly increases the number and function of synaptic connections, which provides further evidence that synaptogenesis is an important process for the treatment of depression, and that loss of synaptic connections contributes to the pathophysiology of depression (Figs. 32.2 and 32.3).

KETAMINE INCREASES SYNAPTOGENESIS AND mTOR SIGNALING

The profound clinical actions of ketamine have stimulated studies to identify the mechanisms underlying its rapid, efficacious antidepressant actions. These studies have been equally exciting, demonstrating that a single dose of ketamine rapidly increases the formation of new synaptic connections and activates neurotrophic factor translational signaling pathways (Fig. 32.3). A single dose of ketamine increases the number and function of spine synapses in layer V pyramidal neurons of the medial PFC (Li, 2010). Biochemical studies demonstrate that ketamine administration increases levels of synaptic proteins by two hours, indicating that synaptogenesis has started to take place at this early time point, which coincides with the therapeutic response to ketamine. The increase in synaptic number is accompanied by increased number of “mushroom” spines, indicative of mature or stable synapses. At a functional level, there is also an increase in 5-HT and hypocretin-induced excitatory postsynaptic potentials (EPSPs), including increased frequency and amplitude, which are directly correlated with the number and maturation/stability of spine synapses, respectively. Behavioral studies also demonstrate that a single dose of ketamine produces a rapid antidepressant response in the FST, learned helplessness paradigm, and novelty-suppressed feeding

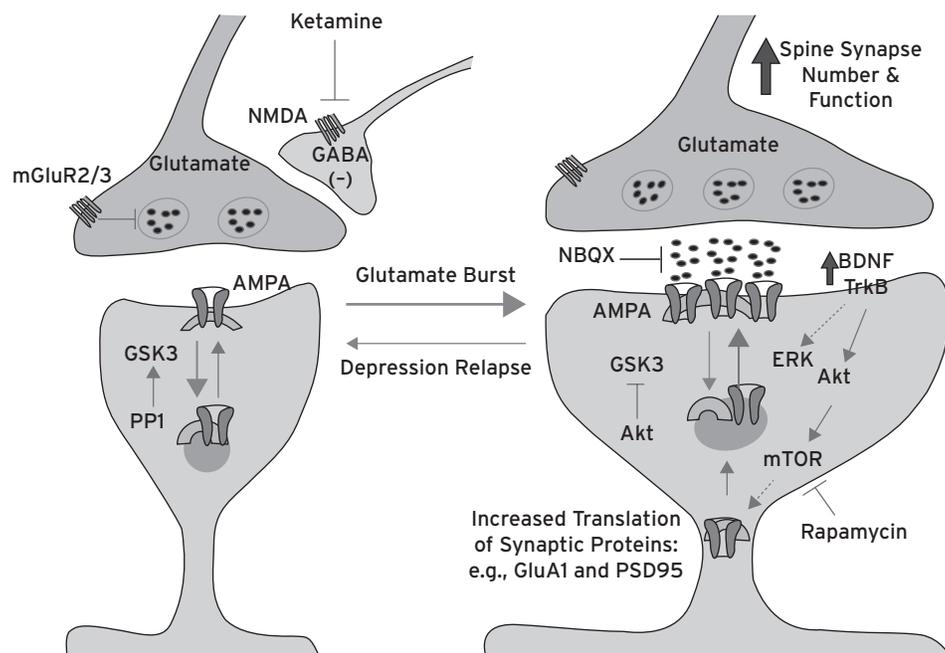

Figure 32.3 Model for the loss of spine synapses caused by stress and rapid reversal by ketamine. The numbers of synapse connections in the PFC and other structures are maintained by homeostatic mechanisms that contribute to regular mood. This includes cycling of glutamate A1 (GluA1) receptors to and from the synapse. Chronic stress exposure decreases the number of spine synapses, as well as the expression of BDNF, which is thought to contribute to the loss of synapses and neuronal atrophy. GSK3, which is increased in depression, can be activated by protein phosphatase 1 (PP1) and may also contribute to synaptic destabilization, by promoting the internalization of GluA1. Ketamine rapidly increases glutamate transmission and synaptogenesis, resulting in a glutamate burst. The induction of spine synapses requires activation of BDNF/TrkB signaling, and stimulation of the Akt and mTOR pathways, resulting in increased translation of synaptic proteins, including GluA1. The behavioral actions of ketamine are also dependent on inhibition of GSK3, which could occur via stimulation of Akt or by blockade of NMDA receptors and PP1 (not shown). Depressed patients treated with ketamine relapse after 7 to 10 days, possibly due to failure to maintain new synaptic connections, which could be a result of genetic mutations or environmental factors such as sustained or uncontrollable stress.

test. In addition, a single dose of ketamine rapidly reverses the deficits in synapses and depressive behavior caused by chronic stress exposure (Fig. 32.2), effects that are only observed after chronic administration of a typical antidepressant (Duman and Aghajanian, 2012).

The increase in synaptogenesis is preceded by induction of the mammalian target of rapamycin (mTOR) signaling pathway (Fig. 32.3). This pathway includes a number of up- and downstream elements that allow for summation of hormonal, metabolic, energy, and cell activity signaling to control cellular rates of protein translation. The mTOR system is found throughout the body, and in neurons is located in cell bodies and nerve terminals, where it has been linked to protein synthesis dependent synaptic plasticity (Hoefer and Klann, 2010). A single dose of ketamine rapidly activates the mTOR signaling pathway in preparations of nerve terminals of PFC, including increased levels of the phosphorylated and activated forms of mTOR, p70S6 kinase, and 4-EB-P1 (Li, 2010). This leads to increased translation and levels of synaptic proteins, including glutamate receptor 1 (GluA1), postsynaptic density protein 95 (PSD95), and synapsin 1. Evidence that mTOR signaling is required for the actions of ketamine is provided by studies showing that the synaptogenic and behavioral responses are blocked by preinfusion of the mTOR inhibitor, rapamycin (Li, 2010).

The mechanisms underlying the rapid synaptogenic and mTOR signaling effects of ketamine are still being studied, but there is evidence that these effects require activation of

AMPA receptors (Duman and Aghajanian, 2012; Li, 2010). There is also evidence that ketamine causes a rapid and transient “burst” of glutamate transmission in the PFC, possibly resulting from blockade of NMDA receptors on GABAergic interneurons and disinhibition of glutamate transmission (Duman and Aghajanian, 2012). The actions of ketamine are blocked by pretreatment with an AMPA receptor antagonist, and studies in cultured cells demonstrate that AMPA receptor activation results in stimulation of mTOR signaling. The studies in cultured cells also demonstrate that stimulation of mTOR signaling requires the release of BDNF, and studies in BDNF deletion mutant mice or BDNF Val/Met mice demonstrate that BDNF is required for the synaptogenic and behavioral actions of ketamine (Duman and Aghajanian, 2012). The clinical response to ketamine is also significantly reduced in carriers of the Met allele, providing the first evidence that antidepressant responses are influenced by a genetic polymorphism (Laje et al., 2012).

NOVEL KETAMINE-LIKE TARGETS FOR THE TREATMENT OF DEPRESSION

Although ketamine produces rapid and robust antidepressant actions, the psychotomimetic effects and abuse potential of this drug limit its widespread use for the treatment of depression. However, based on the evidence that ketamine acts via the glutamate neurotransmitter system there are several

potential targets that could produce ketamine-like actions, without the negative side effects. There is evidence that the NR2B subtype of the NMDA receptor mediates the actions of ketamine, including evidence from preclinical and clinical studies (Duman and Aghajanian, 2012; Li, 2010), and clinical trials are currently underway to further test the efficacy, rapid response, and safety of these agents.

Preclinical studies demonstrating that ketamine causes a transient burst of glutamate suggest that targeting other sites that cause a similar induction of glutamate transmission or directly activate AMPA receptors could produce antidepressant responses. This is supported by studies demonstrating that blockade of Group II metabotropic glutamate receptors (mGluR), which include mGluR2 and 3 (mGluR2/3), that are located presynaptically and regulate the release of glutamate (Fig. 32.1), produce rapid behavioral responses in rodent models that require mTOR signaling (Duman and Aghajanian, 2012; Duman and Voleti, 2012). Studies are currently underway to determine if mGluR2/3 antagonists also produce rapid synaptogenic actions and block or reverse the effects of chronic stress similar to ketamine.

Agents that are directly acting agonists of AMPA receptors cause seizures, but compounds have been developed that are modulators of AMPA receptors and could potentially be used in humans. These agents enhance the opening time or decrease the desensitization of AMPA receptors and thereby serve as positive allosteric modulators (PAMs), also referred to as AMPAkinases. There are reports that AMPAkinases can produce antidepressant responses in rodent models, and can activate mTOR signaling in cultured neurons (Duman and Aghajanian, 2012). Additional studies are needed to determine if these agents also produce rapid synaptogenic actions and antidepressant responses in CUS models. In addition, it will be important to closely examine the safety and side effect profile of AMPAkinases,

as well as other drugs that modulate glutamate transmission, which could also have limitations similar to ketamine.

Another area of research interest is to determine if it is possible to extend the therapeutic response time of a single dose of ketamine. Research studies demonstrate that patients administered ketamine relapse 7 to 10 days after treatment (Machado-Vieira et al., 2011). Work is underway to determine if treatment with another agent after, or even prior to ketamine, could sustain the antidepressant response and thereby negate the need for repeated ketamine administration, which could produce the unwanted side effects. Studies with typical antidepressants, other glutamate compounds, or lithium are currently under investigation.

CONCLUSIONS

Clinical and preclinical studies provide clear evidence of alterations of glutamate and GABA neurotransmission, limbic and cortical brain regions, connectivity, and growth factor and cytokine levels and related signaling pathways. Additional imaging approaches that provide improved static and functional markers of synaptic connections, as well as postmortem studies of ultrastructural changes are needed to further define the abnormal circuitry in depression. There is also evidence for genetic polymorphisms that increase risk for these structural alterations and that are associated with depression, particularly when combined with environmental factors such as lifetime incidence of stress exposure, as well as diet and exercise (Fig. 32.4). Such gene x environment interactions can explain the individual variability and risk for depression. Further studies of single or multiple gene polymorphisms within an individual are needed to better elucidate the basis of depression. Evidence from genetic studies of other psychiatric illnesses, as well as other traits, indicates

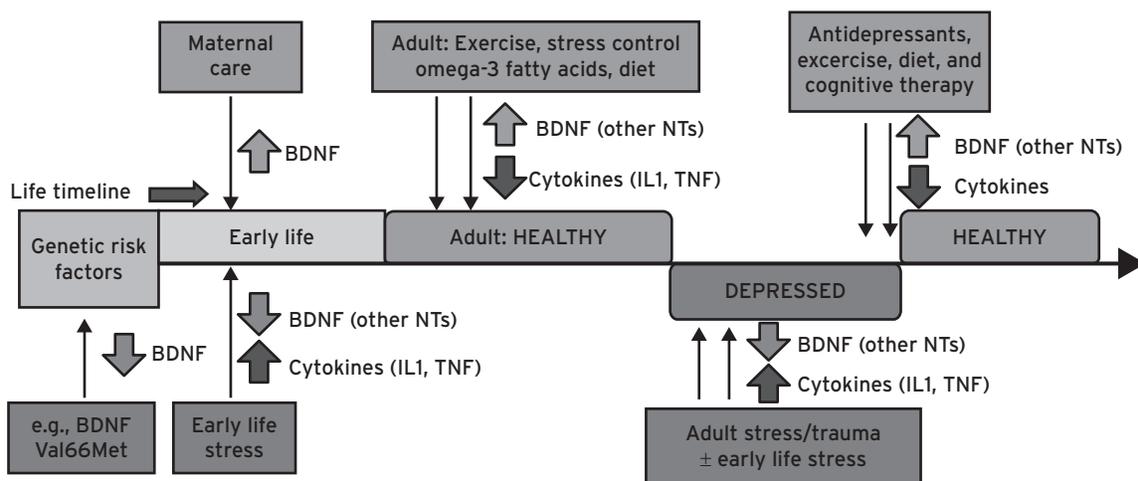

Figure 32.4 Timeline of genetic and environmental factors that regulate neurotrophic factors (NTs) and inflammatory cytokines that influence emotion and mood. Genetic risk factors, such as the BDNF Val/Met polymorphism and stress can exacerbate depressive symptoms, while antidepressants, exercise, and diet may ameliorate depressive symptoms, in part, through regulation of neurotrophic factors and inflammatory cytokines. The up- or downregulation of BDNF and inflammatory cytokines by stress and environmental factors can shift the balance from depressed to healthy, and vice versa. This could explain the heterogeneity of depression, as an individual may have a different combination of genetic risk factors and environmental factors that result in alterations of one or more growth factors and cytokines. Analysis of multiple neurotrophic/growth factors and inflammatory cytokines could provide an individualized signature of depression that would allow targeted, more efficacious treatment strategies (e.g., treatments that increase a particular neurotrophic factor or neutralize/block a specific cytokine).

that there are likely to be hundreds of gene polymorphisms that contribute to depression, accounting for the large degree of heterogeneity of this disorder.

These genetic and environmental factors, however, may have some targets in common, including alterations of the HPA axis, specific neurocircuits, inflammatory cytokines, and neurotrophic factors. While not every case of depression will have the same molecular and cellular signature, evidence is mounting that one or more of these markers (e.g., neurotrophic/growth factors such as BDNF, VEGF, FGF2, and/or IGF1; inflammatory cytokines such as IL-1 β , IL6, and/or TNF α) when combined with functional and structural imaging could be used as biomarkers of depressive illness and response to different antidepressant treatments. This could allow for more efficacious, targeted, individualized medicine. For example, blockade or neutralizing a specific inflammatory cytokine that is elevated, or treatments that enhance a specific neurotrophic factor as needed. These approaches, combined with a new generation of ketamine-like agents that are rapid acting, efficacious, and safe, hold promise for a new era for the treatment of depression.

33 | PATHOGENESIS OF DEPRESSION: CLINICAL STUDIES

MAURA A. FUREY, DANIEL C. MATHEWS, AND CARLOS A. ZARATE Jr.

INTRODUCTION

Interest in the biological mechanism of action underlying depression was stimulated largely by serendipitous use of antituberculosis drugs in the 1950s. One of these drugs, imipramine, became the first tricyclic antidepressant medication. Subsequent understanding of this class of drugs led researchers to speculate on the modulatory effects of noradrenergic and serotonergic systems given their ubiquitous presence in the brain. This led to drug discovery efforts including, but not limited to, tricyclic antidepressants (TCAs), monoamine reuptake inhibitors (MAOIs), and serotonin/norepinephrine reuptake inhibitors (SSRIs/SNRIs), representing the primary therapeutic targets in the treatment of depression. While diseases are largely defined by distinct pathophysiologies, depression as a syndrome manifests clinically as a heterogeneous condition, which suggests various or multiple underlying mechanisms of action (Krishnan and Nestler, 2008, 2010).

Since the first antidepressant was introduced, a vast number of agents that regulate serotonin or norepinephrine have been developed, primarily as refinements over previous versions. With the exception of improvements in safety and side effect profiles, no significant progress in the efficacy of one class of antidepressant over another has occurred. Considerable effort has been made in industry, academia, and government to identify alternative drug targets. Indeed, a number of compounds that produce promising results in preclinical studies failed to translate to an effective antidepressant at the clinical level; examples include NK1 and CRF antagonists (Madaan and Wilson, 2009). There are many reasons for the lack of success in developing novel treatments, most of which are beyond the scope of this chapter. One reason related to the chapter topic is the lack of disease biomarkers that predict clinical efficacy (Leuchter et al., 2010). A biomarker has been defined as “a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacological responses to a therapeutic intervention” (Frank and Hargreaves, 2003). Recent biomarker development has focused on existing antidepressants, and thus is limited by the inherent limitations of conventional treatments.

A potentially more successful approach would be to study treatments that are radically different from existing antidepressants, such as ketamine and scopolamine, where rapid antidepressant effects are observed in contrast to the slow response time associated with conventional treatments. The

rapid clinical response observed with ketamine and scopolamine offers a unique opportunity to evaluate biomarkers quickly with the goal of gaining a better understanding of the pathogenesis of depression and identifying neural signatures of treatment response. Biomarkers can be of great significance as they can prioritize resources and allow for earlier testing in proof-of-concept studies with novel therapeutic agents, especially if a target is well identified. Biomarker studies vary greatly by approach and can target predictors of treatment response based on clinical laboratory markers (e.g., genetic and epigenetic markers, neurotransmitters, hormones, cytokines, neuropeptides, and enzymes), electrophysiological measures (e.g., electroencephalography [EEG] measures, sleep EEG, evoked potentials, magnetic encephalography [MEG], and skin conductance) functional neuroimaging indices (e.g., magnetic resonance imaging [MRI], functional MRI, magnetic resonance spectroscopy [MRS], positron emission tomography [PET], and single photon emission computed tomography [SPECT]), as well as details in clinical history (Wiedemann, 2011).

An improved understanding of the pathogenesis of depression has the potential to contribute to the development of improved therapies. Moreover, insights gained with this strategy would in turn help basic scientists focus on the presumptive molecular and cellular mechanisms that underlie these radically improved treatments. In fact, clinical studies with ketamine have stimulated preclinical research to understand the molecular and cellular underpinnings that might be involved in ketamine’s rapid antidepressant effects (Aan Het Rot et al., 2012).

Consequently, this chapter will not review the serotonergic or noradrenergic systems, but instead will selectively summarize recent developments from well-designed clinical trials on other targets, such as the glutamatergic and cholinergic systems. The chapter will also characterize potential biological markers that may predict treatment response to these agents. In this chapter, when available, we review the randomized, placebo-controlled pharmacological trials in MDD and BD that have been conducted exploring these novel targets/systems. We briefly review uncontrolled studies only when the results lead to a randomized controlled clinical trial, and thus the uncontrolled study provides relevant historical context to the testing of the target being explored. We do not review trials with non-pharmacological approaches (e.g., deep brain stimulation and transcranial magnetic stimulation).

THE GLUTAMATERGIC SYSTEM

HISTORY OF THE GLUTAMATERGIC SYSTEM

Understanding the role of glutamatergic neurotransmission has developed gradually over time, particularly when compared to the current levels of interest for research related to the glutamate system and focus on potential applications. High concentrations of glutamate in the brain were first recognized in the 1930s, which led to several trials in the 1940s utilizing dietary glutamate and glutamine for the potential treatment of epilepsy and learning disorders. In the early 1950s, a pivotal animal study demonstrated that an injection of glutamate into the brain of a rat produced convulsions, which led to speculation that glutamate might be a primary excitatory neurotransmitter in the mammalian brain. Subsequent studies demonstrated that glutamate mediated excitatory action via multiple receptors, which were initially classified as *N*-methyl-*D*-aspartate (NMDA) and non-NMDA receptors. The latter was subdivided into what are now α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) and kainate receptors after learning that agonists and antagonists preferentially interacted with these receptors. By 1977, a study validated NMDA receptors as synaptic receptors, and in the following 20 years key preclinical studies confirmed that NMDA antagonists inhibited long-term potentiation in the hippocampus (important in learning and memory) and mitigated behavioral deficits seen in inescapable stress paradigms comparable to that of clinically effective antidepressants. While much of the early impetus in psychiatry was led by these preclinical studies, recent remarkable clinical observations—particularly the antidepressant effects observed with ketamine—have resulted in increased interest in the identification of potential targets within the complex and dynamic framework of the glutamatergic system (Murrough, 2012; Watkins and Jane, 2006).

GLUTAMATERGIC RECEPTORS AND BASIC PHYSIOLOGY

Glutamate is found in exponentially higher concentrations than monoamines and is considered the most abundant neurotransmitter in the brain. The excitatory effects of glutamate are primarily balanced by another neurotransmitter, γ -aminobutyric acid (GABA), which mediates the greater part of fast inhibitory neurotransmission. This tight regulation of glutamate is of significance as undue glutamate excitotoxicity is implicated in several neuropsychiatric disorders. Most neuronal glutamate is generated either *de novo* via the transamination of α -oxoglutarate through the Krebs cycle or by recycling from the glutamate/glutamine cycle. In a simplified model, glutamate acts in three different cell compartments—the presynaptic neuron, postsynaptic neuron, and surrounding glial cells. This model also involves other targets involved in the regulation of synaptic and extrasynaptic glutamate levels. Broadly, glutamate primarily activates diverse ionotropic (NMDA, α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic (AMPA), and kainate (KA) receptors) and eight types of G protein-coupled metabotropic (mGluR) receptors. Other targets include excitatory amino acid transporters (EAATs), which provide glutamate clearance from

extracellular space, soluble N-ethylmaleimide-sensitive factor attachment receptor (SNARE) complexes, which are thought to play a role in the structural aspects of synaptic vesicle exocytosis, vesicular glutamate transporters (VGLUTs), which are responsible for the uptake of glutamate into the synaptic vesicle, and cytoplasmic postsynaptic density proteins.

Of note, while glial cells have several functions and far outnumber neurons, they are especially crucial in the clearance and recycling of neurotransmitters, such as glutamate via the glutamate/glutamine cycle. The coupling between glutamatergic neurons and surrounding glial cells is fundamental, as impaired glial cell activity may lead to neuronal toxicity or increased glutamatergic activation. Mounting evidence suggests that frontal cortical areas of subjects with major depression or bipolar disorder have lower numbers of glial cells than non-psychiatric controls. Glial loss in the prefrontal cortex induces depressive-like behaviors similar to chronic stress in preclinical models. Other pathophysiological findings associated with glutamatergic neurotransmission have been drawn from postmortem, gene expression, and neuroimaging studies, such as magnetic resonance spectroscopy (MRS). (For a more complete review of the anatomy of the glutamatergic system and its role in depression and mood disorders, see Machado-Vieira et al., 2012; Machado-Vieira, Manji, 2009.) The complex physiological regulation of glutamate may provide an array of targets for future pharmacologic development and drug discovery.

CLINICAL TRIALS WITH GLUTAMATERGIC AGENTS

Placebo-controlled clinical trials (and select uncontrolled trials) with glutamatergic targets are summarized in Table 33.1.

NMDA ANTAGONISTS—KETAMINE

Of the three major subtypes of ionotropic receptors, NMDA and AMPA receptors have shown compelling evidence of their role in antidepressant action. A significant “proof of concept” translation of NMDA antagonists with MDD patients in clinical trials has been notable particularly with ketamine. Ketamine is a noncompetitive, high affinity NMDA antagonist that was first developed by Parke-Davis in 1963 as a safer anesthetic compared to phencyclidine (PCP). Ketamine is metabolized by the liver into two primary metabolites, norketamine (major metabolite) and dehydronorketamine (DHNK—minor, inactive metabolite) with a half-life of two to two and a half hours. A series of other metabolites of ketamine have been identified recently, some lasting up to three days (Zarate et al., 2012a). Several preclinical studies demonstrated that ketamine produces antidepressant- or anxiolytic-like effects in various behavior models of depression (e.g., forced swim test, tail suspension test, learned helplessness, etc.) (Tokita et al., 2012).

The first reported placebo-controlled, double-blinded, randomized trial ($n = 7$) utilizing a single intravenous (IV) dose of ketamine (0.5 mg/kg infusion over 40 minutes) in patients with MDD demonstrated a significant reduction in depressive symptoms 72 hours postinfusion. Profound but transient cognitive deficits and euphoria also were induced by the ketamine

TABLE 33.1. Controlled trials targeting the glutamatergic system

COMPOUND	SAMPLE	TRIAL DESIGN	RATING SCALE	ADMINISTRATIVE ROUTE	OUTCOME
KETAMINE*					
1. Berman <i>et al.</i> (2000)	MDD (N =6); BPD (N = 1)	Placebo-controlled, double-blind crossover. Single dose of ketamine (0.5 mg/kg)	BDI HDRS-25	Intravenous 0.5 mg/kg	Antidepressant response at 24 hr (25%); 72 hr (50%); significant decrease in HDRS score
2. Zarate <i>et al.</i> (2006)	TRD (N = 18)	Placebo controlled, double-blind, crossover. Single dose of ketamine (0.5 mg/kg)	BDI HDRS-21	Intravenous 0.5 mg/kg	Depressive symptoms improved within 110 minutes; 71% of subjects responded to ketamine; 35% at 7 days
3. DiazGranados <i>et al.</i> (2010)	BPD (N = 18)	Placebo controlled, double-blind, crossover. Single dose of ketamine; (while on therapeutic valproate/lithium dose)	BDI HDRS-17 MADRS	Intravenous 0.5 mg/kg	Depressive symptoms improved within 40 minutes; 71% of the subjects responded to ketamine; 41% response at 24 hr
4. Valentine <i>et al.</i> (2011)	MDD (N = 10)	Placebo lead in (1 week prior to ketamine infusion 0.5 mg/kg). Single blind study.	BDIHDRS-25	Intravenous 0.5 mg/kg	Greatest antidepressant effect of ketamine seen after 2 hours; 40% response at 24hr
5. Zarate <i>et al.</i> (2012)	BPD (N = 15)	Placebo controlled, double-blind, crossover. Single dose of ketamine; (while on therapeutic valproate/lithium dose)	BDI HDRS-17 MADRS	Intravenous 0.5 mg/kg	Depressive symptoms and suicidal ideation improved within 40 minutes; 79% responded to ketamine; 43% response at 24hr
MEMANTINE					
1. Zarate <i>et al.</i> (2006)	MDD (N = 32)	Double-blind, placebo-controlled study; 2 wk placebo lead in; randomized to placebo or memantine; 8 wk study	MADRS	Oral 5–20 mg/d (titrated 5 mg weekly)	No difference in efficacy between placebo and memantine groups
2. Lenze <i>et al.</i> (2011)	Depressed/apathy symptoms (N = 35)	Placebo-controlled, double-blind, (memantine: 10 mg twice daily), 12 wk study	HDRS	Oral 20 mg/d (Start 10 mg/d; titrated to 20 mg by 2nd week)	No significant improved affective or functional outcome vs. placebo in older adults
3. Anand <i>et al.</i> (2012)	BPD (N = 29)	Placebo-controlled, double-blind, parallel group design; memantine augmentation (5–20 mg/d) to lamotrigine (100 mg+/day), 8 wk study	HDRS-17	Oral 5–20 mg/d; with 100 mg+ of lamotrigine	Post hoc antidepressant effect with titration of memantine (4 wk); no benefit to memantine augmentation of lamotrigine in BPD depressed patients
RILUZOLE					
1. Mathew <i>et al.</i> (2010)	TRD (N = 26)	Randomized, placebo-controlled, double-blind, continuation trial of riluzole (100–200 mg/day), following single dose ketamine (0.5 mg/kg)	MADRS IDS-C QIDS-SR	Intravenous 0.5 mg/kg ; randomized (to lamotrigine 300 mg pre-infusion; add on riluzole (100–200 mg/d)	65% met response criteria 24 hr post ketamine infusion; 54% met response at 72 hr; no difference in time-to-relapse between add-on riluzole and placebo groups

(Continued)

TABLE 33.1. (Continued)

COMPOUND	SAMPLE	TRIAL DESIGN	RATING SCALE	ADMINISTRATIVE ROUTE	OUTCOME
RILUZOLE					
2. Ibrahim et al. (2012a)	TRD (N = 42)	Randomized, placebo-controlled, double-blind study, add on Riluzole (100–200 mg/day) after single dose ketamine (0.5 mg/kg)	MADRS BDI HDRS-17	Single dose of ketamine Intravenous 0.5 mg/kg. Add on Riluzole (100–200 mg/day)	Ketamine produced a moderate antidepressant effect through day 28. There was no difference in course of antidepressant effect between ketamine-riluzole and ketamine-placebo groups.
NR2B—SUBUNIT SELECTIVE NMDA ANTAGONISTS					
1. Preskorn et al. (2008)	TRD (N = 30)	Open label trial with paroxetine + double-blind single infusion of CP-101,606 or placebo	MADRSHDRS-17 BDI	Paroxetine 40 mg + IV infusion of CP-101,106 (varied dosing)	At day 5 primary outcome measure, 60% met response criteria on MADRS
2. Ibrahim et al. (2012b)	TRD (N = 5)	Placebo-controlled, double-blind, crossover pilot (MK-0657); 12 d study	MADRS HDRS-17	MK-0657 (4–8 mg/day); 12 d	Secondary measures (BDI and HDRS) revealed significant antidepressant effects at day 5; no significant antidepressant effects with MADRS (primary outcome measure)
AZD6765 (LOW-TRAPPING, NONSELECTIVE NMDA ANTAGONIST)					
1. Zarate et al. (2012)	TRD (N = 22)	Placebo controlled, double-blind, crossover. Single dose of AZD6765 (150 mg)	MADRS	AZD6765, Intravenous 150 mg single dose; 7 d	MADRS scores significant at 80 minutes and remaining up to 110 minutes; 32% overall response with AZD6765. No difference in psychotomimetic effects versus placebo.

* Includes controlled trials only; several other trials (case studies and open-label) have observed antidepressant effects with ketamine infusions. MDD: Major depressive disorder; BPD: Bipolar disorder- Depressed; TRD: Treatment-resistant depression; BDI: Beck depression inventory; HDRS: Hamilton depression rating scale; MADRS: Montgomery-Asberg depression rating scale; IDSC: Inventory of Depressive Symptomatology Clinical Rating; QIDS-SR: Quick Inventory of Depressive Symptomatology—Self-Report—Response defined as 50% reduction in depression rating scale score.

infusion. A larger double-blind, placebo-controlled, crossover study at the National Institutes of Mental Health (NIMH) replicated these findings by showing that a single ketamine infusion (0.5 mg/kg over 40 minutes) had rapid and relatively sustained antidepressant effects (lasting one to two weeks) in patients with treatment-resistant MDD. Subjects in this study were medication free at least two weeks prior to infusion and on average failed six prior antidepressants. Effect size for the drug difference was large ($d = 1.46$) after 24 hours and moderate to large ($d = 0.68$) after one week. Thirty-five percent of subjects maintained response for at least one week. Adverse effects included perceptual disturbances, confusion, dizziness, euphoria, derealization, and transient elevation in blood pressure with most symptoms peaking at 40 minutes and ceasing 80 minutes postinfusion.

In a similarly designed study, ketamine was added to therapeutic levels of lithium or valproate and also produced rapid antidepressant effects in patients with treatment-resistant bipolar depression. A recent study replicated these latter findings in bipolar depression and also demonstrated that

ketamine can rapidly improve suicidal ideation in patients for up to three days following a single intravenous dose ($d = .89$). Similar, albeit uncontrolled, open label and naturalistic studies (e.g., emergency room settings) utilizing ketamine have shown significant and rapid antisuicidal effects in depressed patients. Interestingly, one of these studies had preliminary results showing ketamine to have rapid beneficial effects on suicidal cognition as measured by the Implicit Association Test—a reliable behavioral measure assessing implicit suicidal associations (Price et al., 2009). Taken together, ketamine’s use in antisuicidal effects likely will be an area of future interest and research.

Despite ketamine’s positive safety profile as a widely used anesthetic agent for children, an important limitation of ketamine’s clinical application in larger populations is its acute neuropsychiatric side effects (Green et al., 1998). Equally important are the questions of tolerability and sustained efficacy with repeat ketamine treatments. To this regard, only small, open-label studies have shown ketamine to be fairly well tolerated with repeated/sustained antidepressant effects

(Aan Het Rot et al., 2010; Zanicotti et al., 2012). Frequency of repeat infusions were similar to outpatient ECT scheduling (Monday-Wednesday-Friday) with relapse rates varying significantly after the last dose from 6 days to greater than 45 days (Murrough et al., 2011).

Strategies considered to attenuate ketamine's side effect profile mainly include augmentation with other drugs (pre or post ketamine). In an early study, healthy volunteers were administered haloperidol (5 mg), a typical antipsychotic, two hours prior to a ketamine infusion, but the results were unremarkable (Krystal et al., 1999). More recently, a small ($n = 14$), randomized, double-blind study evaluated the potential of riluzole—an inhibitor of glutamate release (reviewed in Zarate and Manji, 2008)—to prevent postketamine relapse in patients with treatment resistant depression (TRD). The study also assessed whether pretreatment with the anticonvulsant and mood-relapse preventive agent lamotrigine would attenuate the psychotomimetic effects and enhance antidepressant activity of ketamine based on an earlier study showing that lamotrigine attenuated the psychotomimetic side effects in healthy volunteers (Anand et al., 2000). In this study, lamotrigine failed to reduce the transient psychotomimetic side effects associated with ketamine in TRD, or enhance its antidepressant effects. Likewise, riluzole did not differ from placebo in preventing postketamine relapse (Mathew et al., 2010).

A larger, four-week, double-blind, randomized, placebo-controlled study (Ibrahim et al., 2012) also was conducted to evaluate the effect of riluzole use following a single ketamine infusion. Four to six hours after a single infusion of ketamine (0.5 mg/kg), 42 subjects with treatment-resistant MDD were randomized to double-blind treatment with either riluzole (100–200 mg/day; $n = 21$) or placebo ($n = 21$) for four weeks. Although the effect size of improvement with ketamine was initially large and remained moderate throughout the 28-day trial, the difference between the riluzole and placebo treatment groups was not significant for postketamine relapse. These two studies continue to highlight the complexity of augmentation strategies for both ketamine's tolerability and sustained efficacy.

Despite the attention and interest from ketamine's early trials, the administration of ketamine for use in the clinic remains under study. Larger, controlled trials will be required to evaluate safety with repeated use of ketamine, and continued research will be required to discover successful relapse prevention or strategies to sustain antidepressant effects. Similarly, more studies will be needed to assess whether alternative delivery routes (e.g. intranasal, intramuscular) might improve pharmacokinetics, with continued assessment of optimal dosing regimens, and improved knowledge and understanding of ketamine's underlying mechanism of actions. (All of the previously noted controlled studies, plus those conducted to date in depression, and additional discussion regarding the maintenance of ketamine's antidepressant response, and its effects on suicidal ideation are reviewed in Aan Het Rot et al., 2012; Mathew et al., 2012.)

Putative Molecular Mechanisms Underlying Ketamine's Antidepressant Response

A growing body of preclinical evidence investigating ketamine's rapid antidepressant effects has led to novel findings and an

increasing body of knowledge toward the neuroplastic effects of this treatment. In addition to NMDA receptor antagonism, ketamine involves enhanced throughput of AMPA receptors, and some inhibitory effects at muscarinic acetylcholine receptors. Prominent preclinical studies have demonstrated ketamine to rapidly phosphorylate/activate the mammalian target of rapamycin (mTOR) pathway with resulting increased levels of synaptic signaling proteins and synaptic plasticity (e.g., new spine synapse formation) in the prefrontal cortex (PFC) of rodents. Included in this cascade of postsynaptic events, literature discusses mixed results for an increased activation of brain-derived neurotrophic factor (BDNF) with ketamine's antidepressant response. Reduced levels of BDNF have been associated with depression, and BDNF's essential role in cell differentiation, nerve growth, and neuronal survival research makes it a likely area of investigation. Preclinical work by others has also implicated the potential role of glycogen synthase kinase-3 beta (GSK-3 β) inhibition in the hippocampus and PFC after ketamine infusions. Patients with MDD are thought to have increased GSK-3 β activity, and inhibition of GSK-3 β is also thought to play a key role in the therapeutic mechanism of antidepressants and mood stabilizers. Overall, further research will still be required to elucidate the neurobiology underlying ketamine's rapid antidepressant response (Aan Het Rot et al., 2012; Mathew et al., 2012; Murrough, 2012).

Biomarkers of Antidepressant Response to Ketamine

Given the heterogeneity of depression and often "trial and error" approach to current treatments, positive predictors of antidepressant response to ketamine would be of great significance and practical value to both patients and clinicians. Several recent studies are investigating ketamine responders via a multimodal systems level approach, and utilize a range of potential markers from genes to the reversal of the complex behavioral phenotype (i.e., genes, gene expression, synaptic plasticity indices, cellular components, neural circuits, behavioral features of depression) using various experimental methods (neuroimaging, genetics, electrophysiological measures, clinical features, etc.). The goal is to both inform regarding the likelihood of response and provide insights into the mechanisms of action of ketamine. This section will briefly highlight some of the more prominent studies.

One neurophysiologic study utilized magnetoencephalography (MEG) to measure rostral anterior cingulate cortex (rACC) activity as drug free patients with MDD were presented with a fearful face paradigm. Previous research has shown that higher pretreatment ACC metabolism predicts antidepressant response in sleep deprivation (also known to induce rapid, but brief antidepressant effects) and several other antidepressant treatments (e.g., SSRIs). In the MEG study, higher pretreatment levels of rACC activity correlated positively with the magnitude of subsequent antidepressant response to a ketamine, while healthy individuals showed reduced activity in this region (Salvadore et al., 2009). Another MEG study incorporating a working memory task demonstrated that patients who showed the least amount of engagement in the pregenual ACC as task difficulty increased showed the largest subsequent

response to treatment, within four hours of ketamine administration. Pretreatment functional connectivity between the pregenual ACC and the left amygdala also negatively correlated with the antidepressant following ketamine. These findings concur with functional studies in healthy volunteers, where pgACC regional blood flow increases with emotional tasks, but decreases during cognitive tasks that demand attention. The results suggest that conservation of this pattern may predict better treatment outcome (Salvadore et al., 2010). Both MEG studies overall contribute to the extant literature supporting the role of ACC activity as a promising predictor of response to antidepressant treatment (Pizzagalli, 2011).

Two electrophysiologic studies utilizing sleep measures have also shown interesting findings. One study ($n = 30$, TRD patients) investigated the acute effects of ketamine on depressive symptoms evaluating EEG slow wave activity (SWA), individual slow wave parameters, and plasma BDNF (230 min postinfusion). Earlier research had demonstrated a relationship between SWA and cortical synaptic activity of cortical neurons suggesting its potential role as a surrogate marker of central synaptic plasticity. Decreased production of sleep slow waves is also a core feature observed in depression. Results of the study showed early sleep SWA (during the first non-REM episode) and BDNF levels increased compared to baseline with ketamine responders having changes to BDNF proportional to changes in EEG parameters. Consistent with an earlier finding (Machado-Vieira, Yuan et al., 2009) from the same lab was no difference in BDNF levels from responders and non-responders. The earlier study did note their lack of placebo control and other cautions, such as interpreting peripheral BDNF as a marker of central BDNF. The study overall suggests that sleep SWA parameters and BDNF may serve as future non-invasive measures for testing novel antidepressants and that ketamine increases synaptic strengthening/efficacy (Duncan et al., 2012). Building on the latter study, baseline delta sleep ratio (DSR) was examined to see if it could predict rapid response to a ketamine infusion in individuals with TRD. DSR is the ratio of slow wave activity between the first two non-REM sleep episodes, and this measure has also been shown to be lower in depressed patients than healthy controls. Findings from the study ($n = 30$) showed a significant positive correlation between baseline DSR and reduced MADRS scores from baseline to day 1 (low baseline scores predicted better mood response). These results are notable, as some traditional antidepressants have been found to normalize slow wave sleep and DSR. Sample size was a known limitation of the findings, and larger replications of the study were recommended by the authors. Nevertheless, this preliminary data could lead to DSR being a useful biomarker of response to ketamine in the future (Duncan et al., 2012).

In regard to genetic studies, a recent study ($n = 62$) demonstrated that MDD patients with the Val/Val BDNF allele were more likely to have an increased antidepressant response to ketamine (from baseline HAM-D score to 210/230 min postinfusion) than Met carriers. These results also support previous clinical data, where Val/Val mice exhibited increased antidepressant effect to ketamine (and prefrontal cortex synaptogenesis) on the basis of this single polymorphism. The Val66Met

SNP is found in 20–30% of humans and has been linked to psychiatric disorders and impaired trafficking/regulation of BDNF (Laje et al., 2012).

Another innovative approach to study both the pathophysiology of MDD and ketamine response has been proton MRS. This research tool allows for the quantification of amino acid neurotransmitters in the brain, and previous MRS research has shown that GABA and Glx (composite peak formed by glutamate and glutamine) are decreased in the medial and dorsal anterolateral PFC of patients with MDD. Subsequently, 14 drug free patients with MDD who were scanned before receiving a single infusion of ketamine showed an association (230 min postinfusion) between lower Glx/ glutamate ratio (a surrogate marker of glutamine) and a greater improvement in response to ketamine treatment. Pretreatment GABA or glutamate did not correlate with improved depressive symptoms, however pretreatment Glx/glutamate in the dorsomedial/dorsal anterolateral PFC was negatively correlated with improvement in depressive symptoms. As glutamine is primarily localized in glia, the authors hypothesized that the decreased Glx/glutamate ratio may reflect a reduced number of glial cells, further signifying that this “neuropathological construct” (Salvadore et al., 2011) may be associated with antidepressant responsiveness to ketamine.

A potential clinical predictor of response to ketamine is family history of alcohol dependence. It is important to acknowledge that family history could represent a biomarker (i.e., genetic, epigenetic influences) or be the result of environment. A recent study found that patients with MDD who had a family history of alcohol dependence had a better short-term response to ketamine infusion than subjects with no family history of alcohol dependence (Phelps et al., 2009). The positive family history group (FHP) had a significantly higher response rate (67%) at 230 minutes (postinfusion) than the group without alcohol dependence family history (FHN) (18%; $p = .02$). In addition, patients with FHP had fewer dysphoric symptoms postinfusion than those with FHN. Previous clinical studies also found compared to healthy controls, subjects with alcohol dependence experienced fewer perceptual differences and decreased dysphoric mood during ketamine infusion (Krystal et al., 2003). Surprisingly, the healthy controls with a positive family history of alcohol also showed fewer ketamine-induced perceptual alterations (Petrakis et al., 2004). Of note, self-reported history of alcohol use disorders or family history of major depression did not predict response. Possible mechanisms explaining these effects include familial, epigenetic, or genetic variations in the NMDA subunit NR2A, which may have the greatest relevance for human alcohol dependence (Schumann et al., 2008).

Lastly, ketamine infusions in healthy volunteers immediately induced changes similar to those gradually induced by monoaminergic-based antidepressant agents as assessed using quantitative electroencephalography (QEEG). The observed reduction in prefrontal theta cordance (a measure that correlates with cerebral perfusion) may represent a potential marker/predictor for the antidepressant effects of ketamine, a hypothesis that could be tested readily in future studies with depressed populations (Horacek et al., 2010; Hunter et al., 2007).

Overall, increased attention in biomarker research in depression and the field of psychiatry will parallel the trend toward individualized and tailored treatment strategies for patients. The progress toward identifying biomarkers and application of these markers to predict treatment response ultimately will help elucidate the pathogenesis of depression and reduce the all-too-frequent “trial and error” approach for the selection of treatments in depression.

NMDA—SUBUNIT-SELECTIVE NR2B ANTAGONISTS

As noted earlier, non-competitive NMDA receptor antagonists like ketamine and PCP can produce psychotomimetic effects when used acutely. These observations promoted investigation into subunit-selective NMDA receptor agents to potentially mitigate the adverse effects, while promoting a therapeutic effect. Structurally, NMDA receptors are comprised of four tetrameric proteins: 2 NR1 subunits and 2 NR2 subunits. NR2 subunits are further divided by four subtypes: NR2A–D. Prior preclinical and clinical literature demonstrated the NR2B-selective NMDA antagonist, CP-101,606 to be well tolerated without prominent psychotropic side effects in a study evaluating traumatic brain injury (Merchant et al., 1999).

Building on this knowledge, Preskorn and colleagues undertook a “proof of concept” study with a recent randomized, placebo-controlled, double-blind trial, evaluating the antidepressant efficacy of the NR2B subunit-selective NMDA receptor antagonist CP-101,606 in 30 treatment-refractory MDD subjects. The study showed that a single infusion of CP-101,606 administered adjunctively to paroxetine, had greater antidepressant effects as compared with placebo (saline) infusion, with 78% of treated responders maintaining their response (50% reduction in HDRS score) for at least one week after infusion (mean difference, 8.6; 80% confidence interval, –12.3 to –4.5) ($P < 0.10$). The authors did note that the initial dose of 0.75 mg/kg was reduced to 0.5 mg/kg during the study given several initial research subjects experienced moderate to severe dissociative symptoms (Preskorn et al., 2008). All of the initial dissociative reactions resolved within six hours of the discontinuation of the infusion. No clinically significant change in labs was noted, however blood pressure changes similar to ketamine trials were observed (i.e., changes ≥ 20 mm Hg for diastolic or 30 mm Hg for systolic from baseline). Although the lower dose of CP-101,606 produced a rapid and significant antidepressant response without producing a dissociative reaction, the study highlights the challenges of optimal dosing for similar compounds. More studies will be necessary to replicate these findings and the overall efficacy and safety of compounds selective for the NR2B receptor (Preskorn et al., 2008).

Subsequently, an *oral* formulation of the selective NMDA NR2B receptor antagonist (MK-0657) was administered using a randomized, double-blind, placebo-controlled, crossover pilot study to evaluate the potential antidepressant efficacy and tolerability of this agent in treatment-resistant MDD patients. Following a one-week drug-free period, MDD patients were randomized to receive either MK-0657 monotherapy (4–8 mg/day) or placebo for 12 days. Due to discontinuation of the compound’s development by the manufacturer and recruitment

challenges, only five patients completed both the MK-0657 and placebo arms of the study. Secondary efficacy scales as assessed by the Hamilton Depression Rating Scale (HAM-D) and Beck Depression Inventory (BDI) demonstrated significant antidepressant effects as early as day 5 in patients receiving MK-0657 compared to placebo; however, no improvement was noted when symptoms were assessed with the primary efficacy measure (MADRS) (Ibrahim et al., 2012). Of note, MK-0657 increased plasma BDNF levels compared to placebo 9 days after treatment was initiated, indicative of a biological effect typically seen with several antidepressants. Although a small study, the role of BDNF may be involved as a potential biomarker of a NR2B antagonist’s treatment effect. No dissociative or serious adverse effects were observed. While larger studies will be needed for confirmation, preliminary data suggests that an oral formulation of an NR2B antagonist may have antidepressant properties (Ibrahim et al., 2012).

NMDA (NONSELECTIVE LOW TRAPPING CHANNEL BLOCKER)

More recently, an IV formulation of a low-trapping, non-selective NMDA channel blocker (AZD6765) produced rapid antidepressant effects in a placebo-controlled study in TRD patients. Following a two-week drug-free period, MDD patients received IV infusions of either AZD6765 (150 mg) or saline solution one week apart with a randomized, double-blind, crossover design. Antidepressant effects were seen within 80 minutes with MADRS scores remaining significant for 110 minutes. Results overall demonstrated that 32% of subjects responded to AZD6765, and 15% to placebo at some point in the trial. Furthermore, 18% of patients reached remission on AZD6765 versus 10% on placebo at some point in the study. Interestingly, no difference was observed between the groups with regard to psychotomimetic or dissociative effects (Zarate et al., 2012b). Onset of antidepressant effects were comparable to that of ketamine, but the duration was more short-lived. Subunit selectivity and trapping blockade may explain some AZD6765’s observed differences compared to ketamine. Similarly, metabolites of ketamine may contribute to its sustained antidepressant effects (Zarate et al., 2012a). Results from larger placebo-controlled, multicenter trials with AZD6765 are pending (NCT01482221).

OTHER GLUTAMATERGIC MODULATORS: MEMANTINE AND RILUZOLE

Memantine

Memantine, a derivative of amantadine, is already FDA approved for the treatment of moderate to severe Alzheimer’s disease and is considered a low-affinity, non-competitive, open-channel NMDA receptor antagonist. Memantine has essentially no psychotomimetic effects at therapeutic doses (5–20 mg/day), a key distinction from ketamine. In addition, memantine has been utilized clinically for over 15 years showing good tolerability in large patient populations. A review of associated preclinical data within depression and anxiety models (e.g., decreased immobility time) is discussed in greater detail by Parsons et al. (1999). Of note, despite amantadine’s

remarkable antidepressant effects observed in patients with the Borna disease virus, it will not be reviewed in this chapter given a lack of data in any randomized controlled trials and due to its likely involvement with multiple pharmacologic mechanisms (Huber et al., 1999).

Unfortunately, most controlled clinical trials have not demonstrated memantine to have robust antidepressant effects. In an eight-week double blind placebo-controlled trial ($n = 32$), memantine (5–20 mg/day) failed to improve symptoms of depression in patients with MDD (Zarate et al., 2006). More recently, a proof of concept study ($n = 29$) also failed to show any benefit of memantine augmentation (5–20 mg/day) of lamotrigine (stable dose of at least 100 mg/daily for four weeks prior to randomization) for patients with bipolar depression over an eight-week trial (primary outcome time point). However, memantine was observed to have a significant antidepressant effect early on in the treatment (up to four weeks) during its titration (Anand et al., 2012). Lastly, a 12-week, double-blind placebo controlled pilot study ($n = 35$) evaluated memantine (10 mg twice daily) for treatment in late-life depression and apathy after a disabling medical event, but no affective or functional improvement was observed when compared with placebo (Lenze et al., 2011).

With regard to positive outcome trials, a larger study ($n = 80$) alcohol-dependent patients with MDD were randomized to memantine 20 mg/day or escitalopram 20 mg/day. Memantine reduces alcohol cravings in preclinical studies, and alcohol dependence commonly is comorbid with major depression. The study concluded that both treatments significantly reduced depression and anxiety (primary outcome measures) (Muhonen et al., 2008). However, a major limitation of this study was the lack of a placebo control. Alcohol dependence may modulate the antidepressant response that is mediated via NMDA receptors, as long-term alcohol use increases the number (Nagy, 2004) and alters the function of glutamate NMDA receptors (Petrakis et al., 2004). Interestingly, a seven-day, placebo-controlled randomized single-blinded psychopharmacology trial study ($n = 127$) that utilized three different ant glutamatergic strategies (lamotrigine 25 mg 4x/day, memantine 10 mg 3x/day, or topiramate 25 mg 4x/day) for ethanol detoxification demonstrated significant improvements for alcohol withdrawal symptoms and dysphoric mood (Krupitsky et al., 2007).

In an effort to better understand memantine's potential antidepressant role, a recent healthy volunteer model of emotional processing attempted to assess the neuropsychological profile of action associated with memantine (10 mg dose; typical dose in clinical studies is at least 20 mg). Overall, the results suggest that memantine produces an early anxiogenic response in the emotion-potentiated startle similar to that seen in studies considering a single dose of the SSRI citalopram. No other significant difference was observed with emotional or non-emotional information processing. Earlier studies have also shown that SSRI treatments initially increase the emotion-potentiated startle effect with acute administration, but that this effect is reversed after seven daily treatments (Browning et al., 2007; Grillon et al., 2007). Given the study only tested one dose; the authors did note that a future study (to 7 days) may help confirm the current profile of effects and provide more clinical

utility. Nevertheless, the authors also suggest that the limited neuropsychological profile associated with memantine may be consistent with the clinical data previously reported, where memantine is no more effective than placebo (Pringle et al., 2012). As already noted, similar but longer studies would help clarify some of these interpretations.

Riluzole

Riluzole currently is approved by the US Food and Drug Administration for treating amyotrophic lateral sclerosis. This agent crosses the blood-brain barrier and modulates the glutamatergic system by inhibiting glutamate release (via inhibition of voltage-dependent sodium channels) and enhancing both glutamate reuptake and AMPA trafficking and glutamate transporters. Riluzole is thought to have neuroprotective and plasticity enhancing properties given its ability to stimulate neurotrophic factors, such as nerve growth factor (NGF), BDNF, and glial cell line-derived neurotrophic factor (GDNF) in cultured astrocytes. A number of publications also discuss its use in neurodegenerative disorders. Combined with its glutamatergic modulating properties, Riluzole has had increased investigation in off label uses in both psychiatric and neurologic disorders (Zarate and Manji, 2008).

In clinical trials, riluzole monotherapy for depression has been evaluated only in open-label trials. One trial ($n = 19$) with TRD and a one-week medication-free period demonstrated significant improvement in depression during weeks three through six of treatment (50–200 mg/day, mean dose = 168.8 mg/day). Improvements were also seen in scales measuring anxiety. The most common side effects were similar (e.g., headache, gastrointestinal distress, and constipation) to those seen in trials of patients with amyotrophic lateral sclerosis. Similar, positive antidepressant and anxiolytic effects were reported with riluzole (50–200 mg/day) as an augmentation antidepressant agent, but only in smaller open-label trials evaluating effects in bipolar depression, generalized anxiety disorder, and obsessive-compulsive disorder (OCD).

Given some of antidepressant findings of riluzole mentioned, two double-blind, randomized, placebo-controlled studies proceeded to apply riluzole as a potential add-on strategy to maintain ketamine's rapid antidepressant effects (see ketamine section for details). Both studies administered riluzole (100–200 mg/day) orally, and both trials failed to show any difference in time to relapse from placebo after a single ketamine infusion. Nevertheless, both trials did replicate earlier ketamine findings showing it to be well tolerated and having rapid antidepressant effects. Overall, double-blind, placebo-controlled clinical trials will still be necessary to confirm some of the promising findings observed in these open-label studies. For a more systematic review of literature regarding riluzole, see Zarate and Manji (2008).

THE CHOLINERGIC SYSTEM

HISTORY OF THE CHOLINERGIC SYSTEM

The cholinergic system was the first of the neurotransmitters to be identified, and as a result has received a tremendous

amount of investigation. Early research characterized the role of the cholinergic system at the neuromuscular junction, in the pathophysiology of Alzheimer's disease, and in cognitive functions including memory and attention. The cholinergic system also is the target of nerve gas, a fact that was accidentally uncovered in Germany in 1936 as researchers were attempting to improve on available insecticides, or organophosphates. These agents target acetylcholinesterase, an enzyme responsible for terminating effects of acetylcholine in the synapse, resulting in continued neural transmission and continued contractions at the neuromuscular junction. After a drop of the potent agent tabun was dropped in the laboratory, the investigator and his assistant began to experience dizziness and severe shortness of breath. These observations led to the development of nerve gas for military purposes during World War II, although it was never used during the war.

The cholinergic neurotransmitter system was implicated in mood disorders in the 1970s, when Janowsky and colleagues demonstrated that the acute administration of the anticholinesterase physostigmine to currently manic bipolar patients results in the rapid development of depressive symptoms (reviewed in Janowsky et al., 1994). Similarly, when physostigmine was administered to currently depressed patients with major depressive disorder, depressive symptoms worsened acutely. Physostigmine produces an increase in available acetylcholine, and thus is non-selective relative to cholinergic receptor type. As a result of this general implication of cholinergic function, interest has been given to both nicotinic and muscarinic cholinergic agents as potential antidepressants. Nonetheless, while the cholinergic system was identified in the early 1970s as a potential target for antidepressant agents, little attention had been given to this system until recently.

CHOLINERGIC RECEPTORS AND BASIC PHYSIOLOGY

The cholinergic neurotransmitter system is supported by two general types of receptors, the nicotinic and the muscarinic receptors (Albuquerque et al., 2009; Pringle et al., 2011). Muscarinic receptors, which are sensitive to muscarine as well as to acetylcholine, are G protein-coupled receptors and thus act through second messenger systems. Five muscarinic subtypes have been described to date, simply called M1 through M5. Muscarinic receptors are located throughout the central nervous system and in the postganglionic neurons of the parasympathetic division of the autonomic nervous system. Nicotinic receptors, which are responsive to nicotine as well as acetylcholine, are ionotropic and thus act by opening or closing ion channels in response to endogenous stimulation by acetylcholine. The nicotinic receptors are made up of five subunits, which surround a central pore. These receptors can be separated broadly based on their location in the nervous system into two subtypes, muscle-type and neuronal-type nicotinic receptor. Muscle-type nicotinic receptors, found at the neuromuscular junction, are either of the embryonic form or the adult form, each with slightly different compositions of the five subunits in the receptors.

The neuronal-type has various combinations of 12 possible receptor subunits.

CLINICAL TRIALS WITH CHOLINERGIC AGENTS

Placebo-controlled clinical trials (and select uncontrolled trials) with cholinergic targets are summarized in Table 33.2.

MUSCARINIC CHOLINERGIC AGENTS

Interest in cholinergic muscarinic agents developed as these receptors explicitly were implicated in aspects of sleep disturbances observed in patients with mood disorders. Specifically, decreased REM latency and increased REM density are observed in this patient population, and these sleep features are mediated through cholinergic muscarinic receptors (reviewed in Janowsky et al., 1994). The pattern of sleep disturbance is consistent with *excessive* muscarinic activity, and thus indicated increased muscarinic cholinergic function in patients with affective disorders.

Biperiden

Early studies looked at the antidepressant properties of a selective M1 antagonist, biperiden (Kasper et al., 1981). In an uncontrolled, open label study evaluating oral biperiden in "severely depressed" patients, the authors report significant improvement in depressive symptoms by the end of study. These findings however did not replicate in a controlled study of biperiden, where no significant benefit was observed over the control condition (Gillin et al., 1995). However, the original study is of interest, as the authors reported that baseline results of a dexamethasone suppression test significantly predicted subsequent clinical response to biperiden.

Scopolamine

More recently, in the context of a dose-finding study designed to evaluate the impact of a muscarinic blocker on cognitive features of mood disorders, unipolar and bipolar patients received intravenous infusions of the cholinergic muscarinic antagonist scopolamine (Furey and Drevets, 2006). Critically, all patients participating in these studies were free of psychoactive medications for a minimum of two weeks, and as patients were not taken off of existing medication, most were free of medications for a longer period of time. Over the course of this three-dose, four-infusion, placebo-controlled pilot study, depressive symptoms notably improved. Despite the small sample size ($n = 8$), the response was sufficiently large to warrant a clinical trial to properly assess the antidepressant potential of scopolamine.

A clinical trial was conducted (Furey and Drevets, 2006) that included a total of seven infusions, and began with a single-blind placebo lead-in infusion. Patients then were randomized into either a P/S or a S/P series, whereby P = a block of three placebo infusions and S = a block of three scopolamine infusions; these infusions were administered under double-blind conditions. Full clinical assessments always preceded infusions, and one follow-up assessment was obtained three to five days after the last infusion for a total of eight assessments. This crossover design allowed for all patients to receive treatment.

TABLE 33.2. Trials targeting the cholinergic system

COMPOUND	SAMPLE	TRIAL DESIGN	RATING SCALE	ADMINISTRATIVE ROUTE	OUTCOME
SCOPOLAMINE					
1. Furey and Drevets (2006)	MDD (N = 9) BPD (N = 9)	Placebo-controlled, double-blind crossover. A series of 3 drug infusions (4 µg/kg); 4 placebo infusions	MADRS	Intravenous 4 ug/kg	Antidepressant response at first post drug assessment (3–5 days after infusion)
2. Drevets and Furey (2010)	MDD (N = 22)	Placebo-controlled, double-blind crossover. A series of 3 drug infusions (4 µg/kg); 4 placebo infusions	MADRS	Intravenous 4 ug/kg	Antidepressant response at first post drug assessment (3–5 days after infusion)
3. Newhouse et al. (1988)	MDD (N = 9)	Placebo-controlled, double-blind crossover with 3 doses of scopolamine (0.1, 0.25 and 0.5 mg), 1 dose lorazepam (1 mg oral), placebo	BDI; BPRS	Intramuscular (0.1, 0.25 and 0.5 mg)	No antidepressant effect at 120 minutes
4. Gillin et al. (1991)	MDD (N = 9) BPD (N = 1)	Open-label	POMS-Depression Subscale	Intramuscular 0.4 mg for 3 consecutive days	Small but significant antidepressant effect at day 2
BIPERIDEN					
1. Kasper et al. (1981)	MDD (N = 5) BPD (N = 5)	Open-label	HDRS	Oral 6–12 mg/d	Antidepressant effect at study end (30 days) (uncontrolled study)
2. Gillin et al. (1995)	MDD (N = 17) BPD (N = 2)	Placebo-controlled, double-blind, randomized, parallel arm 6-week study	HDRS	Oral 4–12 mg /d	No antidepressant effect vs. placebo
NICOTINE					
1. McClernon et al. (2006)	Non-smokers w/CES-D >10	Placebo-controlled, double-blind, 4-week study	CES-D	Transdermal (3.5 mg/day weeks 1–4; 7 mg/day weeks 2–3)	Reduced depressive symptoms by day 8
2. Salin-Pascual (2002)	MDD (N = 15)	Sleep study with baseline night 1; nicotine patch night 2	HDRS-10	Transdermal 17.5 mg	Ten of 15 patients improved (30% reduction) morning after patch administration
MECAMYLAMINE					
1. George et al. (2008)	MDD (N = 21)	Placebo-controlled, double-blind, 8-week study. Randomized,	HDRS-17 MADRS	Oral Up to 10 mg/d	Reduction in depressive symptoms vs. placebo by end of study (8 weeks)
2. AstraZeneca (2012)	MDD (N = 145)	placebo-controlled, double-blind, 8-week trial		Oral 1 or 4 mg TC-5214 or placebo twice daily; or 60 mg Duloxetine once (active comparator) once daily	
VARENICLINE					
1. Philip et al. (2009)	MDD (N = 12) BPD (N = 5) MDD-NOS (N = 1)	Open-label; 8-week augmentation study (patients currently on stable antidepressant or mood stabilizer regimen)	QIDS-SR	Oral 1 mg- 2x/d	Patients showed significant improvement at study end; significant by week 2. No difference among groups at 8-weeks

MDD: Major depressive disorder; BPD: Bipolar disorder–Depressed; BDI: Beck depression inventory; CES-D—Center for Epidemiological Studies Depression Scale; HDRS: Hamilton depression rating scale; MADRS: Montgomery-Asberg depression rating scale; NOS: Not otherwise specified; QIDS-SR: Quick Inventory of Depressive Symptomatology—Self-Report—Response defined as 50% reduction in depression rating scale score.

A rapid antidepressant response was observed in both the P/S and the S/P patient groups. The P/S group showed little change in MADRS while receiving placebo in the first study block, and subsequently had a significant reduction in MADRS with the first assessment following the first infusion of scopolamine ($F = 94.1, p < 0.0001$, Cohen's $d = 3.4$), demonstrating a rapid antidepressant response. Importantly the magnitude of reduction in MADRS increased significantly over the series of three infusions ($p = 0.04$). The S/P group received scopolamine in the first study block, and again showed a significant reduction in MADRS with the first assessment following the first infusion of scopolamine ($F = 34.8, p < 0.0001$; Cohen's $d = 2.2$). This group also showed further improvement over the series of three scopolamine infusions suggesting that ($p = 0.002$), together with the P/S group, patients will improve further with additional infusions of scopolamine. In the S/P group, the clinical benefit experienced during the scopolamine infusions in block 1 persisted to the end of the study, demonstrating that the antidepressant effects continue in the absence of additional treatment for at least two weeks. Importantly, the groups differed in study block 1 ($F = 26.7, p < 0.0001$; Cohen's $d = 2.7$) demonstrating that drug and placebo separated, and this separation occurred by the first evaluation in study block 1 ($t = 2.5, p = 0.02$).

These clinical findings have been replicated (Drevets and Furey, 2010) in an independent sample of patients. The experimental design was unchanged, but the patient sample was limited to patients with major depressive disorder. In this study the overall pattern of rapid antidepressant response was identical, thus providing additional support to these clinical findings. These studies together indicate that the cholinergic muscarinic receptors offer a new neurobiological target for antidepressant treatment that has the potential to produce rapid antidepressant responses.

Patterns of response associated with patient subgroups have been considered in a combined/increased patient sample. In patients studied to date, the magnitude of response is similar for unipolar and bipolar patients, as well as for patients with and without comorbid anxiety disorder. The only patient subgroups that identified differences in response outcome were based on patient gender. While men and women showed significant improvement in symptoms following scopolamine administration, women showed significantly larger responses than men (Furey et al., 2010).

Putative Molecular Mechanism Underlying Scopolamine's Antidepressant Effect The antidepressant effects observed following scopolamine administration appear to be consistent with the hypothesis that cholinergic hypersensitivity contributes to the pathophysiology of mood disorders. However, the response latency of one to three days together with the persistence of the antidepressant response may suggest that the mechanism of action includes effects beyond the direct influence on muscarinic receptors.

Elevated glutamatergic transmission is associated with the pathophysiology of mood disorders, and like other antidepressant treatments, scopolamine reduces NMDA receptor activity. Muscarinic receptor stimulation enhances NMDA receptor

gene expression (Liu et al., 2004), and thus the increased muscarinic receptor sensitivity seen in mood disorders may lead to increased NMDA receptor activity. In rat brain, the administration of scopolamine has been shown to reduce mRNA concentrations for NMDA receptor types 1A and 2A (Liu et al., 2004), and thus may reduce NMDA receptor activity via this mechanism.

A recently described effect of ketamine on synaptic plasticity (described previously) that is thought to underlie the observed antidepressant effects also has been shown following scopolamine administration (Li et al., 2011-Online). Like ketamine, scopolamine administration in rats activates the mTOR pathway, which leads to increases in synaptic signaling protein expression and increases in the number and function of new spine synapses in prefrontal cortical areas. Rapamycin, which blocks mTOR signaling, disrupts both the scopolamine induced increase in synaptogenesis as well as the antidepressant behavioral response observed in rodent models of depression. The timing and the magnitude of these effects following scopolamine administration are similar to those seen following ketamine administration. The authors hypothesize that increases in mTOR signaling depend on increases in extracellular glutamate levels, and both ketamine and scopolamine have been shown to increase glutamate concentration. This work suggests that the rapid antidepressant effects observed following both scopolamine and ketamine administration may involve influences on synaptic plasticity.

Biomarkers of Antidepressant Response to Scopolamine Biomarkers of treatment response to scopolamine have been identified using functional neuroimaging. Baseline neuroimaging assessments attained prior to drug administration have been utilized to predict subsequent response to scopolamine. As highlighted earlier, the pursuit and identification of biomarkers of treatment response offers the potential to provide insight into the underlying pathophysiology of mood disorder, and subsequently lead to improved clinical treatment.

The role of the cholinergic system in cognitive functions, and the existing literature on cholinergic modulation during cognitive tasks and functional brain response, renders cognitive studies in patients with cholinergic dysfunction potentially very informative. The role of cholinergic activity in executive functions such as working memory (WM) and attention has been hypothesized to act via stimulus processing mechanisms (reviewed in Furey, 2011). Working memory refers to a process by which information (visual or auditory) is encoded, maintained for a short period of time, and is then used during recall or recognition. The information subsequently is not long available (i.e., no long-term storage). The preclinical literature indicates that increasing cholinergic activity through the direct application of acetylcholine has effects on stimulus processing, and alters signal-to-noise (S/N) mechanisms to enhance the representation of target stimuli. Functional imaging studies in humans also have demonstrated that increased cholinergic function increases response to task-relevant stimuli in visual processing areas, much like an increased S/N at the brain region or brain network level, and results in improved performance

on WM and attention tasks. Thus, cholinergic function likely influences cognition by modifying neural representations of task-relevant stimuli.

The role of the cholinergic system specifically in WM processes has been well studied, and the results similarly highlight the impact of cholinergic function specifically on the processing of task-relevant stimuli. The best-characterized cognitive feature in mood disorders is described as a negative processing bias, where negative emotional information is preferentially processed over positive information. The excessive cholinergic activity in mood disorders may underlie this negative processing bias, and potentially could be evident in measures obtained with functional neuroimaging methodologies (reviewed in Furey, 2011).

A WM task was utilized to determine if levels of neural activity to specific stimulus information in visual processing brain areas could predict subsequent treatment response to the cholinergic muscarinic agent, scopolamine (Frankel et al., 2011-Online). A face WM task was used that included two task conditions: one which instructed participants to encode and remember the identity of the face and another which instructed participants to encode and remember the emotional expression in the face. In both conditions, the face to encode was presented, followed by a memory delay period, and then by a test image (Frankel et al., 2011-Online). The task was to indicate if the test image matched the encoded image based on the attended (i.e., identity or emotion) stimulus feature.

Functional magnetic resonance imaging (fMRI) was conducted in patients with MDD and healthy individuals during multiple sessions using the infusion schedule described previously. Blood oxygen-level dependent (BOLD) signal was measured, a surrogate measure of neural activity, as participants performed the two conditions in the WM task. Response magnitude was estimated separately for each task component and for each task condition from the data collected during the baseline session, prior to scopolamine infusions. The BOLD estimates of neural activity were correlated with the magnitude of subsequent treatment response to scopolamine (percent change in MADRS from baseline to study end).

Only the two stimulus processing conditions (i.e., stimulus encoding and test components) when patients were processing emotional expressions in the faces produced significant findings. Importantly, these correlations were observed exclusively in visual processing areas. Specifically, significant negative correlations were observed bilaterally in middle occipital cortex (MOC) between BOLD response and the magnitude of treatment response. While the analyses for the emotion encoding and emotion test components were conducted independently, the areas of significant correlation in MOC were largely overlapping, highlighting the selectivity of these particular brain regions in this effect. Importantly, no correlation emerged when patients were processing the same stimuli but encoding face identity, highlighting the selectivity of this effect to emotion processing.

These findings indicate that in MDD, the baseline, pretreatment levels of neural activity in MOC during the processing of emotional information reflects the potential for a clinical response to scopolamine. These results may suggest that the

level of underlying cholinergic dysfunction is expressed in levels of neural response to emotional information, and that this underlying level of cholinergic dysfunction represents a biomarker for subsequent response to a cholinergic muscarinic antagonist agent. Healthy participants on average show higher levels of activity in these same MOC regions than MDD patients. Importantly, those patients who do not respond to scopolamine have BOLD estimates that fall well within the range observed in healthy participants, consistent with the interpretation that those patients who do not respond to scopolamine also do not show processing dysfunction in these areas. Similarly, those who do respond to scopolamine show increased levels of dysfunction in these brain regions at baseline.

BOLD estimates also were obtained from the scanning session that followed the scopolamine infusion, and thus reflects the acute response to muscarinic blockade. To determine the extent to which neural response in visual cortex (with a particular interest in MOC) during the same stimulus processing components of the emotion WM task is susceptible to cholinergic modulation in a manner that predicted treatment outcome, the change in BOLD response was calculated (BOLD drug—BOLD baseline), and this delta BOLD measure was correlated with subsequent treatment response. The change in BOLD response following acute scopolamine administration (thus prior to antidepressant effects) during stimulus processing components of the emotion working memory task also correlated with subsequent treatment response. The brain regions of significance were found to substantially overlap with the MOC regions identified in the analyses described previously (Frankel et al., 2011-Online). These findings may suggest that the visual processing brain regions that show predictive value at baseline also respond to cholinergic modulation in a manner that predicts treatment outcome, an interpretation that would support the conclusion that baseline levels of neural dysfunction in MOC are cholinergically mediated.

NICOTINIC CHOLINERGIC AGENTS

In addition to the early literature implicating cholinergic receptors in general, interest in nicotinic cholinergic receptors as possible targets for antidepressant agents originated based on the observation in 2005 that smoking rates were substantially higher in major depressive disorder (between 40% and 60%) than in the general population (22%) (reviewed in Philip et al., 2010). This observation led to the hypothesis that increased levels of smoking reflected an effort to self-medicate, and that nicotine may have antidepressant effects. Related observations included that smokers with a history of major depression have more difficulty quitting smoking, and patients with depression are at greater risk for developing a major depressive episode during smoking cessation (Philip et al., 2010). Conversely, smokers also have reduced levels of monoamine oxidase (MAO), an enzyme involved in the breakdown of monoamines including serotonin, norepinephrine, and dopamine, which is proposed to result in depressed mood (Philip et al., 2010).

Nicotine

An open-label clinical trial using transdermal nicotine in depressed smokers provided some evidence that nicotine may have

potential for producing antidepressant effects (Salin-Pascual, 2002). The authors report that 10 of 15 non-smoking patients with major depressive disorder showed a 30% improvement in depressive symptoms. While the group as a whole did not show a significant response, this change was observed the morning after administration of the nicotine patch, suggesting a potential rapid antidepressant response. Several replications in uncontrolled studies have been reported (reviewed in Salin-Pascual, 2002). A placebo-controlled study also was conducted (McClernon et al., 2006), which showed that depressive symptoms improved by day 8 of nicotine administration, but this study was conducted in a mildly depressed cohort (not reaching criteria for MDD) and thus offers limited utility with regard to implications for patients with depression.

As health concerns prevent the clinical use of nicotine as an antidepressant agent, these clinical findings primarily have led to the evaluation of the antidepressant potential of other agents that target nicotinic receptors. A paradox within this literature does emerge. Some antidepressant medications used clinically for smoking cessation, including bupropion, a norepinephrine and dopamine reuptake inhibitor, and nortriptyline, a tricyclic antidepressant that inhibits reuptake of norepinephrine and serotonin, also have nicotinic antagonistic properties. Thus agents with nicotinic agonist effects and agents with nicotinic antagonist effects reportedly produce antidepressant effects. A potential explanation has been offered (reviewed by Philip et al., 2010), which suggests that nicotine initially activates nicotinic receptors but this activation is rapidly followed by desensitization. Continued binding to the nicotinic receptor potentially leads to ongoing desensitization, which is thought to result in chronic antagonism. Thus, antidepressant effects are thought to result from nicotinic antagonistic action.

Mecamylamine

The potential for the non-selective nicotinic cholinergic receptor antagonist mecamylamine to produce antidepressant effects has been evaluated. In a population of adolescents with Tourette's syndrome and comorbid major depression antidepressant effects were reported, which led to a placebo-controlled clinical trial in patients with MDD (George et al., 2008). MDD patients showing little to no response after receiving a minimum of three months of SSRI treatment were randomized to placebo or mecamylamine (10 mg/d) for an eight-week trial. More patients receiving mecamylamine showed significant improvement (>50% reduction in symptoms) (45%) than those receiving placebo (10%) at end of study, suggesting that MDD patients who are SSRI refractory showed an antidepressant response to mecamylamine.

A double-blind, placebo controlled phase-II study also was conducted with MDD patients who were refractory follow a six-week trial of the SSRI citalopram. Patients were randomized to 5–10 mg/day of mecamylamine or to placebo for a 10-week trial. The group receiving mecamylamine showed more improvement than those receiving placebo (reviewed in Bacher et al., 2009). Nonetheless, a multicenter randomized, double-blind, placebo controlled phase-II study of a non-selective nicotinic receptor antagonist (TC-5214;

S-mecamylamine) failed to show antidepressant efficacy in an eight-week trial (AstraZeneca, 2012), raising questions as to the potential utility of these agents.

Varenicline

In a clinical trial designed to evaluate the effect on smoking cessation, varenicline, a nicotinic agonist, was found to alleviate negative symptoms associated with nicotine withdrawal including depression (reviewed in Philip et al., 2010). This observation led to an eight-week open label augmentation study in currently depressed patients with MDD or BD who were unresponsive to current treatment. Fourteen of 18 patients completed the study, and showed improvement in depressive symptoms as compared to baseline. Eight patients met criteria for full response, six of whom also met criteria for remission. Interestingly, observed improvement in depressive symptoms correlated with patient smoking cessation (reviewed in Philip et al., 2010).

OTHER POTENTIAL TARGETS AND FUTURE CONSIDERATIONS

While this chapter has focused primarily on the glutamatergic and cholinergic systems given recent promise with rapid acting agents in these respective classes, this should not minimize the research being done in other potential areas including the dysregulation of dopamine neurotransmission (Dunlop and Nemeroff, 2007; Nestler and Carlezon, 2006), the pathophysiology of the hypothalamic-pituitary-adrenal axis (HPA) (Pariante and Lightman, 2008; Wasserman et al., 2010), circadian rhythm regulation (Adrien, 2002; Harvey, 2011), stress hormone regulation (Holsboer and Ising, 2010; Nugent et al., 2011), inflammatory/neuroimmune system (Leonard and Maes, 2012; Miller et al., 2009; Muller et al., 2011), involvement of corticotrophin-releasing factors (Holsboer, 2000; Paez-Pereda et al., 2011), tachykinin/neurokinin (NK-1, NK-2) receptors (Herpfer and Lieb, 2005; Mantyh, 2002), and neurotrophic factors (Autry and Monteggia, 2012; Voleti and Duman, 2012).

Despite advances in the previously mentioned areas, there is still limited success with randomized, placebo-controlled trials with non-monoamine based compounds. For example, corticotropin-releasing factor (CRF, a peptide containing 41 amino acids) and its primary receptor (CRF-1) are well known to regulate behavioral responses to stress. CRF is also distributed throughout the CNS with its interneurons widely localized in the neocortex to areas (prefrontal, cingulate, and insular cortices) well known to be involved in depression and affective disorders. Its relation to impaired regulation of the HPA axis further supports rationale to target this system. While an initial open label trial of NBI-30775/R121919, a non-peptidic tricyclic CRF-1 receptor antagonist with high oral bioavailability and blood-brain barrier penetration, showed initial promising results, clinical development later stopped because of a reversible increase of liver enzymes in healthy controls during an unpublished safety study with high dosages (despite absence of CRF-1 receptor expression in the liver). Phase II controlled clinical trials with CP-316,311 (Pfizer) and BMS-562086 (Bristol-Myers Squibb, pexacerfont) also did not

provide therapeutic results over placebo (Paez-Pereda et al., 2011). Results are currently pending regarding SSR-125543A another CRF-1 antagonist with recent completion of a Phase II clinical trial of 580 Russian subjects with MDD (Connolly and Thase, 2012). Despite these lackluster results, published results seem to indicate that CRF-1 receptor antagonism is safe and not intrinsically associated with adverse side effects. Interestingly, it should be noted that none of the mentioned studies included a stratification of patients for HPA abnormalities (Paez-Pereda et al., 2011). Similar to CRF-1 antagonists, NK-1 antagonists have also had disappointing results with a pooled analysis (>2,500 patients) of five, eight-week placebo-controlled clinical trials finding no benefit of the NK-1 antagonist aprepitant over placebo (Connolly and Thase, 2012). Lastly, with regard to inflammation, a recent proof-of-concept study ($n = 60$) demonstrated that tumor necrosis factor (TNF) antagonism does not have generalized efficacy in TRD (Raison et al., 2013). The study incorporated infusions of the TNF antagonist infliximab (5 mg/kg) in a double-blind, placebo-controlled trial and included outpatients that were both medication-free and on a consistent antidepressant regimen. Despite the negative primary findings, an association was observed between high baseline concentrations of the inflammatory biomarker high-sensitivity C-reactive protein (hs-CRP) and subsequent improved response to infliximab. In addition, infliximab-treated patients with a low level of inflammation appeared to do worse than placebo-treated patients. As a result, the study suggests there may be a subgroup of patients with TRD who have increased inflammation and respond to TNF antagonism, but not to placebo. Future development with inflammatory biomarkers may prove promising for personalizing antidepressant treatment. Opium and its derivatives have an extensive history dating several centuries back, both in medicinal and recreational settings. While opioids are utilized largely for the management of pain, endogenous opioid peptides and their receptors have been identified as potential candidates for novel antidepressant treatments given their expression in notable brain areas known to play major roles in affective disorders (e.g., ventral tegmental area, nucleus accumbens [NAc], PFC). Likewise, antidepressants that increase the availability of noradrenaline and serotonin through the inhibition of the reuptake of these monoamines also enhance the opioid pathway (Berrocoso et al., 2009). Of the main receptor subtypes (delta, kappa, mu, and nociceptin), the delta opioid agonists (DOP) are gaining increasing attention, as recent preclinical evidence has provided promising results. DOP agonists have both reduced analgesic properties and less reinforcing/respiratory depression effects than those observed with classic μ receptors (Jutkiewicz, 2006). Currently, two DOP agonist trials (Phase II development) have been completed (AZD-2327 and AZD-7268) for the treatment of MDD with pending efficacy results (Connolly and Thase, 2012). For an excellent and more complete review of novel and emerging drugs/targets for depression, such as sigma receptors, the interested reader should refer to Connolly and Thase (2012).

While barriers to clinical translation for psychiatric drugs are beyond the scope of this chapter, some key issues include the limited predictive value of preclinical models and the ever

present challenge of target validation for clinical validity. For example, with CRF-1 antagonism, it is not known if the compounds given in trials are actually blocking CRF-1 receptors in the brain (i.e., target and functional engagement). In this example, we are largely assuming the effects in a preclinical model will extend to functional effects in humans (Potter, 2012). With regard to target validation, a target is often defined as a molecular or cellular structure involved in the pathology of interest that the intervention (e.g., drug) is meant to act on. This is clearly challenging in psychiatry and other CNS areas, as establishing valid targets requires a sound understanding of the underlying pathophysiology. Developing a drug against a specific target can often take several years with escalating costs in the billions of dollars. As a result, “reducing failures early in development is far more important than filling a pipeline with poorly chosen late-stage products likely to fail, and fail expensively” (Smith, 2003). For an optimistic future, collaboration will certainly be required, and an open-source model may provide for more rapid data sharing and better prioritizing of successful targets. Such steps may “de-risk” some of the current barriers for future “bench to bedside” therapeutics. Ideally, continuing advances in other tools such as molecular genetics, systems neuroscience, and translational medicine will lead to innovative tools and biomarkers to ultimately better serve patients suffering with depression and other debilitating disorders. For a more detailed discussion on novel CNS drug development, see Potter (2012).

EXPERIMENTAL MEDICINE

Experimental medicine characterizes a different method designed to understand the pathophysiology underlying mood disorders that merits comment (reviewed in Pringle et al., 2011). This approach proposes a cognitive neuropsychological model to understand antidepressant action, and suggests that pharmacologically mediated changes in emotional processing biases early in treatment contribute to subsequent clinical improvements in mood. Moreover, the delay in treatment response seen following conventional treatment is explained as the time during which the patient learns new associations following social interactions. Much of this work has been conducted in healthy volunteers, demonstrating that conventional antidepressant agents modulate neural responses to emotional information following several days of administration, well before clinical response generally is observed in clinical populations. These findings provide important insights into potential mechanisms of action that require follow-up evaluation in patient groups.

In patient populations, this approach has demonstrated that early in treatment and prior to clinical improvement, antidepressant agents modulate neural responses during emotional processing as measured using fMRI. Similarly, effects on behavioral measures that demonstrate emotional processing biases have been reported at three hours following the first administration of an antidepressant in patients with MDD. As these changes are associated exclusively with drug administration, the question as to whether these early changes predict subsequent clinical response to treatment remains empirical.

CONCLUSION

MDD is a severe, disabling, and potentially life-threatening medical illness that disrupts the lives of millions of individuals worldwide. Despite a considerable number of antidepressant agents developed over the years, significant limitations exist with regard to the utility and efficacy of available drugs. Critically, no specific agent or class of agents has proven to be more efficacious than any other. In addition, a considerable lag in the onset of therapeutic response is observed, often requiring weeks to months for full therapeutic response, thus leaving patients at risk for ongoing impairment and elevated risk of self-harm. Progress in the development of new and better medications that are particularly geared toward accelerating the onset of improvement of depressive symptoms has stalled despite considerable efforts from industry, academia, and government. The translation from targets in preclinical models to clinic populations has not succeeded as of yet in delivering better treatments. One approach for addressing these shortcomings is to focus on new neurophysiological targets, with the goal of identifying rapid acting interventions, and to simultaneously incorporate biomarkers of treatment response to facilitate the understanding of underlying mechanism.

This chapter primarily reviews two drugs that are radically unique and distinct from current antidepressants due to their rapid antidepressant effects; ketamine and scopolamine. Ketamine produces antidepressant effects within hours, while scopolamine produces effects within a few days. Research to date for both drugs is unique in that controlled studies have been conducted and replicated demonstrating rapid antidepressant effects. The inability to replicate clinical experiments recently has been highlighted as a concern in psychiatry. In addition, the evidence showing rapid efficacy of these compounds is augmented with multimodal biomarkers. Using rapid onset antidepressants permits the simultaneous study of multiple biomarkers and thus allows for the examination of biological signatures of rapid improvement using a systems level approach, extending from genes to behavioral phenotype across the cellular, molecular, neurochemical, and circuit domains. This approach permits the careful study of correlations of multiple biomarkers, precisely timed at the onset of antidepressant effects, thus potentially offering an opportunity to obtain greater insight into the molecular and cellular changes that accompany treatment response. In this way, ketamine and scopolamine are experimental tools being used to uncover clues that can then be characterized more precisely to determine what molecular targets are involved in these rapid antidepressant effects. Indeed, this strategy has already led to significant advances in the last several years reinvigorating and solidifying industry, academia, and government partnerships with moving forward toward the development of drugs with a rapid onset of antidepressant action. Specifically with the antidepressant response to ketamine, the systems level approach has led to the identification of genetics correlates associated with SNP on BDNF, molecular correlates identifying the involvement of mTOR, GSK-3 inhibition, and eEF2 as putative targets, the identification of brain areas and brain function associated with clinical improvement, such as increases

in slow wave activity during sleep, and cortical excitability gamma power in sensory regions. Although these findings are promising, much more is needed before we gain a comprehensive understanding of biological underpinning of rapid antidepressant effects. These insights will be critical to the development of the next generation of treatments if they are to provide faster, more effective options than existing treatments offer. Similar approaches are being applied to the cholinergic antagonist scopolamine, and we anticipate that data gleaned from this approach will contribute to that of ketamine and other agents with a rapid onset of action to identify the neural and molecular requirements for fast acting treatments.

DISCLOSURES

The authors gratefully acknowledge the support of the Intramural Research Program of the National Institute of Mental Health, National Institutes of Health (IRP-NIMH/NIH; Bethesda, MD, USA), and thank the 7SE Research Unit of the NIMH/NIH for their support. Role of funding source: This review was supported by the IRP-NIMH/NIH. The NIMH had no further role in the writing of this chapter, or in the decision to submit the chapter for publication.

The authors gratefully acknowledge the support of the IRP-NIMH/NIH, and the NARSAD Independent Investigator Award and Brain and Behavior Foundation Bipolar Research Award (Dr. Zarate).

Dr. Mathews has no conflict of interest to disclose, financial or otherwise.

Dr. Zarate is listed as a co-inventor on a patent application for the use of ketamine and its metabolites in major depression. Dr. Zarate has assigned his rights in the patent to the US government but will share a percentage of any royalties that may be received by the government.

Dr. Furey is listed as a co-inventor on a patent application for the use of scopolamine and its metabolites in major depression. Dr. Furey has assigned his rights in the patent to the US Government but will share a percentage of any royalties that may be received by the government.

34 | NEURAL CIRCUITRY OF DEPRESSION

JOSEPH L. PRICE AND WAYNE C. DREVETS

This review of the neural systems that underlie mood disorders is divided into two main sections dealing with (1) the neuroanatomy of the neural circuits that have been implicated in mood disorders, largely taken from studies of non-human primates, and (2) observations on humans, largely taken from clinical studies. The first section describes circuits linking specific structures that have been implicated in mood disorders, including the ventromedial prefrontal cortex (VMPFC), amygdala and other limbic structures, ventromedial striatum, and medial thalamus. The second section reviews data from *in vivo* neuroimaging and postmortem neuropathological studies of humans with mood disorders in light of the relevant neural circuitry. Finally, observations from the neuroanatomical networks implicated in mood disorders are integrated into neurocircuitry-based models of the pathophysiology of mood disorders aimed at explaining the diverse neurobiological systems that are affected in these conditions and the potential mechanisms underlying neurosurgical and neuromodulation approaches that have proven effective in treatment-refractory depression.

HISTORICAL INTRODUCTION

It has been suggested since the early studies of Broca and Papez that a system of interrelated “limbic” structures, including the hippocampus and amygdala, the anterior and medial thalamus, and the cingulate gyrus, is centrally involved in emotion and emotional expression. Visceral reactions are tightly linked to emotion, often providing the means of emotional expression itself, and it is apparent that these structures are closely connected to visceral control areas in the hypothalamus and brainstem. More recent studies with effective neuroanatomical methods have now defined the circuitry related to emotion in sufficient detail that it is possible to recognize how disorders of this neural mechanism may underlie mood disorders (Price and Drevets, 2010).

The amygdaloid complex of nuclei forms a focal point in the circuitry related to emotion. The connections of the amygdala therefore are a good starting point for understanding emotion-related circuitry. Experiments in rats, cats, and monkeys show that the basal and lateral amygdala have reciprocal connections to orbital and medial prefrontal, insular, and temporal cortical areas, as well as to the mediodorsal thalamic nucleus and the ventromedial striatum (Öngür and Price, 2000). Outputs to hypothalamic and brainstem areas involved directly in visceral control were also found from the central,

medial, and other nuclei. These projections include not just the medial and lateral hypothalamus, but also the periaqueductal gray, parabrachial nuclei, and autonomic nuclei in the caudal medulla. The strongest prefrontal cortical projections of the amygdala are with the medial prefrontal cortex (PFC) rostral and ventral to the genu of the corpus callosum, but there are also amygdaloid projections to parts of the orbital cortex, the insula, and the temporal pole and inferior temporal cortex (Fig. 34.1). Other amygdaloid connections are with the entorhinal and perirhinal cortex and hippocampus (subiculum) (Amaral et al., 1992), and the posterior cingulate cortex (Buckwalter et al., 2008).

In the striatum, the amygdaloid projection terminates throughout the ventromedial striatum, including the nucleus accumbens, medial caudate nucleus, and ventral putamen (Öngür and Price, 2000). These striatal areas in turn project to the ventral and rostral pallidum, which itself sends GABAergic axons to the mediodorsal thalamic nucleus (MD). The perigenual PFC also projects to the same ventromedial part of the striatum, and is interconnected to the same region of MD (Öngür and Price, 2000; Price and Drevets, 2010). The connections constitute essentially overlapping cortical-striatal-pallidal-thalamic and amygdalo-striatal-pallidal-thalamic loops (Fig. 34.1). As discussed in the following, these circuits form the core of the neural system implicated in mood disorders.

PREFRONTAL CORTEX (PFC)

In the 1990s, a series of axonal tracing experiments in macaque monkeys more completely defined the cortical and subcortical circuits related to the orbital and medial PFC (OMPFC). Two connectional systems or networks were recognized within the OMPFC, which have been referred to as the “orbital” and “medial prefrontal networks” (Fig. 34.2). The areas within each network are preferentially interconnected with other areas in the same network, and also have common extrinsic connections with other structures (Öngür and Price, 2000) (see following).

Recently, a similar analysis has been made of the organization and connections of the lateral PFC (LPFC). Based on architectonic and connectional analysis, three regions can be recognized in monkeys: a dorsal prefrontal region dorsal to the principal sulcus (DPFC), which is similar to the medial prefrontal network, a ventrolateral region ventral to the principal sulcus (VLPFC), which is related to the orbital prefrontal network, and a caudolateral region just rostral to the arcuate sulcus (CLPFC), which includes the frontal eye fields and is

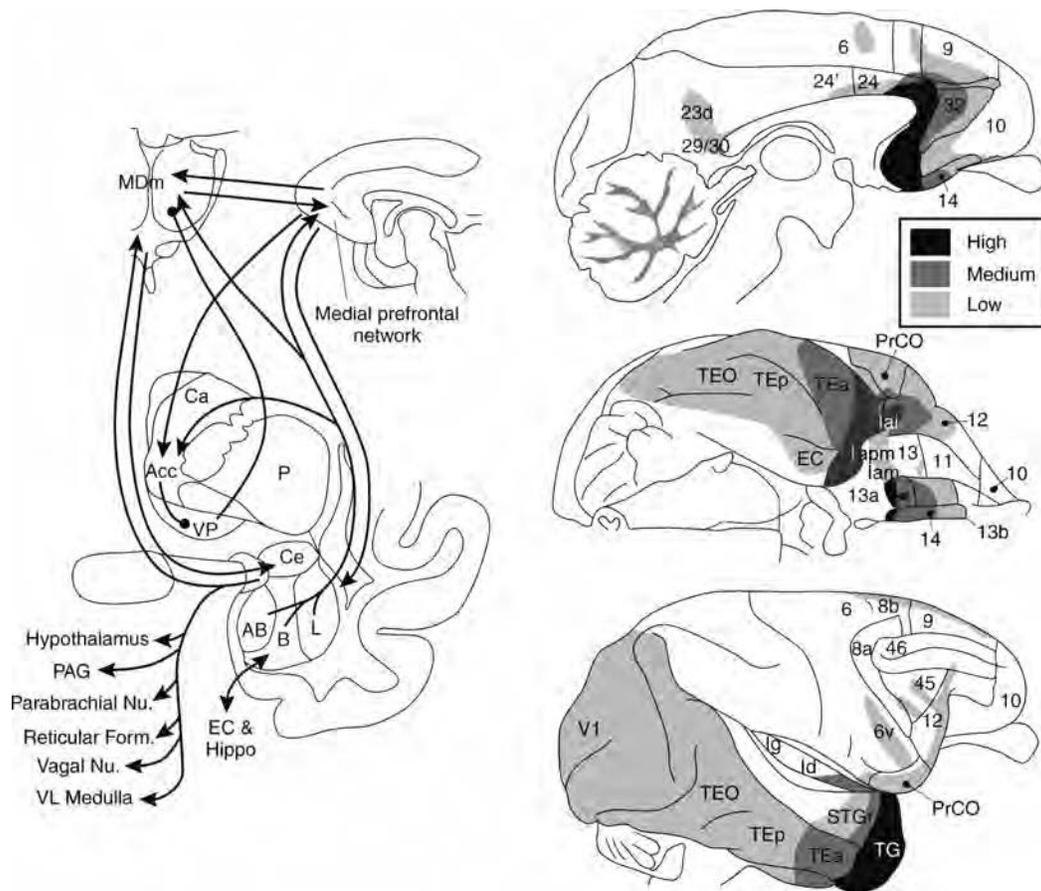

Figure 34.1 Summary of amygdaloid outputs. Left: Diagram of amygdaloid circuits involving the striatum pallidum medial thalamus and prefrontal cortex and output to the hypothalamus and brainstem. Right: Diagram of areas of the cerebral cortex that receive axonal projections from the amygdala. The dark, medium, and lightly shaded areas represent high, medium, and low density of amygdaloid fibers. (Modified from Amaral et al., 1992, as reproduced by permission from Price and Drevets, 2011.)

probably part of an attention system (Öngür and Price 2000; Saleem et al., 2008).

ORBITAL PREFRONTAL NETWORK AND VLPFC

The orbital network consists of areas in the central and caudal part of the orbital cortex and the adjacent anterior agranular insular cortex (Fig. 34.2); it does not include the gyrus rectus, nor a small region in the caudolateral orbital cortex. The network is characterized by specific connections with several sensory areas, including primary olfactory and gustatory cortex, visual areas in the inferior temporal cortex (TEa, and the ventral bank of the superior temporal sulcus, or STSv), somatic sensory areas in the dysgranular insula (Id), frontal operculum (Opf), and parietal cortex (area 7b) (Öngür and Price, 2000; Saleem et al., 2008).

Neurophysiological studies have indicated that neurons in the orbital network areas respond to multimodal stimuli (e.g., the sight, flavor, and texture of food stimuli). Notably, these neuronal responses reflect affective as well as sensory qualities of the stimuli. Responses to food stimuli change with satiety (Pritchard et al., 2008; Rolls, 2000), and many neurons code for the presence or expectation of reward (Schultz et al., 1997) or the relative value of stimuli (Padoa-Schioppa and Assad, 2006). Further, lesions of the orbital cortex produce a deficit in the ability to use reward as a guide to behavior (Rudebeck

and Murray, 2008). The orbital network therefore appears to function as a system for assessment of the affective value of multimodal stimuli.

The ventrolateral convexity of the LPFC, is closely related to the orbital network. This “VLPFC system” occupies the cortex ventral to the principal sulcus in monkeys, and includes areas 12l, 12r, 45b, and the ventral part of area 46 (Saleem et al., 2008). These areas are preferentially connected with each other, and to the areas of the orbital network. Further, they have most of the same extrinsic connections as the orbital network, including interconnections with the dysgranular insula, frontal operculum, area 7b, and inferior temporal cortex. The main difference from the medial network is that the VLPFC does not receive direct olfactory or gustatory inputs. These areas of the VLPFC may function to assess value of non-food sensory stimuli.

MEDIAL PREFRONTAL NETWORK AND DPFC

The medial network in the OMPFC is particularly significant for mood disorders. It consists of areas in the vmPFC rostral and ventral to the genu, areas along the medial edge of the orbital cortex, and a small caudolateral orbital region at the rostral end of the insula (Öngür and Price, 2000) (Fig. 34.2). The medial network receives few direct sensory inputs, but it has prominent connections with the amygdala and other limbic

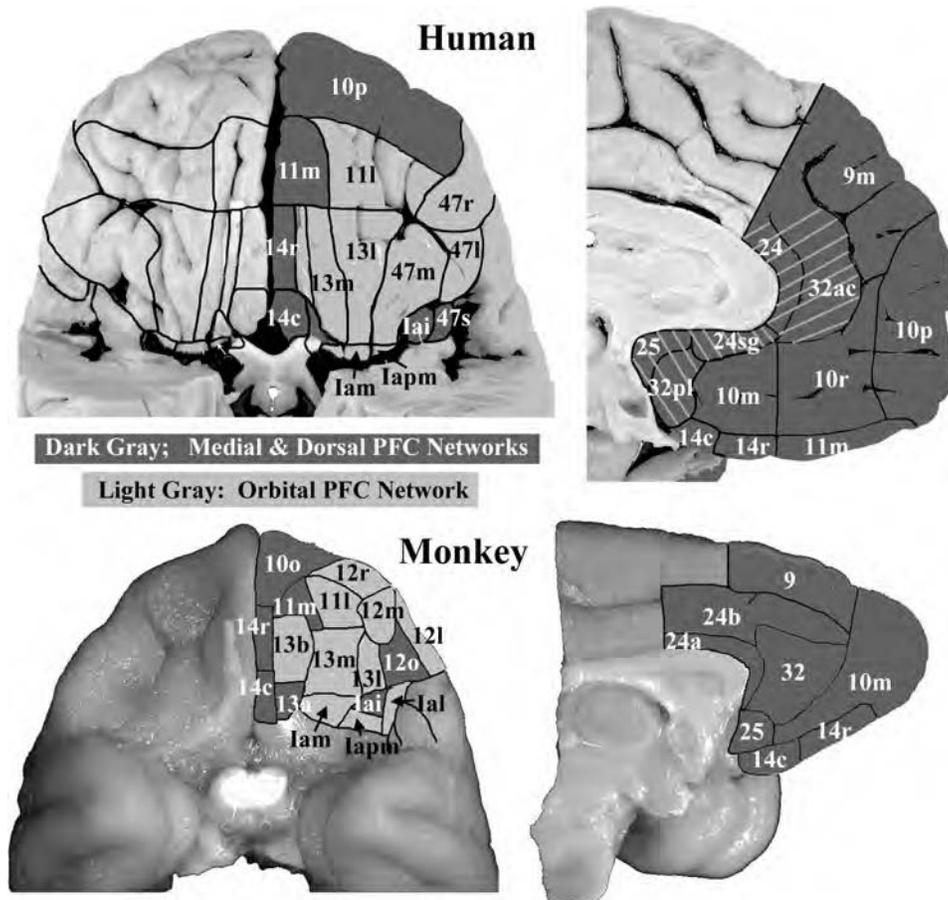

Figure 34.2 Maps of the orbital and medial surfaces of a human brain (above) and a macaque monkey brain (below), showing architectonic areas as defined in (Öngür et al., 2003) (human) and (Carmichael and Price, 1996) (monkey). The architectonic areas of the OMPFC are grouped into networks or systems based on connective data (see text). The medial and dorsal prefrontal networks are shaded dark gray, while the orbital network is shaded light gray. Note that the “medial” network includes some areas on the medial orbital surface as well as areas 14j and 47s (the human homologue of monkey 12o), in the lateral orbital cortex. In addition, the regions referred to as the subgenual and pregenual anterior cingulate cortex (sgACC and pgACC) are indicated on the human brain with backwards or forwards slanted stripes.

structures (Carmichael and Price, 1995a, b), and it is characterized by outputs to visceral control areas in the hypothalamus and periaqueductal gray (PAG). It can be considered a visceromotor system with strong relation to emotion and mood.

The medial network is connected to a very specific set of other cortical regions, particularly the rostral part of the superior temporal gyrus (STGr) and dorsal bank of the superior temporal sulcus (STSd), the anterior and posterior cingulate cortex, and the entorhinal and parahippocampal cortex (reviewed in Price and Drevets, 2010). This corticocortical circuit is distinct from, but complementary to the circuit related to the orbital network.

The medial network is closely related to the areas of the DPFC, on the dorsal medial wall, and the dorsomedial convexity, including area 8b, area 9, the dorsal part of area 46, and the polar part of area 10 (Fig. 34.2). The DPFC is interconnected with itself and with the medial prefrontal network, but less with the VLPFC or CLPFC. It also is connected to the same set of extrinsic cortical areas as the medial network, including the anterior and posterior cingulate cortex, the rostral superior temporal gyrus, and the entorhinal and parahippocampal cortex. Further, there are outputs from areas of the DPFC to the hypothalamus and PAG, so this system can also modulate visceral functions.

The medial network, the DPFC, and the other cortical areas with which they connect, taken together, closely resemble the “default mode network” (DMN), which has been defined by fMRI and functional connectivity MRI (fcMRI) in humans (Raichle et al., 2001) (Fig. 34.3). The DMN is characterized as interconnected areas that are active in a resting state but decrease activity in externally directed tasks. This network has been linked to a variety of self-referential functions such as understanding others’ mental state, recollection, and imagination (Buckner et al., 2008).

CAUDOLATERAL PREFRONTAL CORTEX

The caudal part of the LPFC, the caudolateral prefrontal cortex (CLPFC) is largely unrelated to either the medial or orbital networks. It includes the frontal eye fields and adjacent cortex (areas 8av, 8ad, and caudal part of area 46 in the caudal part of the principal sulcus) (reviewed in Price and Drevets, 2010). The extrinsic connections of this system are with the dorsal premotor cortex, the posterior part of the dorsal STS (area TPT), and areas LIP and 7a in the posterior parietal cortex. The CLPFC may be part of the dorsal attention system (Raichle et al., 2001).

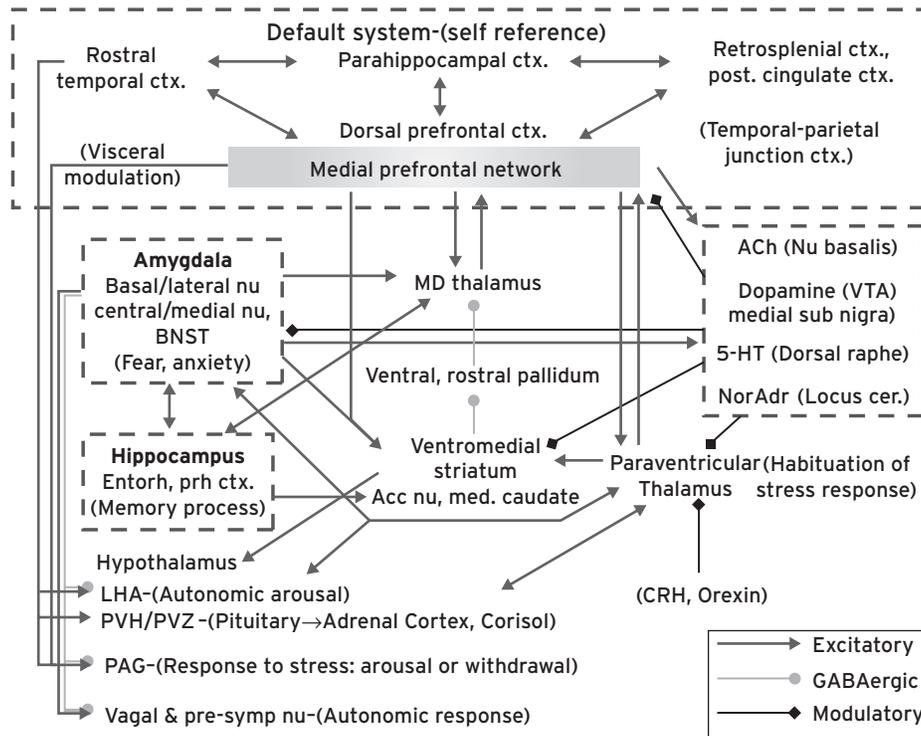

Figure 34.3 Anatomical circuits involving the medial and dorsal prefrontal networks, and the amygdala. Glutamatergic, presumed excitatory, projections are shown with pointed arrows, GABAergic projections are shown with round tipped arrows, and modulatory projections with diamond tipped arrows. In the model proposed herein, dysfunction in the medial prefrontal network and/or in the amygdala results in dysregulation of transmission throughout an extended brain circuit that spans from the cortex to the brainstem, yielding the cognitive, emotional, endocrine, autonomic, and neurochemical manifestations of depression. Intra-amygdaloid connections link the basal and lateral amygdaloid nuclei to the central and medial nuclei of the amygdala and the bed nucleus of the stria terminalis (BNST). Parallel and convergent efferent projections from the amygdala and the medial prefrontal network to the hypothalamus, periaqueductal grey (PAG), nucleus basalis, dorsal raphe, locus coeruleus, and medullary vagal nuclei organize neuroendocrine, autonomic, neurotransmitter, and behavioral responses to stressors and emotional stimuli (Davis and Shi, 1999; LeDoux, 2003). In addition, the medial prefrontal network and amygdala interact with the same cortical-striatal-pallidal-thalamic loop, through substantial connections both with the accumbens nucleus and medial caudate, and with the mediodorsal and paraventricular thalamic nuclei, which normally function to guide and limit responses to stress. Finally, the medial prefrontal network is a central node in the cortical “default mode network” (DMN) that putatively supports self-referential functions such as mood. Other abbreviations: 5-HT—serotonin; ACh—acetylcholine; Cort.—cortisol; CRH—corticotrophin releasing hormone; Ctx—cortex; NorAdr—norepinephrine; PVN—paraventricular nucleus of the hypothalamus; PVZ—periventricular zone of hypothalamus; STGr—rostral superior temporal gyrus; VTA—ventral tegmental area.

REGIONS WITH EXTENSIVE CONNECTIONS TO MULTIPLE NETWORKS (AREA 45a AND 47s)

Area 45a in the caudal-ventral PFC represents an exception to the dorsal, ventral, and caudal systems of the LPFC. Injections of axonal tracers into this area label connections with areas in all parts of the LPFC. The extrinsic connections resemble those of the dorsal and medial prefrontal systems, but also include the auditory parabelt and belt areas, as well as face areas in the ventral STS. Responses to both faces and species-specific auditory stimuli have been recorded in this region (Romanski, 2007; Tsao et al., 2008). Conceivably this region may represent a multimodal cortex that also is connected to circuits responsible for emotional processing.

AREA 12o/47s

Another area that appears to subserve a similar multimodal processing role with a strong link to emotional processing is area 12o/47s. In monkeys Walker designated the lateral orbitofrontal cortex as area 12, and four subdivisions subsequently

were recognized within this cortex. Brodmann, however, designated approximately the same region in humans as area 47. Because the human area equivalent to the “orbital” part of area 12 (12o) in monkeys is not on the orbital surface but instead lies on the dorsal surface of the lateral orbital gyrus within the horizontal ramus of the lateral sulcus, this region was termed the sulcal part of area 47 (47s). Area 12o/47s shares extensive anatomical connections with several of the regions located on the medial wall (e.g., areas 25, 32pl, 24b, 10m) and in the anterior agranular insula (Iai) that form the medial prefrontal network. Area 12o/47s also projects to visceral control centers in the hypothalamus and periaqueductal gray, and receives auditory or polymodal input from the superior temporal sulcal region similar to the medial prefrontal network (reviewed in Öngür and Price, 2000). Thus area 12o/47s is considered part of the medial prefrontal network that subserves a “visceromotor” or “emotomotor” system that modulates visceral activity in response to affective stimuli. For example, the area corresponding to 47s coactivates within the subgenual ACC during induced sadness (Mayberg et al., 1999). Nevertheless, area

12o/47s also shares extensive connections with the orbital network, providing an interface between sensory integration and emotional expression (Öngür and Price, 2000).

CORTICAL PROJECTIONS TO HYPOTHALAMUS AND BRAINSTEM

Substantial outputs exist from the medial prefrontal network to the hypothalamus, PAG, and other visceral control centers, with the strongest projection from the subgenual cortex (Öngür and Price, 2000; Price and Drevets, 2010). The origin of the projection includes the STGr/STSd and area 9 in the DPFC, which are both connected to the medial network. Electrical stimulation of the medial PFC cause changes in heart rate and respiration, and fMRI studies show that activity in medial PFC correlates with visceral activation related to emotion (reviewed in Price and Drevets, 2010).

Lesions of the VMPFC in humans abolish the automatic visceral response to emotive stimuli (Bechara et al., 2000). Individuals with these lesions also are debilitated in terms of their ability to make appropriate choices, although their cognitive intelligence is intact. To account for such deficits, the “somatic marker hypothesis” proposes that the visceral reaction accompanying emotion serves as a subconscious warning of disadvantageous behaviors (Damasio, 1995). The full basis for this effect is complex, presumably involving the visceral reactions (e.g., sweaty palms, “butterflies” in the gut, etc.), subconscious “as-if” circuits, and circuits such as the cortical-striatal-pallidal-thalamic system. In mood disorders, overactivation of this system (e.g., due to excessive activity in the subgenual cortex) could produce the chronic sense of “unease” that is a common experiential component of depression.

CORTICAL-STRIATAL-THALAMIC CIRCUITS RELATED TO OMPFC

Like other cortical areas, the PFC has specific connections with the striatum and thalamus. These include reciprocal thalamo-cortical connections with the medial part of the mediodorsal thalamic nucleus (MDm). Closely related to these is the cortical-striatal-pallidal-thalamic loop through the ventromedial striatum and connections between the midline thalamic nuclei and the same striatal and cortical areas (Öngür and Price, 2000; Price and Drevets, 2010) (Figs. 34.3, 34.4, and 34.5).

MEDIAL SEGMENT OF MEDIODORSAL THALAMIC NUCLEUS

MDm receives substantial subcortical inputs from many limbic structures, including the amygdala, olfactory cortex, entorhinal cortex, perirhinal cortex, parahippocampal cortex, and subiculum (Öngür and Price, 2000). All of these areas also send direct (non-thalamic) projections to the OMPFC (Öngür and Price, 2000).

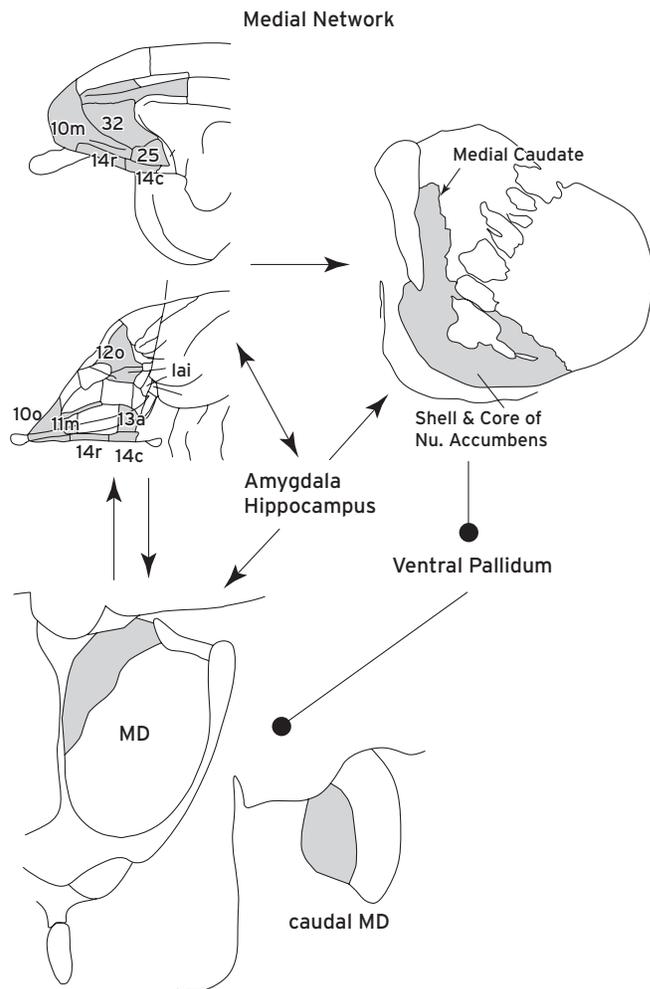

Figure 34.4 Illustration of the cortical-striatal-pallidal-thalamic loop related to the medial prefrontal network. Note that limbic structures such as the amygdala and hippocampus are also related to several parts of this circuit.

In addition to these inputs from limbic structures, which are excitatory and probably glutamatergic, MDm also receives GABAergic inputs from the ventral pallidum and rostral globus pallidus (Öngür and Price, 2000) (Figs. 34.3 and 34.4). It can be expected that these convergent but antagonistic inputs would interact to modulate the reciprocal thalamocortical interactions between the OMPFC and MDm. Limbic inputs would promote ongoing patterns of thalamocortical and corticothalamic activity and consistent behavior, while pallidal inputs would interrupt ongoing patterns, allowing a switch between behaviors involving mood, value assessment of objects, and stimulus-reward association. Indeed, lesions of the ventral striatum and pallidum, MD, or the OMPFC have been shown to cause perseverative deficits in stimulus-reward reversal tasks in rats and monkeys, where there is difficulty extinguishing responses to previously rewarded (Ferry et al., 2000). A similar deficit in subjects with mood disorders might be reflected by the difficulty in “letting go” of a negative mood or mind-set long after the resolution of any traumatic events that might have justified it.

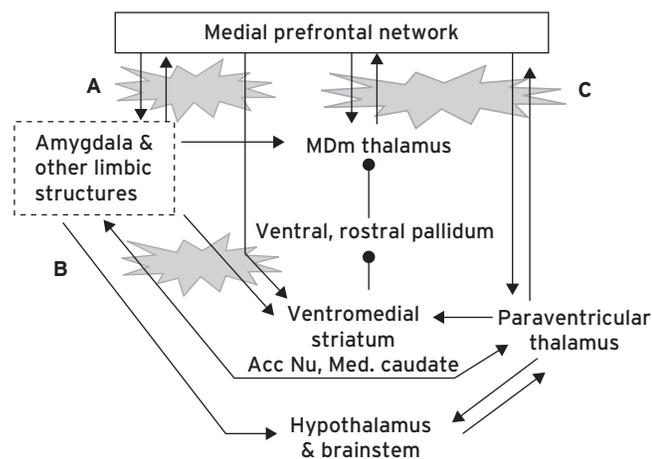

Figure 34.5 A diagrammatic illustration of the cortical-striatal-pallidal-thalamic loop circuit, involving the medial prefrontal network and the amygdala, together with the ventromedial striatum (nucleus accumbens and medial caudate nuclei), the ventral and rostral globus pallidus, and the medial part of the mediodorsal thalamic nucleus (MDm). The midline paraventricular thalamic nucleus also has prominent connections with the medial network, the ventromedial striatum, and the amygdala, as well as with the hypothalamus and brainstem. The substantial connections from the medial network to the hypothalamus and brainstem are not shown in this figure. The shaded clouds depict areas where the targeted neuromodulation and neurosurgical treatments that have shown benefit in treatment-refractory depression would putatively influence white matter tracts within these circuits. A. Deep brain stimulation of the subgenual anterior cingulate (sgACC; Mayberg et al., 2005) and stereotaxic surgical ablations such as the anterior cingulotomy and prefrontal leukotomy would influence neural afferents and efferents of the sgACC as well as some projections running within the ventral cingulum bundle, thereby modulating or interrupting neurotransmission between the medial prefrontal network and the striatum, the amygdala and other limbic structures, as well as the hypothalamus, PAG, and brainstem structures. B. Deep brain stimulation of the ventral capsule/ventral striatum (Malone et al., 2009) and stereotaxic surgical ablations such as the subcaudate tractotomy would influence neural afferents to the ventral striatum emanating from the sgACC and other medial prefrontal network regions (Fig. 34.3) as well as from the amygdala and other limbic structures. C. Deep brain stimulation (Schlaepfer et al., 2008) or surgical lesions (i.e., anterior capsulotomy) administered within the anterior limb of the internal capsule would influence neural projections running between the medial prefrontal network and the mediodorsal thalamic nucleus. (Modified from Price and Drevets, 2012.)

PREFRONTAL PROJECTIONS TO THE STRIATUM

The OMPFC projects principally to the rostral, ventromedial part of the striatum. The orbital network areas connect to a relatively central region that spans the internal capsule, while the medial network areas project to the nucleus accumbens and the rostromedial caudate nucleus (Öngür and Price, 2000) (Fig. 34.4). The amygdala input to the striatum is essentially coextensive with that of the medial network. These striatal regions, in turn, project to the ventral pallidum, which projects to the portion of MDm that is connected to the medial network areas (Fig. 34.4).

MIDLINE “INTRALAMINAR” NUCLEI OF THALAMUS

In addition to the prefrontal connections with MD, there also are connections with the midline-intralaminar nuclei of the

thalamus, which include the paraventricular thalamic nucleus (PVT), and nuclei that extend ventrally on the midline. These nuclei are reciprocally connected to the medial prefrontal network areas, with little connection to the orbital network, and they have a substantial projection to the same areas of the ventromedial striatum that receives input from the medial network areas (Hsu and Price, 2007) (Fig. 34.4). They also have connections with the amygdala, hypothalamus, and brainstem areas, including the PAG (Fig. 34.3).

Considerable evidence links the PVT to the stress response. In particular, lesions of the PVT facilitate central amygdala neuronal responses to acute psychological stressors and block habituation to repeated restraint stress in rats (Bhatnagar et al., 2002). In humans, habituation to the stress response caused by recurrent hypoglycemia is associated with activity in the midline thalamus (reviewed in Price and Drevets, 2012). It is likely that the role of the PVT is general across many types of stressors.

OVERVIEW OF RECENT OBSERVATIONS IN HUMANS WITH MOOD DISORDERS

Converging evidence from neuroimaging and lesion analysis studies of mood disorders implicates the medial and orbital prefrontal networks along with anatomically related areas of the striatum, thalamus, and temporal lobe previously described in the pathophysiology of depression. Depressed subjects show abnormal hemodynamic responses in both networks during fMRI studies involving reward and emotional processing tasks (reviewed in Murray et al., 2010; Phillips et al., 2008). In addition, however, many of the prefrontal regions that compose the medial network and of the areas of convergence between the medial and orbital networks (i.e., BA 45a, 47s) contain reductions in gray matter and histopathological changes in neuroimaging and/or neuropathological studies of mood disorders. These data support extant neural models of depression positing that dysfunction within the medial network and anatomically related limbic and basal ganglia structures underlies the disturbances in cognition and emotional behavior seen in depression.

NEUROIMAGING ABNORMALITIES IN MOOD DISORDERS

The neuroimaging abnormalities found in mood disorders generally have corroborated hypotheses regarding the neural circuitry of depression that were based initially on observations from the behavioral effects of lesions. Degenerative basal ganglia diseases and lesions of the striatum and orbitofrontal cortex increased the risk for developing major depressive episodes (Folstein et al., 1985; MacFall et al., 2001; Starkstein and Robinson, 1989). Because these neurological disorders affect synaptic transmission through limbic-cortical-striatal-pallidal-thalamic circuits in diverse ways, it was hypothesized that multiple types of dysfunction within these circuits can produce depressive symptoms.

BRAIN STRUCTURAL ABNORMALITIES IN MOOD DISORDERS

Structural abnormalities found in the population of individuals with mood disorders can be distinguished broadly with respect to the age at illness-onset of the sample being considered. Patients with early-onset mood disorders (i.e., first mood episode arising within the initial four to five decades of life) manifest neuromorphometric abnormalities that appear relatively selective for areas within the OMPFC and anatomically related structures within the temporal lobe, striatum, thalamus, and posterior cingulate (reviewed in Price and Drevets, 2010). Cases with affective psychoses also have been differentiated from controls by gray matter loss within the OMPFC (Coryell et al., 2005; MacFall et al., 2001). In contrast, elderly subjects with late-onset depression (i.e., first mood episode arising later than the fifth decade of life) show a higher prevalence of neuroimaging correlates of cerebrovascular disease relative both to age-matched healthy controls and to elderly depressives with an early age at depression-onset (Drevets et al., 2004). MDD and BD cases that have either psychotic features or late-life illness-onset show nonspecific signs of atrophy, such as lateral ventricle enlargement.

Within the OMPFC a relatively consistent abnormality reported in early onset MDD and BD has been a reduction in gray matter in *left* subgenual anterior cingulate cortex (sgACC). This volumetric reduction exists early in illness and in young adults at high familial risk for MDD, yet shows progression in longitudinal studies in samples with psychotic mood disorders (reviewed in Price and Drevets, 2010). Moreover, individuals with more chronic or highly recurrent illness show greater volume loss than those who manifest sustained remission (Fig. 34.6) (Salvadore et al., 2011). The abnormal reduction in

sgACC volume primarily has been identified in mood disordered subjects with evidence for familial aggregation of illness (Hirayasu et al., 1999; Koo et al., 2008; McDonald et al., 2004), suggesting that genetic factors that increase risk for the development of depression also affect neuroplasticity within this region (e.g., Pezawas et al., 2005).

The subgenual cortex areas implicated by volumetric MRI or postmortem neuropathological studies of mood disorders include both the infralimbic cortex (BA 25; e.g. Coryell et al., 2005) and the adjacent sgACC corresponding to BA 24sg (e.g., Drevets et al., 1997; Öngür et al., 1998; Öngür et al., 2003)]. Reductions in gray matter also have been identified consistently in PFC regions that share extensive connectivity with this portion of the medial prefrontal network, such as the BA 47s cortex in BD (Lyo et al., 2004; Nugent et al., 2006) and BA 45a area of VLPFC in MDD (Bowen et al., 1989), as well as in the caudal orbitofrontal cortex (BA 11), frontal polar/dorsal anterolateral PFC (BA 9,10), hippocampus, parahippocampus and temporopolar cortex in MDD, and in the superior temporal gyrus and amygdala in BD (Coryell et al., 2005; Lyo et al., 2004; Nugent et al., 2006; Price and Drevets, 2010). Finally, the pituitary and adrenal glands appear enlarged in MDD (Drevets, Gadde et al., 2004; Krishnan et al., 1991), consistent with other evidence that hypothalamic-pituitary-adrenal axis activity is elevated in mood disorders.

Discrepant results exist across studies, conceivably reflecting clinical and etiological heterogeneity extant within the MDD and BD syndromes. For example, in the hippocampus one study reported that reduced volume was limited to depressed women who suffered early-life trauma (Vythilingam et al., 2002), while others reported that hippocampal volume

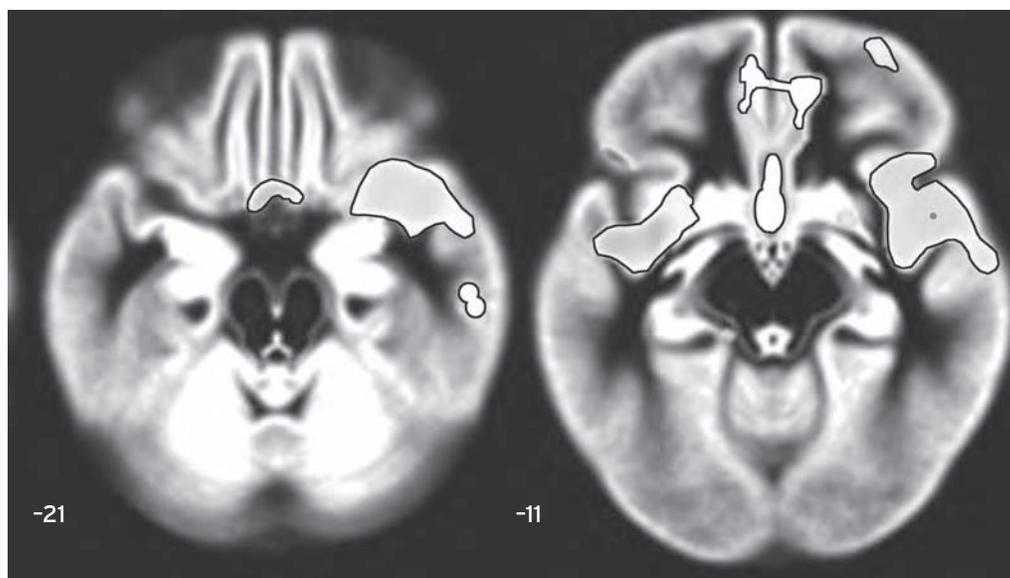

Figure 34.6 Regions where gray matter volume was reduced in unmedicated, currently depressed subjects with major depressive disorder ($N = 58$) compared to unmedicated, currently remitted MDD subjects ($N = 27$). The mean time spent in the current major depressive episode for the former group was about four years, and the mean time spent in remission for the latter group was over three years. The depressed group showed reduced gray matter relative to the remitted group in the subgenual and ventromedial prefrontal cortices and the rostral temporal cortex, a pattern that resembles that depicting the density of amygdala projections to the cortex in Fig. 34.1. Results are superimposed on axial slices of the average gray matter map of the 192 subjects participating in this study. The axial slices are located at 21 mm and 11 mm ventral to the bicommissural plane. (Modified from Salvadore et al., 2011.)

correlated inversely with time spent depressed and unmedicated (e.g., Sheline et al., 2003). In addition, the amygdala volume appears abnormally smaller in unmedicated BD subjects, but larger in BD subjects receiving mood stabilizing treatments associated with neurotrophic effects in experimental animals (Savitz et al., 2010).

NEUROPATHOLOGICAL CORRELATIONS WITH NEUROIMAGING ABNORMALITIES

The structural imaging abnormalities found in mood disorders have been associated with histopathological abnormalities in postmortem studies. Such studies report reductions in gray matter volume, thickness, or wet weight in the sgACC, parts of the orbital cortex, and accumbens (reviewed in Price and Drevets, 2010), and greater decrements in volume following fixation (implying a deficit in neuropil) in the hippocampus (Stockmeier et al., 2004) in MDD and/or BD subjects relative to controls. The histopathological correlates of these abnormalities include reductions in glia with no equivalent loss of neurons, reductions in synapses or synaptic proteins, and elevations in neuronal density, in MDD and/or BD samples in the sgACC, and of glial cell counts and density in the pgACC, dorsal anterolateral PFC (BA9), and amygdala (reviewed in Price and Drevets, 2010). The density of non-pyramidal neurons also appears decreased in the ACC and hippocampus in BD (Benes et al., 2001; Todtenkopf et al., 2005) and in the dorsal anterolateral PFC (BA9) in MDD (Rajkowska et al., 2007). Reductions in synapses and synaptic proteins were evident in BD subjects in the hippocampal subiculum/ventral CA1 region, which receives abundant projections from the sgACC (reviewed in Price and Drevets, 2010). Subjects with MDD studied postmortem also manifested dysregulation of synaptic function/structure related genes in the hippocampus and dalPFC, and with a corresponding lower number of synapses in the dorsolateral PFC (Duric et al., 2013; Kang et al., 2012). Notably, Kang et al. (2012) additionally identified a transcriptional repressor, GATA1, that was overexpressed in the dalPFC of MDD subjects, and that when expressed in PFC neurons is sufficient to decrease the expression of synapse-related genes, cause loss of dendritic spines and dendrites, and produce depressive behavior in rat models of depression.

The glial cell type implicated most consistently is the oligodendrocyte (reviewed in Price and Drevets, 2010). The concentrations of oligodendroglial gene products, including myelin basic protein, are decreased in frontal polar cortex (BA 10) and middle temporal gyrus in MDD subjects versus controls, potentially compatible with reductions in white matter volume of the corpus callosum genu and splenium found in MDD and BD. Perineuronal oligodendrocytes also are implicated in mood disorders by electron microscopy and reduced gene expression levels in PFC tissue. Perineuronal oligodendrocytes are immunohistochemically reactive for glutamine synthetase, suggesting they function like astrocytes to take up synaptically released glutamate for conversion to glutamine and cycling back into neurons.

CORRELATIONS WITH RODENT MODELS OF CHRONIC AND REPEATED STRESS

In regions that appear homologous to areas where gray matter reductions are evident in depressed humans (i.e., medial PFC, hippocampus) repeated stress results in dendritic atrophy and dysregulation of synaptic function/structure related gene expression, and these effects can be reversed at least partly by antidepressant drug administration (Banasr and Duman, 2007; Czeh et al., 2006; Duric et al., 2013; McEwen and Magarinos, 2001; Radley et al., 2008; Wellman, 2001). Dendritic atrophy putatively would be observed as a decrease in gray matter volume (Stockmeier et al., 2004). Moreover, both repeated stress and elevated glucocorticoid concentrations impair the proliferation of oligodendrocyte precursors in rodents, leading to reductions in oligodendroglial cell counts (Alonso, 2000; Banasr and Duman, 2007). In rats the stress-induced dendritic atrophy in the medial PFC was associated with impaired modulation of behavioral responses to fear-conditioned stimuli (Izquierdo et al., 2006), suggesting this process can alter emotional behavior.

The similarities between the histopathological changes that accompany stress-induced dendritic atrophy in rats and those found in humans suffering from depression suggest the hypothesis that homologous processes underlie the neuropathological changes in the hippocampal and medial PFC in both conditions (McEwen and Magarinos, 2001). Stress-induced dendritic remodeling depends on interactions between *N*-methyl-*D*-aspartate (NMDA) receptor stimulation and glucocorticoid secretion (McEwen and Magarinos, 2001). Notably, the depressive subgroups that show reductions in regional gray matter volume also show evidence of having elevated glutamatergic transmission in the same regions together with increased cortisol secretion (Drevets et al., 2002b). For example, cerebral glucose metabolism largely reflects energetic requirements associated with glutamatergic transmission (Shulman et al., 2004), raising the possibility that excitatory amino acid transmission contributes to the neuropathology of mood disorders (Paul and Skolnick, 2003). Elevated glutamatergic transmission in discrete anatomical circuits may explain the targeted nature of gray matter changes in depression (e.g., selectively affecting *left* sgACC) (Drevets and Price, 2005; McEwen and Magarinos, 2001; Shansky et al., 2009).

INTERRELATIONSHIP BETWEEN FUNCTIONAL AND STRUCTURAL NEUROIMAGING IN DEPRESSION

The co-occurrence of increased glucose metabolism and decreased gray matter within the same regions in mood disorders has been demonstrated most consistently by comparing image data from depressed patients before versus after treatment (e.g., Drevets et al., 2002a) and from remitted patients scanned before versus during depressive relapse (Hasler et al., 2008; Neumeister et al., 2004). In resting metabolic images in contrast, the reduction in gray matter volume in some structures appears sufficiently prominent to produce partial volume

effects due to their relatively low spatial resolution of functional brain images. Notably, in some depressed samples the resting metabolism appears *reduced* in the sgACC relative to healthy controls, while in contrast, other studies reported increased metabolic activity in the sgACC in primary or secondary depression, suggesting that these apparent discrepancies may be explained by differing magnitudes of gray matter loss across samples (reviewed in Drevets et al., 2008). Consistent with this hypothesis, in MDD and BD samples who show abnormal reductions of both gray matter volume and metabolism in the sgACC (Drevets et al., 1997), correction of the metabolic data for partial volume (atrophy) effects reveals that metabolism is *increased* in the sgACC in the depressed phase, and decreases to normative levels with antidepressant treatment. This finding is consistent with evidence that the sgACC metabolism decreases during *symptom-remission* induced by a variety of antidepressant treatments (Drevets et al., 1997, 2002a; Holthoff et al., 2004; Mayberg et al., 2000), including electroconvulsive therapy (Nobler et al., 2001) and deep brain stimulation (Mayberg et al., 2005).

EMOTIONAL PROCESSING IN THE MEDIAL PREFRONTAL NETWORK

The sgACC participates generally in the experience and/or regulation of dysphoric emotion. In non-depressed subjects

the hemodynamic activity increases in the sgACC during sadness induction, exposure to traumatic reminders, selecting sad or happy targets in an emotional go/no-go study, monitoring of internal states in individuals with attachment-avoidant personality styles, and extinction of fear-conditioned stimuli (reviewed in Price and Drevets 2010). Moreover, enhanced sgACC activity during emotional face processing predicted inflammation-associated mood deterioration in healthy subjects under typhoid vaccine immune challenge (Harrison et al., 2009). Finally remitted MDD subjects show decreased coupling between the hemodynamic responses of the sgACC, rostral superior temporal gyrus, hippocampus, and medial frontal polar cortex during guilt (self-blame) versus indignation (blaming others) (Green et al., 2010) (Fig. 34.7).

The ventral pgACC and vmPFC situated anterior to the sgACC have been implicated in healthy subjects in reward processing, and conversely in depressed subjects, in anhedonia (inability to experience pleasure in or incentive to pursue previously rewarding activities). In healthy humans the BOLD activity in this region correlates positively to ratings of pleasure or subjective pleasantness in response to odors, tastes, water in fluid-deprived subjects, and warm or cool stimuli applied to the hand, and the ventral pgACC shows activity increases in response to dopamine-inducing drugs and during preference judgments (reviewed in Wacker et al., 2009). Conversely in depressed subjects this region showed reduced BOLD activity during reward-learning and higher resting EEG delta current

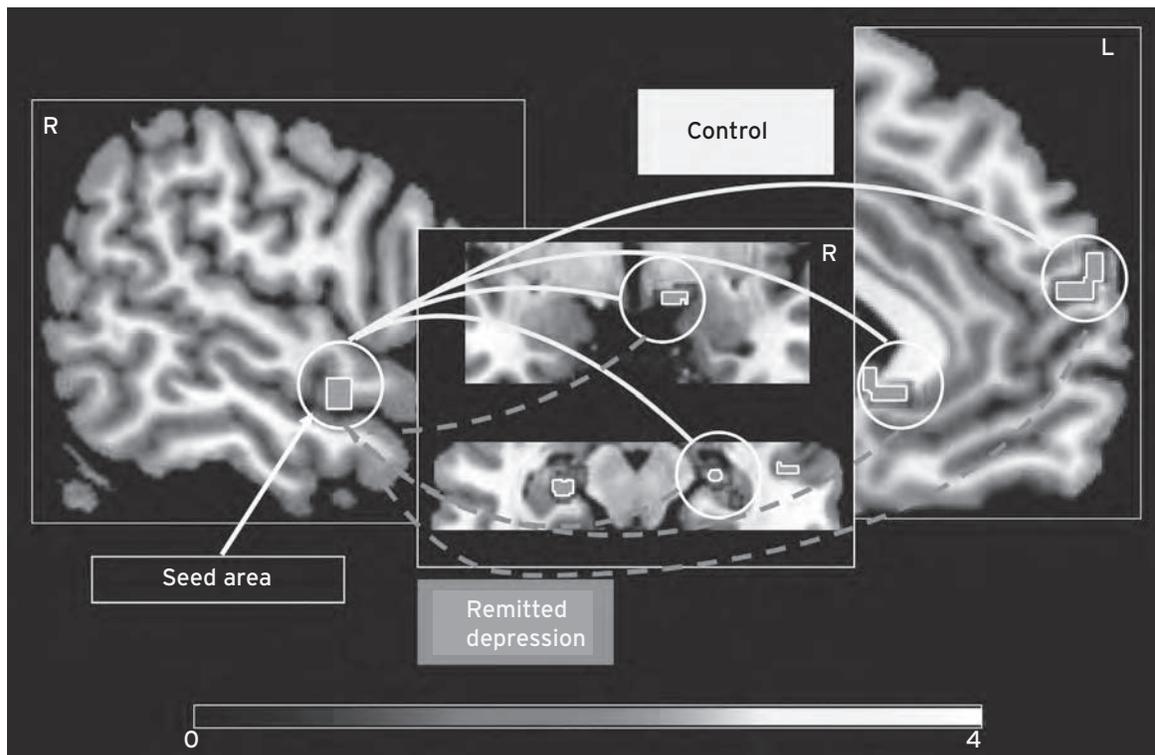

Figure 34.7 Regions showing decreased coupling with the right superior temporal gyrus during the experience of guilt versus indignation in individuals with remitted MDD compared with healthy controls, including the lateral hypothalamus, hippocampus, medial frontal polar cortex, and subgenual anterior cingulate cortex/septal region. The shaded bar depicts voxel t-values, computed using Statistical Parametric Mapping (SPM) software. (Modified from Green et al., 2010.)

density (putatively corresponding to decreased resting neural activity) in association with anhedonia ratings (Wacker et al., 2009).

More dorsal regions of the pgACC show physiological responses to diverse types of emotionally valenced or autonomically arousing stimuli. *Higher activity* in the pgACC holds *positive prognostic significance* in MDD, as depressives who improve during antidepressant treatment show abnormally elevated pgACC metabolism, MEG, and EEG activity *prior to treatment* relative to treatment-non-responsive cases or healthy controls (Pizzagalli, 2011).

Moreover, in the supragenual ACC depressed subjects show attenuated BOLD responses versus controls while recalling autobiographical memories (Young et al., 2012), associated with lower subjective arousal ratings experienced during memory recall. Behaviorally, MDD subjects are impaired at generating specific autobiographical memories, particularly when cued by positive words. These deficits were associated with reduced activity in the hippocampus and parahippocampus (Young et al., 2012).

Notably, preclinical evidence indicates that distinct medial prefrontal network structures are involved in opponent

processes with respect to emotional behavior (Vidal-Gonzalez et al., 2006). Regions where metabolism correlates positively with depression severity include the sgACC and ventromedial frontal polar cortex; metabolism increases in these regions in remitted MDD cases who experience depressive relapse under catecholamine or serotonin depletion (Hasler et al., 2008; Neumeister et al., 2004) (Fig. 34.8). In contrast, the VLPFC/lateral orbital regions that include BA45a, BA47s and the lateral frontal polar cortex show inverse correlations with depression severity, suggesting they play an adaptive or compensatory role in depression (reviewed in Price and Drevets, 2010).

FUNCTIONAL IMAGING OF LIMBIC STRUCTURES ASSOCIATED WITH THE MEDIAL NETWORK

Subcortical structures that share extensive connections with the medial prefrontal network also show correlations to depressive symptoms. In the accumbens area the elevation of metabolism under catecholamine depletion correlates positively with the corresponding increment in anhedonia ratings (Fig. 34.8). In

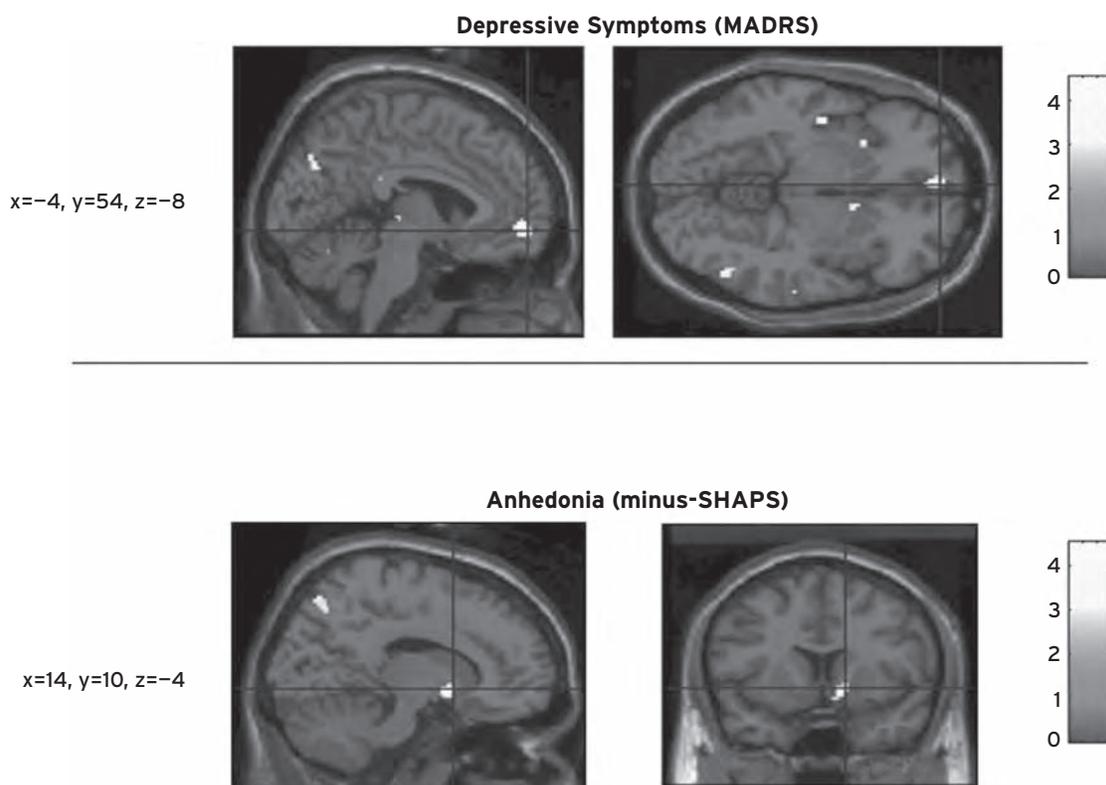

Figure 34.8 Statistical parametric mapping image sections illustrating catecholamine depletion (CD)-induced metabolic changes and correlations between associated depressive symptoms and regional metabolism displayed on an anatomical MRI brain image in the voxel-wise analyses in a combined group of healthy controls and unmedicated individuals with major depressive disorder in remission (who are prone to develop depressive symptoms under CD produced via alpha-methyl-para-tyrosine administration). Upper Panel: Area where changes in metabolism correlated with CD-induced depressive symptoms (rated using the Montgomery-Asberg Depression Rating Scale) in the ventromedial frontal polar cortex, as shown by voxel t-values corresponding to $p < 0.001$ in the correlational analysis. Lower Panel: Area where glucose metabolism correlated with CD-induced anhedonia (rated by negative scores from the Snaith-Hamilton Pleasure Scale) in the right accumbens, shown as voxel t-values corresponding to $p < 0.005$. Coordinates corresponding to the horizontal and vertical axes are listed to the left of each image set, and correspond to the stereotaxic array of Talairach and Tournoux (1988) with the distance denoted in mm from the anterior commissure, with positive x = right of midline, positive y = anterior to the anterior commissure, and positive z = dorsal to a plane containing both the anterior and the posterior commissures. The gray shaded bars indicate voxel t values. (Reproduced by permission from Hasler et al., 2008.)

addition, fMRI studies show that hemodynamic responses of the ventral striatum to rewarding stimuli are decreased in depressives versus controls, and that higher levels of anhedonia are associated with blunted ventral striatal responses to rewarding stimuli in both healthy and depressed subjects (reviewed in Treadway and Zald, 2011). Furthermore, during probabilistic reversal learning, depressed subjects showed impaired reward (but not punishment) reversal accuracy in association with attenuated ventral striatal BOLD response to unexpected reward (Robinson et al, 2012).

In the amygdala glucose metabolic abnormalities appear more selective for depressive subgroups. In the left amygdala, metabolism increased during tryptophan depletion-induced relapse only in MDD subjects homozygous for the long allele of the 5HTT-PRL polymorphism (Neumeister et al., 2006b). In addition, elevated resting amygdala metabolism was reported specifically in depressed subjects classified as BD-depressed, familial pure depressive disease (FPDD), or melancholic subtype (reviewed in Price and Drevets, 2010). These subgroups also shared the manifestation of hypersecreting cortisol under stress, which is noteworthy here because the amygdala plays a major role in driving the stressed component of cortisol release (Drevets et al., 2002). In contrast, task-based hemodynamic responses of the amygdala show a pattern of abnormalities reflecting negative emotional processing biases in depression that appear more generalizable across depressed samples.

FUNCTIONAL NEUROIMAGING CORRELATES OF NEGATIVE EMOTIONAL PROCESSING BIAS IN MDD

Depressed individuals bias stimulus processing toward sad information as evidenced by enhanced recall for negatively versus positively valenced information on memory tests, greater interference from depression-related negative words versus happy or neutral words on emotional stroop tasks, faster responses to sad versus happy words on affective attention shifting tasks and more negative interpretation of ambiguous words or situations (reviewed in Victor et al., 2010). This bias also is evident in neurophysiological indices. Depressed subjects show exaggerated hemodynamic responses of the amygdala to sad words, explicitly or implicitly presented sad faces, and backwardly masked fearful faces, but blunted responses to masked happy faces (Suslow et al., 2010; Victor et al., 2010). A similar pattern of abnormal amygdala responses to masked sad and happy faces is observed in *unmedicated*-remitted subjects with MDD (Neumeister et al., 2006a; Victor et al., 2010) suggesting this abnormality is trait-like. Conversely, antidepressant drug administration shifts emotional processing biases toward the positive direction in both healthy and MDD samples (Geddes et al., 2003; Harmer, 2008; Victor et al., 2010). This shift is in the normative direction, as healthy subjects show a positive attentional bias (Erickson et al., 2005; Sharot et al., 2007; Victor et al., 2010) as well as greater amygdala responses to masked happy versus sad faces (Killgore and Yurgelun-Todd, 2004; Victor et al., 2010).

Taken together these data indicate that both the normative *positive* processing bias in healthy individuals and the pathological *negative* processing bias in MDD occur automatically, below the level of conscious awareness, and are mediated at least partly by rapid, non-conscious processing networks involving the amygdala (Victor et al., 2010). The differential response to masked-sad versus masked-happy faces in the amygdala is associated with concomitant alterations in the hemodynamic responses of the hippocampus, superior temporal gyrus, anterior insula, pgACC, and anterior orbitofrontal cortex (Victor et al., 2010). These regions may participate in setting a context or in altering reinforcement contingencies that conceivably may underlie these biases in MDD.

Similarly, during probabilistic reversal learning depressed MDD subjects showed exaggerated behavioral sensitivity to negative feedback versus controls, in association with blunted BOLD activity in the dorsomedial and ventrolateral PFC during reversal shifting, and absence of the normative deactivation of the amygdala in response to negative feedback (Taylor Tavares et al., 2008). Disrupted top-down control by the PFC over the amygdala thus may result in the abnormal response to negative feedback observed in MDD (Murphy et al., 1999).

IMPLICATIONS FOR NEUROCIRCUITRY-BASED MODELS OF DEPRESSION

Within the larger context of the limbic-cortical-striatal-pallidal-thalamic circuits implicated in the pathophysiology of depression, the basic science literature regarding specific limbic-cortical circuits involving the medial prefrontal network hold clear functional implications to guide translational models. The anatomical projections from the medial prefrontal network to the amygdala, hypothalamus, PAG, locus coeruleus, raphe, and brainstem autonomic nuclei play major roles in organizing the visceral and behavioral responses to stressors and emotional stimuli (Davis and Shi, 1999; LeDoux, 2003) (Fig. 34.4). In rats lesions of the medial PFC enhance behavioral, sympathetic, and endocrine responses to stressors or fear-conditioned stimuli organized by the amygdala (Morgan and LeDoux, 1995; Sullivan and Gratton, 1999). Nevertheless, these relationships appear complex, as stimulation of the amygdala inhibits neuronal activity in the mPFC, and stimulation of infralimbic and prelimbic projections to the amygdala excites intra-amygdaloid GABA-ergic cells that respectively inhibit or excite neuronal activity in the central amygdaloid nucleus (ACe) (Garcia et al., 1999; Likhtik et al., 2005; Perez-Jarany and Vives, 1991; Vidal-Gonzalez et al., 2006).

For example, the amygdala mediates the *stressed component* of glucocorticoid hormone secretion by disinhibiting CRF release from the hypothalamic paraventricular nucleus (Herman and Cullinan, 1997). Moreover, lesions in the ventral ACC thus increase ACTH and CORT secretion during stress in rats, suggesting that the glucocorticoid response to stress is inhibited by stimulation of glucocorticoid receptors (GR) in this cortex (Diorio et al., 1993). Similarly, in

monkeys Jahn et al. (2010) showed that PET measures of the subgenual PFC metabolism consistently predicted individual differences in plasma cortisol concentrations across a range of contexts that varied in stress load. It thus is conceivable that in humans with mood disorders dysfunction within the medial prefrontal network would disinhibit the efferent transmission from the ACe and BNST to the hypothalamus, contributing to elevated stressed cortisol secretion (Price and Drevets, 2010). Compatible with this hypothesis, cortisol hypersecretion in mood disorders has been associated with increased metabolic activity in the amygdala and with reduced gray matter in rostral ACC (Drevets et al., 2002b; Gold et al., 2002; McEwen and Magarinos, 2001; Treadway et al., 2009).

Furthermore, dysfunction of the medial prefrontal network may impair reward learning, potentially contributing to the anhedonia and amotivation manifest in depression. The ACC receives extensive dopaminergic innervation from the VTA and sends projections to the VTA that regulate phasic dopamine (DA) release. In rats, stimulation of these medial PFC areas elicits burst firing patterns in the VTA-DA neurons, while inactivation of the medial PFC converts burst firing patterns to pacemaker-like firing activity (reviewed in Price and Drevets, 2010). The burst firing patterns increase DA release in the accumbens, which is thought to encode information about reward prediction (Schultz et al., 1997). The mesolimbic DA projections from the VTA to the nucleus accumbens shell and the mPFC thus play major roles in learning associations between operant behaviors, or sensory stimuli and reward (Nestler and Carlezon, 2006). If the neuropathological changes in the ACC in mood disorders interfere with the cortical drive on VTA-DA neuronal burst firing activity, they may impair *reward learning*. Compatible with this hypothesis, depressives show attenuated DA release relative to controls in response to unpredicted monetary reward (Martin-Soelch et al., 2008) and fail to develop a response bias toward rewarded stimuli during reinforcement paradigms (reviewed in Treadway and Zald, 2011).

Furthermore, the patterns of physiological activity within the default mode system that involves the medial network are hypothesized to relate to self-absorption or obsessive ruminations (Grimm et al., 2009; Gusnard et al., 2001). In depressed subjects increasing levels of default mode network (DMN) dominance over the putative “task-positive network” (TPN; a group of structures that activate during volitional attention and thought) were associated with higher levels of maladaptive, depressive rumination and lower levels of adaptive, reflective rumination (Hamilton et al., 2011). Crucially, hemodynamic activity increased in the BA47s region in depressed subjects at the onset of increases in TPN activity. It thus was hypothesized that the DMN supports representation of negative, self-referential information in depression, and that activity within the vicinity of BA 47s in conjunction with increased levels of DMN activity may initiate an adaptive engagement of the TPN (Hamilton et al., 2011). Such an adaptive relationship potentially could explain the inverse correlation between depression severity and metabolic activity in BA 47s described previously. Notably, interpersonal psychotherapy, which can reduce depressive symptoms in

MDD, enhanced activity in the vicinity of BA 47s (Brody et al., 2001; Öngür et al., 2003). Cognitive-therapeutic strategies for depression also have been hypothesized to depend on enhancing the function of neural substrates that serve as convergence zones between multiple prefrontal networks, such as BA 47s.

As described earlier, somatic antidepressant treatments also influence activity within the limbic-cortical-striatal-pallidal-thalamic circuitry. Such treatments reduce basal metabolic activity that putatively is pathologically elevated in some limbic and medial prefrontal structures. In addition, however, antidepressant drugs have been shown more specifically to reduce limbic responses to negative or sad stimuli, and in some cases, to additionally enhance such responses to positive stimuli (e.g., Victor et al., 2010). For example, functional imaging studies in depressed humans indicate that metabolism and blood flow decrease in the sgACC/vmPFC in response to chronic treatment with antidepressant drugs, vagus nerve stimulation, or deep brain stimulation of the sgACC or anterior capsule, and activity in the relevant limbic-thalamocortical circuitry also decreases during effective treatment with antidepressant drugs or electroconvulsive therapy (e.g., Mayberg et al., 1999; Mayberg et al., 2005; reviewed in Price and Drevets, 2010). Preliminary reports also indicate that chronic SSRI treatment or deep brain stimulation of the anterior capsule reduces the abnormally elevated metabolism in the accumbens area in MDD or in depression associated with obsessive-compulsive disorder (reviewed in Price and Drevets, 2010). Most notably, the observations that deep brain stimulation (DBS) and neurosurgical lesions placed within the circuits formed by these structures can alleviate treatment refractory depression (TRD) implicate directly the medial prefrontal network and its associated limbic, striatal, and thalamic targets in the mechanisms of antidepressant therapy.

Mayberg et al. (2005) initially demonstrated that DBS applied via electrodes situated in the white matter immediately adjacent to the sgACC produced antidepressant effects in TRD. This site was located in the vicinity of loci where neurosurgically placed lesions had shown efficacy in TRD in association with the prelimbic leukectomy procedure, and also would have involved some white matter tracts interrupted in the anterior cingulotomy procedure (Fig. 34.5). Similarly, Malone et al. (2009) showed that DBS administered within the accumbens area/ventral internal capsule improved depressive symptoms in TRD. This locus targeted by this procedure is in the vicinity of that affected by the subcaudate tractotomy procedure used for TRD. A third site where both DBS and neurosurgical lesions have shown efficacy in TRD is the anterior limb of the internal capsule, an area that had been surgically targeted by the anterior capsulotomy (Schlaepfer et al., 2008). Finally, a fourth site where DBS improved TRD in a single case report is the habenula, an epithalamic structure implicated in the pathophysiology of depression by both preclinical and human neuroimaging studies (Sartorius et al., 2010). Some of the major circuits in which these procedures putatively would modulate or interrupt neurotransmission in mood disorders are depicted in Figure 34.5.

SUMMARY

The results of studies conducted using neuroimaging lesion analysis, and postmortem techniques support models in which the pathophysiology of depression involves dysfunction within an extended network involving the medial prefrontal network and anatomically related limbic, striatal, thalamic, and basal forebrain structures. The abnormalities of structure and function evident within the extended visceromotor network may impair this network's roles in cognitive processes such as reward learning, emotional processing, and autobiographical memory, and may dysregulate visceral, behavioral, and cognitive responses to emotionally salient stimuli and stress, potentially accounting for the disturbances in these domains seen in mood disorders.

DISCLOSURES

Anatomy of Melancholia

K. RANGA RAMA KRISHNAN

ABBREVIATIONS

ACC	anterior cingulate cortex
BDNF	brain-derived neurotrophic factor
COMP	catechol- <i>O</i> -methyltransferase
DLPFC	dorsolateral prefrontal cortex
fMRI	functional magnetic resonance imaging
GABA	glycerol and gamma-aminobutyric acid
MRI	magnetic resonance imaging
OFC	orbitofrontal cortex
PFC	prefrontal cortex

INTRODUCTION

“The first of these ‘Causes,’ which is natural to all, and which no man living can avoid, is old age, which being cold and dry, and of the same quality as melancholy is, must needs cause it.” (Burton, 1638).

Depression is common in later life, which was recognized as early as 1638 by Robert Burton (1638). Interestingly he recognized the brain as the possible anatomical location for depression: “but forasmuch as this malady is caused by precedent imagination, with the appetite, to whom spirits obey, and are subject to those principal parts, the brain must needs primarily be misaffected” (Burton, 1638). Large-scale epidemiological work from Kendler et al. (2002, 2006) suggests that multiple pathways can lead to depression in the elderly. These pathways include a strong vascular component (Fig. 35.1). The vascular pathway is one that some have suggested is critical in the development of depression in the elderly.

The study of depression in late life enables an interesting opportunity to dissect the anatomy of melancholia. This is because genetic factors appear to be less important in late-onset depression than in early-onset depression (Krishnan et al., 1988, Maier et al., 1991) and structural vascular or ischemic changes appear to be of greater importance. This is not a new idea. In 1905, Robert Gaupp, a German psychiatrist, described elderly patients with depression secondary to arteriosclerosis, many with persistent apathy and depressed mood (as quoted by Post [1962]). These early findings were based purely on clinical evidence of cerebral vascular lesions, typically strokes. This type of depression was termed arteriosclerotic depression.

More recently, magnetic resonance imaging (MRI) and other imaging techniques have enabled the *in vivo* depiction of subtle and surprisingly widespread structural brain changes in depressed patients. Early studies by our group using MRI suggested that subcortical ischemic changes are more prevalent in patients with late-onset depression, and these changes may play a role in the pathophysiology of this type of depression (Krishnan et al., 1988). This finding has since been replicated in numerous studies (Coffey et al., 1989, 1990; Greenwald et al., 1998; Steffens et al., 1998). This difference has also been demonstrated by Steffens et al. (1999) in community populations with depressive symptoms, thus extending the finding beyond individuals who meet the criteria for major depression. A recent meta-analysis confirmed the consistent increase in vascular disease in elderly depressed patients (Arnone et al., 2012).

We can therefore use these patients as a model to study the neural substrates of unipolar depression due to the occurrence of naturally occurring lesions that relate to depression. The scientific importance of this possibility is obvious: if vascular lesions in the brains of older individuals lead to secondary depressions with clinical characteristics that are similar to primary depressions, then these sites may provide important clues to the brain sites that are involved in depression in general. Lesions disrupt the mood circuit, and this increases the risk of depression by impairing the formation and alternation of stimulus-reward relationships, and by impairing the effect of negative reinforcement and the ability to handle stress.

In this review, we have focused primarily on the brain aspects of depression, but the relationship between vascular disease and depression is complex and most likely bidirectional (see Fig. 35.2). Thus, vascular disease predisposes to depression, but depression may also heighten the risk for vascular disease and worsen the prognosis of vascular disease. A summary of this line of work can be seen in Jiang et al. (2005).

LOCATION OF LESIONS

The first question that arises is: at what locations in the brain do the lesions that relate to depression occur? Figiel et al. (1991) showed that these lesions were more prevalent in patients with late-onset depression than in those with early-onset depression, and they were located in the frontal cortex and basal ganglia regions. Recent data in a large number of patients has identified

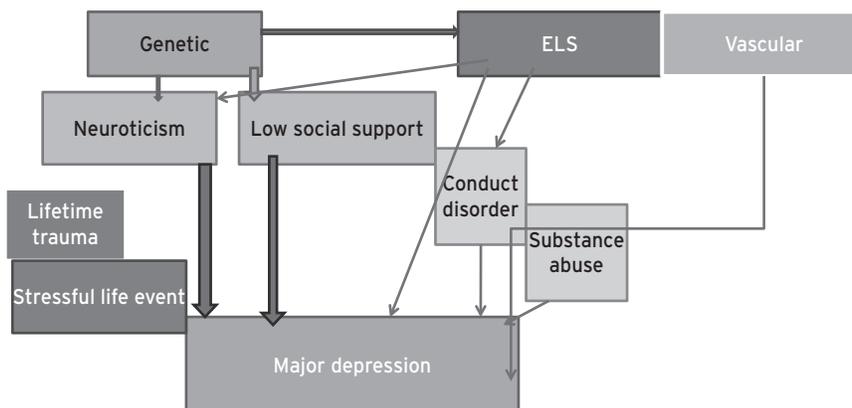

Figure 35.1 Pathways to depression based on large-scale and epidemiological and twin data. Four pathways to depression have been identified: internalizing, externalizing, adversity, and vascular. The basic thrust is that all four pathways to depression lead to structural and functional changes in the neural circuit (described later in text) that lead to risk for depression. Abbreviations: ELS = early life stress. (Simplified and modified from Kendler et al., 2002, 2006.)

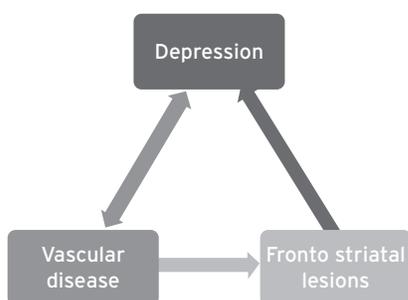

Figure 35.2 Link between vascular disease, lesions, and depression.

the medial orbital prefrontal cortex and the basal ganglia as the regions where the lesions, when present, link to depression (MacFall et al., 2001). This study used statistical parametric mapping to examine the location of lesions in patients and controls to see where the excess lesions were located. Using subtraction mapping, excess lesions were located in the medial orbital frontal cortex and the basal ganglia region.

The next questions that arise are: How do these changes predispose to depression? What neuroanatomical circuits and structural, functional, and biochemical changes are related to the lesions that can lead to depression? Also, what factors lead to the development of these lesions? We will first explore the circuit that affects mood, and then we will explore how these lesions could lead to the development of depression by disrupting the circuit. We will then discuss further the underlying pathophysiology of the lesions.

NEUROANATOMY OF MOOD CIRCUITS

It is not entirely possible to define a mood state in terms of rational, cognitive processes. The mood state, like other emotions, seems to have its own existence in the cognitive state of

the individual, often with a momentum that outlasts any triggers it may have had in rational thought (Saper, 1996). Mood is an internal personal state and is, therefore, anthropomorphic. There are inherent difficulties in studying mood in humans through the study of mood in other species. The motoric expression of emotion is recognized in animals and inferences can be drawn about the underlying basis, but these inferences are based on our human experience. Thus, animal models are limited, but they do enable us to evaluate components—especially motoric, that are consistent across species—permitting us to understand relevant biological processes (Saper, 1996).

A mood state is often defined as an emergent property of forebrain connections that supports cognitive processes. These connections, in turn, project to parts of the limbic cortex from which output functions are derived. The limbic cortex, especially the amygdala, is believed to be involved in the evaluation of emotion (LeDoux, 1992). Outputs from the limbic cortex influence cortical processing (cognitive processing), and also regulate sympathetic, parasympathetic, and motoric expressions through mechanisms regulated by the hypothalamus, brainstem, and ventral striatum. These feed-forward mechanisms are important for the development of the momentum that is a common feature of the continued persistence of a mood alteration.

Mayberg (1997) proposed that three brain systems constitute the neurological substrate of depression: (1) a dorsal attention-cognitive system composed of the prefrontal cortex (PFC), the anterior cingulate, and the inferior parietal area; (2) a ventral vegetative-somatic system composed of the ventral frontal cortex, amygdala, hippocampus, subgenual cingulate, and ventral insula; and (3) a rostral cingulate region that integrates the dorsal and ventral systems. Mayberg (1997) proposed that a reciprocal relationship between the dorsal and ventral system regulates mood: sadness and depression decrease activity in the dorsal system and increase activity in the ventral system, and the remission of depression reverses

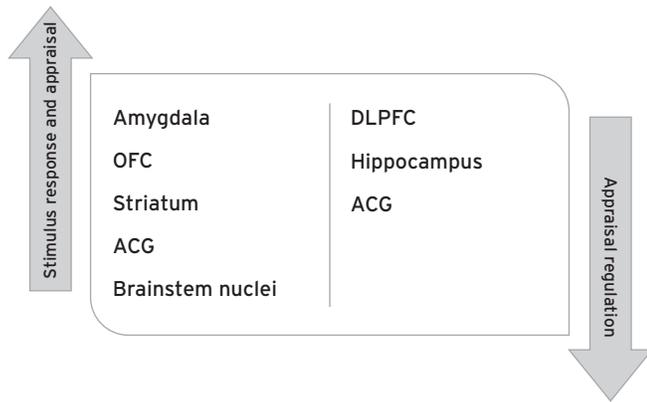

Figure 35.3 Mood circuit. Abbreviations: ACG = anterior cingulate gyrus; DLPFC = dorsolateral prefrontal cortex; OFC = orbitofrontal cortex. (Derived from Phillips et al., 2003a.)

these relationships. Studies using functional MRI (fMRI) support this hypothesis (Drevets and Raichle, 1992; Gemar et al., 1996). In these, the amygdala, posteromedial orbitofrontal cortex, and ventral anterior cingulate were activated by the processing of emotional stimuli, but deactivated during attention-demanding cognitive tasks. Conversely, the dorsolateral prefrontal cortex (DLPFC) and dorsal anterior cingulate were activated by cognitive tasks and deactivated during experimentally induced and pathological emotional states. Studies by Drevets and Raichle (1992) and Gemar et al. (1996) are also supportive of such a reciprocal relationship. Phillips et al. (2003a) proposed a more detailed synthesized model (Fig. 35.3).

Three main processes are important for emotion. These are: (1) evaluation and identification emotional significance of the

stimulus; (2) production of a specific affective state and its attendant behavior in response to the stimulus; and (3) regulation of the affective state and emotional behavior. The latter may involve inhibiting or modulating the first two processes, ensuring that the emotional experience affective state and generated behaviors are contextually appropriate (Phillips, 2003a).

The ventral system is important for the identification of the emotional significance of a stimulus and the production of an affective state, whereas the dorsal system is important for the regulation of the affective states. A reciprocal functional relationship exists between these two neural systems.

LESIONS DISRUPT BRAIN MOOD CIRCUITS

The basic premise is that structural lesions and functional impairments within the components of the ventral neural system are associated with reduced stimulus-reward relationships and motivation, and are biased toward the perception of negative rather than positive emotions, which leads to apathy, depression, and anhedonia under additional socioenvironmental conditions (Fig. 35.4a). Structural lesions and functional impairments within the dorsal neural system, associated with impairments in executive function, can lead to poor regulation of emotional behavior and perpetuate these phenomena (Fig. 35.4b). Depression can also occur through the disruption of the monoamine system that regulates these two systems.

A recent twin study clearly showed that these lesions can produce atrophy and a decrease in frontal lobe metabolism (DeCarli et al., 1995). This study did not evaluate depression, but it showed that these lesions can produce functional and structural changes (DeCarli et al., 1995; Krishnan et al., 1993)

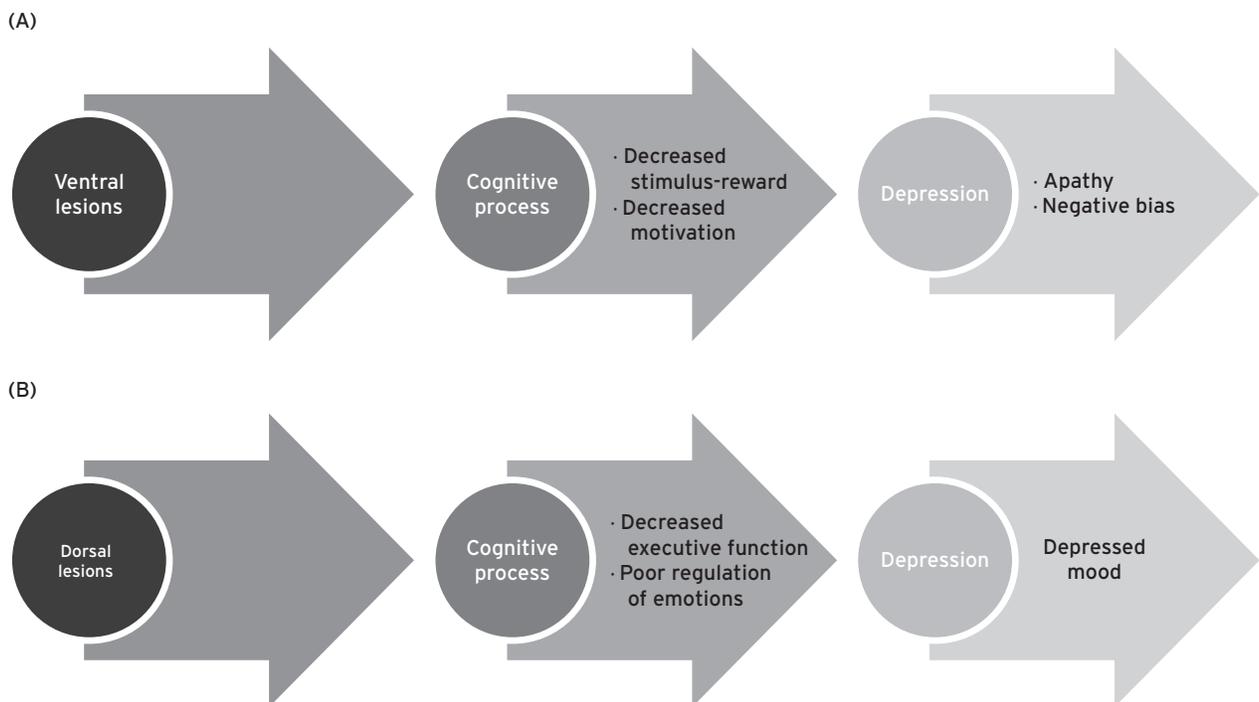

Figure 35.4 Disruption of the mood circuit by lesions in the neural system. (A) Ventral lesions; (B) Dorsal lesions.

Figure 35.5 Pathway for depression secondary to vascular disease.

(Fig. 35.4). Lesions seen in elderly depressed patients are similar to those characterized as of ischemic origin (Taylor et al., 2001). Subcortical vascular disease, silent lacunar infarctions or hyperintense lesions also disrupt prefrontal basal ganglia circuits. These cognitive functions localize to a series of parallel pathways (Tekin and Cummings, 2002) that are tightly segregated, start in the frontal lobe, project to the ventral striatum, pass to the globus pallidus and substantia nigra, and pass through the thalamus back to the frontal lobe. Three of these circuits exhibit behavioral correlates: executive dysfunction (dorsolateral prefrontal circuit), apathy (anterior cingulate circuit), and mood lability and disinhibition (orbitofrontal circuit).

Prefrontal lesions are related to a reduction in caudate volume (Hannestad et al., 2006). In elderly depression, there are both increased lesions of the basal ganglia and an impact of prefrontal lesions on caudate volume (Hannestad et al., 2006; Krishnan et al., 1993). Basal ganglia lesions are related to a reduction in orbitofrontal cortex (OFC) volume. Lesions disrupt white matter tracts and the uncinata appears to be particularly affected in patients with depression, which suggests a disconnection between the amygdala and PFC (Taylor et al., 2008a). These studies suggest that lesions change the circuits that regulate mood. The data generated by these studies clearly supports the notion that when these lesions damage the circuits, it predisposes to depression (Fig. 35.5).

CIRCUIT CHANGES IN ELDERLY DEPRESSION

DORSAL CIRCUIT

DORSOLATERAL PREFRONTAL CORTEX

The dorsolateral part of the PFC forms a neuroanatomical substrate for attention (Puce et al., 1996). This circuit interacts with the cingulate, amygdala, and medial OFC (Carmichael and Price, 1995).

Individuals with DLPFC lesions have deficits on working memory tasks (Bechara et al., 1998), which is consistent with the findings of functional imaging studies regarding DLPFC activation on working memory tasks (Courtney et al., 1997; McCarthy et al., 1994). Reduced superior and middle frontal cortex volumes are reported in geriatric

depression (Ballmaier et al., 2004). Many positron emission tomography studies of depression, mostly conducted in the young, have found DLPFC metabolism to be changed (Drevets et al., 1992; Mayberg et al., 1994). Taylor et al., demonstrated microstructural differences in the white matter of the DLPFC in elderly depressed individuals (Taylor et al., 2004). Initial studies by Rajkowska et al. (1999) also suggest that there is glial pathology in this region in elderly depressed patients. Functional imaging studies in late-life depression demonstrated a reciprocal connectivity between the DLPFC and OFC and persistent deficits in DLPFC functioning in remission (Wang et al., 2008). This supports the concept that even for remitted elderly depressed individuals the DLPFC is not appropriately modulating the response to negative stimuli.

ROSTRAL ANTERIOR CINGULATE CORTEX

The rostral anterior cingulate cortex (ACC) is involved with motor function, cognitive function, and the regulation of arousal and drive states. It has dense projections to the motor cortex and spinal cord, reciprocal connections with the lateral PFC, and extensive afferents from the midline thalamus and brainstem nuclei. The affective division further projects to autonomic brainstem nuclei (Devinsky et al., 1995).

Due to this functional overlap, it has been proposed that the ACC may translate thoughts into action (Ebert and Ebmeier, 1996; Paus et al., 2001). The affective division of the ACC includes the subgenual anterior cingulate (BA 25), BA 33, and the pregenual, dorsal, or rostral anterior cingulate gyrus (rostral regions of BA 24) (Phillips et al., 2003). The caudal supragenual ACC (BA 32) is generally classified as the cognitive division of the ACC, but it may also play a role in mood regulation through its efferents to the amygdala (Phillips et al., 2003). We will discuss the subgenual PFC separately.

Bilateral volume reductions of the ACC have been reported in geriatric depression (Ballmaier et al., 2004), and the geriatric depressed population also has been found to have more caudal metabolic deficits (de Asis et al., 2001). Taylor et al. (2004, 2007a) found changes in the fractional anisotropy of the anterior cingulate in geriatric depression. When individuals with geriatric depression perform tasks, there is impairment in ACC response (Wang et al., 2008).

HIPPOCAMPUS

The hippocampus has a complex role in affective regulation and in facilitating or inhibiting defensive behavior and anxiety in response to environmental stimuli (Corcoran et al., 2005; Phillips et al., 2003a; Van Den Hove et al., 2005). Thus, it may have a role in resolving goal conflicts and facilitating exploratory behavior patterns (Phillips et al., 2003a, b).

Some have reported a smaller hippocampal volume in mixed-age groups with depression (Bremner et al., 2000; Frodl et al., 2002; Krishnan et al., 1991; Mervaala et al., 2000; Shah et al., 1998; Sheline et al., 1996), while others have found no difference (Axelson et al., 1993; Hastings et al., 2004; MacQueen et al., 2003; Posener et al., 2003; Vakili et al., 2000). Our group and others have found smaller hippocampal volumes to be associated with recurrent depression (Axelson et al., 1993; Sheline et al., 1999), an earlier age of depression onset (Axelson et al., 1993; MacQueen et al., 2003; Sheline et al., 2003), a longer duration of untreated depression (Sheline et al., 2003), and poorer antidepressant response over one year (Frodl et al., 2004). Similar findings in older depressed populations have been reported, including both positive (Bell-McGinty et al., 2002; Steffens et al., 2000a) and negative studies (Ashtari et al., 1999; Pantel et al., 1997). In the elderly depressed, Steffens et al. (2000a, 2008) found decreased hippocampal volume with depression along with shape of the hippocampus (Qiu et al., 2009; Zhao et al., 2008) and cognitive changes.

VENTRAL CIRCUIT

AMYGDALA

The amygdala is critical for the evaluation of emotions. In animals and humans, bilateral damage to the amygdala results in the organism becoming placid and disinterested in the environment (Aggleton, 1992). In monkeys, bilateral lesions of the amygdala lead to an absence of emotional responses such as fear (LeDoux, 1992). The amygdala has extensive reciprocal projections with the frontal lobe, ventral striatum, thalamus, and cortex, as well as projections with regions that regulate behavioral, autonomic, arousal, and neuroendocrine responses, such as the hypothalamus and brainstem (Cardinal et al., 2002; Morgane et al., 2005). The amygdala is also involved in emotional appraisal and response (Bechara et al., 2003), assigning emotional significance to sensory stimuli (Russchen, 1986) and decision making, and it affects memory consolidation by influencing the hippocampus. The amygdala is necessary for the development of somatic and emotional states from actual environmental stimuli, although such states from secondary inducers such as memories or hypothetical events may be more reliant on the OFC (Bechara et al., 2003).

Neuropathological studies in depressed individuals of mixed ages show reduced glia density and a reduced glia/neuron ratio in the amygdala (Bowley et al., 2002). Structural imaging studies have shown mixed results, with some finding smaller amygdala core nuclei volumes in depressed adults (Sheline et al., 1998) and smaller volumes in adult depressed women (Hastings et al., 2004), whereas others have found no difference in amygdala volumes between depressed and non-depressed adults (Axelson et al., 1993; Frodl et al., 2004). Response to

negative emotional context results in amygdala activation (Hare et al., 2005). Transient sadness results in the activation of the left amygdala (Levesque et al., 2003), which is similar to the increased glucose metabolism in the left amygdala in depression (Drevets et al., 2002). The amygdala interfaces with layers of the OFC in a region that has been shown to have a reduction in pyramidal cell neurons in the elderly (Rajkowska et al., 2005). Imaging studies using the oddball task have also demonstrated that amygdala-OFC-DLPFC circuit activity is altered during depression (Wang et al., 2008).

SUBGENUAL CINGULATE CORTEX

The subgenual ACC has extensive reciprocal connections with several structures, including the OFC, nucleus accumbens, amygdala, and hypothalamus (Carmichael and Price, 1996). These connections likely represent a feedback circuit that regulates the amygdala's response to environmental stimuli, as the ACC can inhibit amygdala function (Rosenkranz et al., 2003).

Smaller left subgenual ACC volumes are seen in depressed individuals (Drevets et al., 1997). Volumetric differences in the left subgenual ACC have also been reported in adult samples with familial affective disorders (Drevets et al., 1997; Hirayasu et al., 1999) and adolescent-onset depression (Botteron et al., 2002). Others have found no differences in the volume of BA 24 or BA 25 in depression (Bremner et al., 2002; Kegeles et al., 2003). Consistent with the positive neuroimaging findings, neuropathological studies demonstrate a reduction in subgenual cingulate volume and a reduction in the number of glia in depressed individuals (Ongur et al., 1998). Sadness results in activation of the subgenual ACC (George et al., 1995; Liotti et al., 2000). Baseline functional imaging studies have found decreased metabolism and cerebral blood flow in the subgenual ACC in depressed individuals (Drevets et al., 2002; Kegeles et al., 2003; London et al., 2004; Mayberg et al., 1994); however, others have found no such difference between depressed and non-depressed individuals (Videbech et al., 2001). It is important to note that if functional imaging data is corrected for the partial volume effect of reduced gray matter volume, the metabolic activity in the subgenual ACC may actually be increased in depressed individuals. Very limited data has been gathered regarding this subject in elderly depressed individuals.

THE ORBITAL PREFRONTAL CORTEX

A variety of studies have implicated the OFC with regard to mood disorders (Bremner et al., 2002). Animal studies have demonstrated that lesions in this region of the PFC produce a behavioral pattern of timidity and reduction in novelty-seeking (Rolls, 1992). The OFC cortex connections have been detailed in a series of elegant studies by Carmichael and Price (1995, 1996). In primates, the orbital cortex has two selected patterns of connectivity that form two networks. One links sensory- and limbic-related areas within the orbital medial PFC. In the second, the orbital cortex is very closely linked to the amygdala. Projections from the medial and dorsal part of the basal nucleus of the amygdala reach areas 1AM, 1APM, 1AU, 13A, and 13M. Other amygdala nuclei also project to the medial orbital frontal cortex. The OFC projects widely upon higher-order multimodal association areas in the frontal,

parietal, and temporal lobes (Carmichael and Price, 1995, 1996). The OFC is involved in representing reinforcers and in rapid stimulus-reinforcement learning for both positive and negative reinforcers (Elliott et al., 1997, 1998; Rolls, 2000).

Damage to the OFC impairs the learning and reversal of stimulus-reinforcement associations, and thus impairs the correction of behavioral responses when these are no longer appropriate (Rolls, 1992, 2000). Research with humans and non-human primates with selective damage to the OFC supports the role of these prefrontal territories in reversal learning (changing emotional behavior in response to previously rewarded or punished stimuli) (Anderson et al., 1999; Bechara et al., 1999, 2000). Suppressing negative affect in response to stimuli that previously aroused such emotions can be conceptualized as a form of reversal learning. This suppression of negative affect leads to an inability to correct reward- and punishment-related behaviors, and thus leads to impairments in the ability to modulate emotion. This impaired learning of stimulus-reinforcement associations may explain a key component of severe depression in the elderly, namely apathy. The inability to reverse/extinguish stimulus-reinforcement associations can explain why damage to the OFC impairs the ability to suppress transient sadness (Rolls, 2000). The OFC output pathways to the striatum are believed to be important in the implementation of these functions (Rolls, 1992, 2000).

The intradimensional/extradimensional discrimination task and the Tower of London tasks can be used to assess PFC function (Murphy et al., 1999). These tasks are related to the OFC, and performance on this task has been shown to be deficient in elderly depressed individuals. This task is also impaired during tryptophan depletion (Rogers et al., 1999) and in younger depressed patients (Davidson et al., 2003).

The right OFC exhibits increased activation during attempts to suppress emotional reactions to sad stimuli (Levesque et al., 2003). Using fMRI, depressed individuals have been shown to exhibit less activation in the left lateral OFC in response to negative stimuli (Elliott et al., 2002), as well as differential neural response in the right lateral OFC in response to sad distractors in an emotional go/no-go task (Elliot et al., 2002). Higher choline/creatinine ratios and cytosolic choline/neutral amino acid ratios have been reported in the OFC in depressed adolescents compared to the OFC of healthy adolescents (Steingard et al., 2000).

Hannestad et al. (2006) showed for the first time that the OFC is reduced in size in *elderly* depressed patients and that this change is related to the occurrence of prefrontal lesions. Neuropathological studies in elderly depressed individuals have identified decreases in OFC neuronal size and neuronal and glial densities in depression (Rajkowska et al., 1999). Several neuroimaging studies have reported smaller OFC volumes or smaller OFC gray matter volumes in depressed individuals (Botteron et al., 2002; Lacerda et al., 2004; Lai et al., 2000). Hyperintense lesions within the OFC are also associated with depression in elderly populations (MacFall et al., 2001), and OFC volume is negatively correlated with subcortical gray matter lesion severity (Lee et al., 2003), which supports the theory of orbitofrontal-striatal circuits (Tetkin and Cummings, 2002). OFC volume is related to performance on the Benton

Visual Retention Task and with impaired stimulus-reward relationships, and it is negatively correlated with severity of functional disability (Taylor et al., 2003d). In addition, functional imaging studies have supported the role of OFC in depression (Levesque et al., 2003).

BASAL GANGLIA CIRCUITS

These circuits appear to be of major importance in our understanding of both the motivation and motoric expression of the mood state. The entire cortical mantle projects topographically to the striatum (Alexander and Crutcher, 1990). Thus, in classical reports, the nucleus accumbens and the ventral striatum are considered to be the limbic part of the striatum. The striatal circuits have been well described by Alexander and Crutcher (1990). The ventral striatum projects to the ventral pallidum and then innervates the mediodorsal nucleus of the thalamus, which is reciprocally related to the PFC. The ventral striatum outflow has been conceived as being involved in the regulation of behaviors and thought processes. The striatum is no longer seen as homogeneous, but as consisting of compartments on the basis of connections as well as neurotransmitters. The importance of the basal ganglia is shown by the variety of studies that have implicated it in mood alterations, such as Huntington's disease, Parkinson's disease, Wilson's disease, strokes of the basal ganglia, and so forth (Caine and Shoulson, 1983; Charpier and Deniau, 1997; Folstein et al., 1979; Saint-Cyr et al., 1992; Swerdlow and Koob, 1987). In the elderly, basal ganglia lesions and reduced volume of the caudate are associated with depression. Prefrontal lesions are linked to smaller caudate volume.

SUBCORTICAL ISCHEMIC DISEASE

Subcortical ischemic disease is common in normal elderly patients (Bryan et al., 1999; de Leeuw et al., 2001; Price et al., 1997). The lesions arise in both periventricular and deep white matter and in subcortical gray matter nuclei. The vascular changes are age-related (Awad et al., 1986; Bryan et al., 1997, 1999; Guttmann et al., 1998; Longstreth et al., 1996). Cerebrovascular risk factors, such as hypertension and diabetes, are strongly linked to the development of subcortical ischemic disease (de Leeuw et al., 2002; Fazekas et al., 1988; Liao et al., 1997; Longstreth et al., 1996; Ylikoski et al., 1995). Specific genetic factors also contribute (Schmidt et al., 2000; Viitanen and Kalimo, 2000).

Ischemia negatively affects cognition (Butters et al., 2004) and is associated with disability (Steffens et al., 2002b); either of these factors may also further increase the risk of depression. The lesions are related to medical comorbidity, particularly cerebrovascular risk factors. Greater subcortical lesion severity is associated with hypertension (Dufouil et al., 2001; Fukuda and Kitani, 1995; Liao et al., 1996; Schmidt et al., 1999; Veldink et al., 1998), as well as metabolic factors including hypofolatemia (Iosifescu et al., 2005). The ischemic nature of these lesions has been demonstrated in postmortem studies (Thomas et al., 2002). Interestingly, a recent twin study by Kendler et al. (2009) showed that for older twins, an older age of depression onset in one twin is associated with a higher risk of vascular disease in the other twin, whereas a younger age of

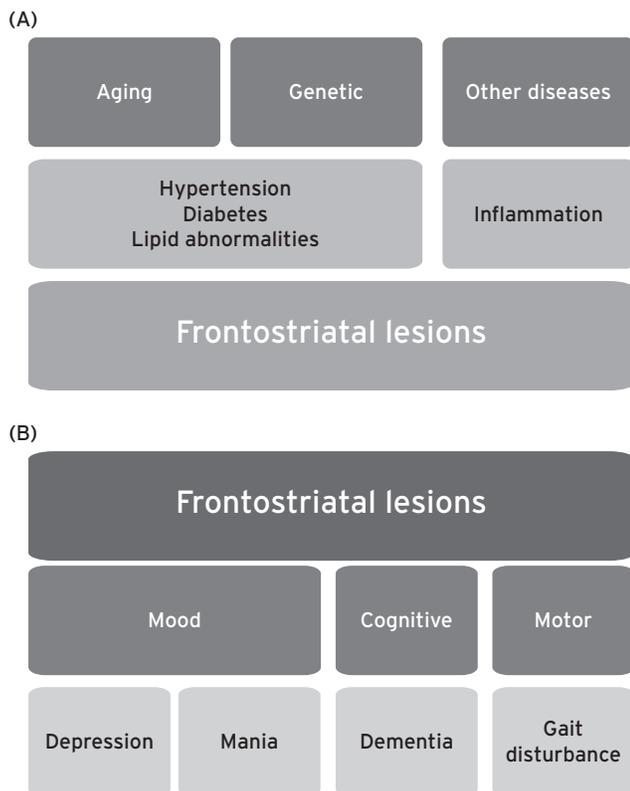

Figure 35.6. Frontostriatal lesions. (A) Factors leading to frontostriatal lesions; (B) consequences of frontostriatal lesions.

depression onset in one twin is associated with a higher risk for depression in the other twin (Kendler et al., 2009).

Subcortical vascular disease may have manifold clinical presentations (Kuo and Lipsitz, 2004; Pugh and Lipsitz, 2002) (Fig. 35.6). The clinical presentation for any individual is dependent on lesion location (which determines which neural circuits are affected) and medical illnesses or psychosocial risk factors. Subcortical ischemic disease associated with cognitive impairment is referred to as “vascular cognitive impairment” (O’Brien et al., 2003; Roman and Royall, 1999), and when it is associated with late-life depression, it is referred to as “vascular depression” (Krishnan et al., 1997, 2004; Steffens and Krishnan, 1998; Taylor et al., 2005). Vascular changes can be associated with other psychiatric and medical patterns, including psychosis and visual hallucinations (Breitner et al., 1990; Tonkonogy and Geller, 1999), manic depressive illness (McDonald et al., 1999), gait dysfunction (Whitman, 2001), and urinary incontinence (Sakakibara et al., 1999; Tarvonen-Schroder et al., 1996).

CONSEQUENCES OF SUBCORTICAL ISCHEMIC DEPRESSION

Subcortical ischemic depression is associated with adverse outcomes, including a higher risk for mortality (Baldwin, 2000; Levy et al., 2003) and functional impairment (Krishnan et al., 1997; Sachdev et al., 2005; Steffens et al., 2000a). Subcortical lesions are associated with poor antidepressant outcomes (O’Brien et al., 1998; Papakostas et al., 2005; Simpson et al., 1998) and with the persistence or worsening of depressive

symptoms over time (Steffens et al., 2002b). A poorer depression course is also associated with greater increases in subcortical lesion volume over that time (Taylor et al., 2003c). There may also be a biological gradient, wherein lesions that contribute to depression need to occur in specific regions (Greenwald et al., 1998; MacFall et al., 2001, 2006; Taylor et al., 2003b).

Subcortical ischemic depression also exhibits differences in (1) clinical symptoms of depression (Krishnan et al., 2004); (2) long-term course of depression, with a higher risk of developing dementia (Baldwin, 2000; Steffens et al., 2000b; Steffens et al., 2004); (3) familial pattern of depression (Krishnan et al., 2004); and (4) response to antidepressant medications (O’Brien et al., 1998; Papakostas et al., 2005; Simpson et al., 1998).

VASCULAR DEPRESSION AS A DISTINCT SUBTYPE

In the definition of our original proposals for a diagnosis of MRI-defined vascular depression (Krishnan et al., 1997; Steffens and Krishnan, 1998) and refined proposal for subcortical ischemic depression (Krishnan et al., 2004) is the notion that these lesions are causal risk factors for depression. Robins and Guze (1970) proposed formal criteria for establishing the validity of psychiatric diagnoses: (1) clinical description; (2) laboratory studies (including psychological tests, radiology, and postmortem findings); (3) delimitation from other disorders; (4) follow-up studies; and (5) family studies. However, of the more than 400 entities in the *Diagnostic and Statistical Manual of Mental Disorders*, few meet these criteria, and the concept of discrete disease entities in the psychiatric context may be problematic (Kendell and Gourlay, 1970; Kendell and Jablensky, 2003). One of the hallmarks for symptom- and course-based identification is to demonstrate points of non-overlap between similar syndromes, but the differences between psychiatric diseases are not as distinct as one would like. Any proposal of diagnostic criteria that claims a psychiatric disorder is due to a medical condition should undergo intense scrutiny (Evans, 1978; Hill, 1965).

We have previously proposed other criteria for defining disease (Krishnan, 2005) that may be more applicable to psychiatric disorders. The first criterion is that the condition should be one that leads to a risk for adverse outcomes, specifically mortality or functional impairment. The second criterion is that when an identifiable environmental factor, pathology, or genetic factor can be clearly defined, that factor should be expected to separate the entity from similar entities on at least one of the following domains: (1) clinical symptoms; (2) course and outcome; (3) familial pattern; or (4) response to specific treatment.

Subcortical ischemic depression meets these criteria. Given our current understanding of cerebrovascular disease in subcortical ischemic depression, treatment options that address vascular risk factors may prove to be of benefit.

The calcium-channel blocker nimodipine is one potential treatment approach, as studies have shown that it may augment response to antidepressant medications in patients with vascular depression (Taragano et al., 2001, 2005). The cited

double-blind studies suggest that nimodipine improves remission rates and improves the odds of sustained response. Testing has not yet been performed to determine whether therapy to prevent the progression of subcortical ischemic disease affects the rates or outcomes of depression, but such a study is needed to examine whether lesions are causal risk factors for depression and to provide a rationale for identifying and treating vascular depression as a separate entity.

GENETICS

As noted multiple times, genetic factors affect many aspects of the development and possibly progression of subcortical ischemic depression (Fig. 35.7). The findings so far are limited to a few candidate genes that we have assessed. They include the gene for serotonin transporter as well as brain-derived neurotrophic factor (BDNF), catechol-*O*-methyltransferase (COMT) and angiotensin receptor.

SEROTONIN-TRANSPORTER-LINKED PROMOTER REGION

The serotonin-transporter-linked promoter region (*5HTTLPR*) polymorphism contains either a 44-base pair insertion (long allele or *l*) or deletion (short allele or *s*). Compared to the *l* allele, the *s* allele is associated with a lower level of 5-HT uptake and transcriptional efficiency of the serotonin transporter. The *s* allele is associated with reduced gray matter volume in the perigenual cingulate and amygdala (Scherk et al., 2009), resulting in the hypothesis that the *5HTTLPR* genotype may affect brain development and be a potential risk for depression and anxiety.

Depressed individuals with the *l/l* genotype have smaller hippocampal volumes than those without the genotype (Janssen et al., 2004). In older individuals, later depression onset is associated with smaller hippocampal volumes in individuals with the *l/l* genotype, while an earlier age of depression onset is associated with smaller hippocampal volumes in individuals homozygous for the *s* allele. Elderly individuals with early-onset depression who are homozygous for the *s* allele exhibit reduced fractional anisotropy in the left uncinate fasciculus,

the fiber tract that connects the hippocampus and amygdala with the PFC (Taylor et al., 2007b) as well as a lower fractional anisotropy of the frontal gyri white matter. Other structures and links have not been tested, including the amygdalo-thalamic connection, the link between the amygdala and the basal ganglia (putamen), and the indirect pathway through the subthalamic nucleus. Preliminary studies have also shown that *5HTTLPR* heterozygotes have higher rates of subcortical ischemic disease (Steffens et al., 2008). The gene was not related to OFC volume (Taylor et al., 2007b).

BRAIN-DERIVED NEUROTROPHIC FACTOR

In animal models, BDNF appears to protect against cerebral ischemia. In older patients, the BDNF Met66 allele has been found to be associated with greater white matter hyperintensity volumes (Taylor et al., 2007b, 2008c). Depressed individuals have been shown to be more likely to be Met66 allele carriers than are individuals who are not depressed (Taylor et al., 2007b). In addition, although often viewed as a purely environmental construct, the perception of social support may be influenced by genetic factors that in studying the relationship between the BDNF, Val66Met polymorphism and social support measures in older individuals (Taylor et al., 2008c). After controlling for diagnosis and education level, the Met66 allele was associated with lower levels of subjective social support. This supports previous work that genetic factors may influence social support perception (Taylor et al., 2008a; Wang et al., 2012).

ANGIOTENSIN RECEPTOR (AGTR) GENE POLYMORPHISMS

In men, AGTR1 1166A allele homozygotes have shown significantly less change in white matter lesion volume than do 1166C carriers. Men with the AGTR2 3123C allele who report hypertension exhibit less change in white matter lesion volume than do hypertensive men with the 3123A allele, or men without hypertension. No such significant relationships have been found in women. Also, no significant gene-gene or gene-depression interactions have been observed (Taylor et al., 2010). The results are similar to gender differences in the relationship between other renin-angiotensin system polymorphisms and hypertension. It is not known whether these relationships are secondary to the polymorphisms that affect response to antihypertensive medication, or whether antihypertensive medications can slow the progression and lower the risk of morbidity.

METABOLOMIC STUDIES

Metabolomics is the global science of biochemistry. This emerging field enables the detection and quantification of small molecules that are involved in metabolic and signaling pathways. Metabolic signatures for disease and disease treatment could provide valuable biomarkers and insights regarding disease mechanisms. Metabolites that are altered in currently depressed patients compared to controls include several fatty acids, glycerol, and gamma-aminobutyric acid (GABA) (Paige et al.,

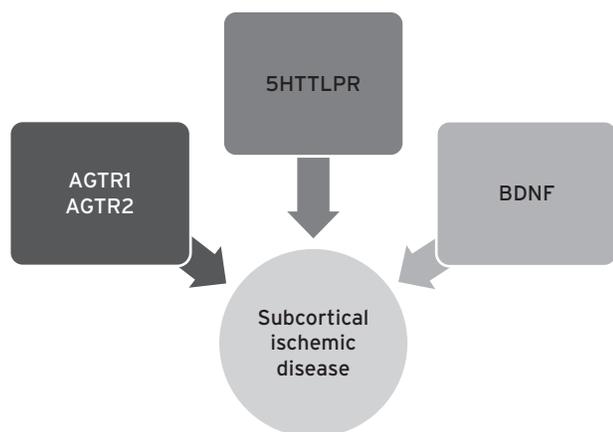

Figure 35.7 Genetic risk factors for subcortical cerebrovascular disease.

2007). Analyses that compared concentrations in remitted and currently depressed patients (Paige et al., 2007) revealed a pattern of metabolite alterations similar to the control versus currently depressed analyses. These observations suggest that the depressed state may be associated with alterations in the metabolism of lipids and neurotransmitters, and that treatment with antidepressants adjusts some of the aberrant pathways in disease so that the patients in remission have a metabolic profile more similar to controls than to the depressed population. These results will need to be examined and validated in larger longitudinal cohorts (Paige et al., 2007).

DEGENERATIVE DISEASE AND LATE-LIFE DEPRESSION

Depression can sometimes be the early stage of a neurodegenerative disorder. This is indeed well known in Huntington's disease. But it can also occur in Alzheimer's and Parkinson's disease.

As in most cases of depression, depressed mood and anhedonia are essential symptoms. Other features that can overlap with the primary disease, such as loss of appetite, sleep disturbance, weight gain, loss of libido, loss of concentration, and fatigue, make diagnosis challenging. However feelings of guilt or worthlessness are not common in these patients. (Aarsland et al., 2009). A robust link between history of depression and increased risk of subsequent development of Parkinson's was identified in a majority of studies (Ishihara and Brayne, 2006). The brain circuits implicated in depression in the context of Parkinson's disease is similar to the mood circuit and lends further credence to the circuit.

Another interesting aspect of this link is the finding of Lewy body pathology, a known attribute in Parkinson's in patients with late-life depression, thus reinforcing the link and the notion that depression may be a prodrome in Parkinson's (Tsopelas et al., 2011).

A similar story emerges in the context of Alzheimer's disease. Depression is quite common in early Alzheimer's and is also seen as a risk factor for the disease. A common myth was that patients with depression could present with a full dementia syndrome that would be totally reversed with treatment. This is the concept of pseudodementia, considered to be a reversible form of cognitive impairment due to depression. This concept is erroneous. Patients with depression, presenting with severe cognitive impairment, were at a much higher risk of developing dementia (Kral and Emery, 1989). Interestingly there are now reports of increased amyloid pathology (the classic feature of Alzheimer's) in late-life depressed patients with cognitive impairment thus again reinforcing the link but also highlighting the possibility that depression can be a prodrome in Alzheimer's (Butters et al., 2008).

SUMMARY

Depressive disorders in the elderly provide a clinical model in which brain lesions are present, and thus they present a clinical patient population which, when coupled with postmortem and

transgenic approaches, can increase our understanding of the brain circuits that are involved in mood disorders. It has been proposed that vascular lesions in critical regions of the brain are an important factor in the development of depression in the elderly. The scientific importance of this possibility is obvious: if vascular lesions in the brains of older individuals lead to secondary depressions that have clinical characteristics similar to primary depressions, then these sites may provide important clues to the brain sites involved in depression in general. This has led to a number of crucial findings:

- 1) OFC and basal ganglia lesions are related to depression;
- 2) Lesions seen in elderly depressed patients are similar to those characterized as of ischemic origin;
- 3) Prefrontal lesions are related to a reduction in caudate volume;
- 4) OFC volume is reduced in depressed patients;
- 5) Basal ganglia lesions are related to reduction in OFC volume;
- 6) Lesions disrupt white matter tracts, and the uncinate fasciculus appears to be particularly affected in patients with depression, which suggests fronto-amygdala disconnection;
- 7) Postmortem cell counts in the OFC among these patients show a reduction in layer-3 pyramidal neurons and layer-5 pyramidal neurons;
- 8) Postmortem vascular changes, including an increased density of vessels with larger perivascular spaces, are present in the white matter of OFC in elderly patients with depression;
- 9) BDNF genetic variation is linked to depression and subcortical ischemic disease;
- 10) A reciprocal interaction between the OFC and DLPFC has been shown using functional imaging;
- 11) In depressed patients, there is a decreased hemodynamic response in the amygdala, OFC, and striatum in the oddball task during the emotion-distractor condition, and this response is only partially ameliorated following remission;
- 12) In depressed patients, prefrontal function is impaired in a variety of functional tasks;
- 13) AGTR1 and AGTR2 genetic variations are linked to the risk of progression of subcortical ischemic disease;
- 14) Genetic variation in 5HTTLPR is related to lesions and changes in hippocampal volume;
- 15) Subjective social support, although generally construed as an environmental factor, is also related to change in BDNF genetic variation.
- 16) Late-life depression can be a prodrome to neurodegenerative disorders such as Alzheimer's and Parkinson's disease.

The net result of these findings is the considerable progress in our understanding of the neural circuits and neuropathology that underlie depression in late life. These findings have an obvious implication in the development of our understanding of other forms of depression.

DISCLOSURE

Dr. Krishnan serves on the Advisory Board of Cenerx, Health Sciences authority and Atentiv. He is Dean Duke NUS, Chairman SCRI and member of the specialist accreditation board Singapore. He is a member of the board for the National Medical Research Council (NMRC) in Singapore. He has stock ownership in Orexigen and indirect holdings in Cenerx. Patents have been licensed to Atentiv.

36 | GONADAL STEROIDS AND MOOD DISORDERS

DAVID R. RUBINOW, PETER J. SCHMIDT, AND CLAIRE D. CRAFT

Despite lack of recognition until recently of the importance of gonadal steroids in affective regulation, the role of these hormones in mood and behavior can be traced back to the very origins of our understanding of the pathophysiology of mood and behavioral disturbances. Aristotle noted that castration of male birds “when young” not only prevented the development of physical sex characteristics, but also further extinguished sex-specific behaviors such as male singing and sexual interest. In 1849, Berthold observed that the behavioral changes accompanying castration of roosters could be reversed through testicular transplant, leading him to infer that the testes must contain secretions that are responsible for the regulation of behavior. This, and the subsequent work of Charles Brown-Sequard, gave rise to the field of organotherapy, which was based on the premise that the administration of extracts of organs such as the testes and ovaries could treat a variety of mood disorders in humans, ranging from depression to the “anergy of senescence.” The use of hormones as psychotropic agents continued after the isolation of estradiol in 1929, when Werner et al. (1934) described the antidepressant efficacy of an estradiol preparation called “theelin” in a study of perimenopausal and early postmenopausal women. This placebo-controlled study established the historical precedent for the use of gonadal steroids for the treatment of depression occurring during periods of reproductive endocrine transition. Throughout much of the 20th century, the possible role of gonadal steroids in affect regulation was inferred from two indirect sources: the twofold greater prevalence of depression in women, and the existence of reproductive endocrine-related mood disorders.

Reproductive endocrine-related mood disorders are affective disturbances that appear in concert with changes in reproductive endocrine activity. They include psychiatric disturbances occurring during menarche, pregnancy or postpartum, the perimenopause, or the menstrual cycle. Also included are disturbances consequent to manipulation of gonadal steroids or reproductive status (e.g., hormone replacement therapy or gonadal suppression). In this chapter, we will review the following: (1) the neurobiology of gonadal steroids; (2) the impact of gonadal steroids on the physiological systems implicated in depression; and (3) the neurobiology of reproductive endocrine-related mood disorders (old models, new models, and therapeutics).

WHAT ARE GONADAL STEROIDS AND WHAT UNDERLIES THEIR BIOLOGICAL EFFECTS?

Gonadal steroids are made in the gonads and adrenals and, like all steroid hormones, are metabolites of cholesterol. They include estradiol (E2), progesterone (P), testosterone (T), as well as precursors (e.g., the androgens DHEA and androstenedione) and metabolites (e.g., the potent androgen, dihydrotestosterone [DHT] and neurosteroid metabolites such as allopregnanolone). As shown in Figure 36.1, T is the immediate precursor of E2. The gonads are under control of the pituitary hormones follicle-stimulating hormone (FSH) and luteinizing hormone (LH), which in turn are under the control of a hypothalamic releasing hormone (GnRH), similar to other neuroendocrine axes. Hormonal changes during the menstrual cycle, the female climacteric (perimenopause), and the menopause are shown in Figure 36.2. In men, blood levels of T and DHT are stable (i.e., not cyclical), albeit with circadian variation and an age-related decrease of plasma levels of 1% per year after age 30. The cellular and molecular effects of gonadal steroids are protean. Many of these effects are mediated by steroid receptors, which, unlike neurotransmitter membrane receptors, are intracytoplasmic proteins that serve as transcription factors. By regulating genomic transcription, gonadal steroids influence the synthesis and metabolism of a wide range of neurotransmitters and neuropeptides.

Both the scope of and variance in the neuroregulatory potential of gonadal steroids are revealed in the details of their signaling effects. First, as the mechanics of transcription became elucidated, it became clear that activated steroid receptors influence transcription not as solitary agents but by forming combinations with other intracellular proteins. These protein–protein interactions are such that an activated receptor might enhance, reduce, initiate, or terminate transcription of a particular gene solely as a function of the specific proteins with which it interacted. The expression or activation state of these proteins—coregulators (coactivators or corepressors)—proved to be tissue specific, thus suggesting the means by which a hormone receptor modulator (e.g., tamoxifen) could act like an (estrogen) agonist in some tissues (e.g., bone) and like an (estrogen) antagonist in others (e.g., breast). In addition to their role in the recruitment of components of the general transcription factor apparatus, many of the coactivator proteins

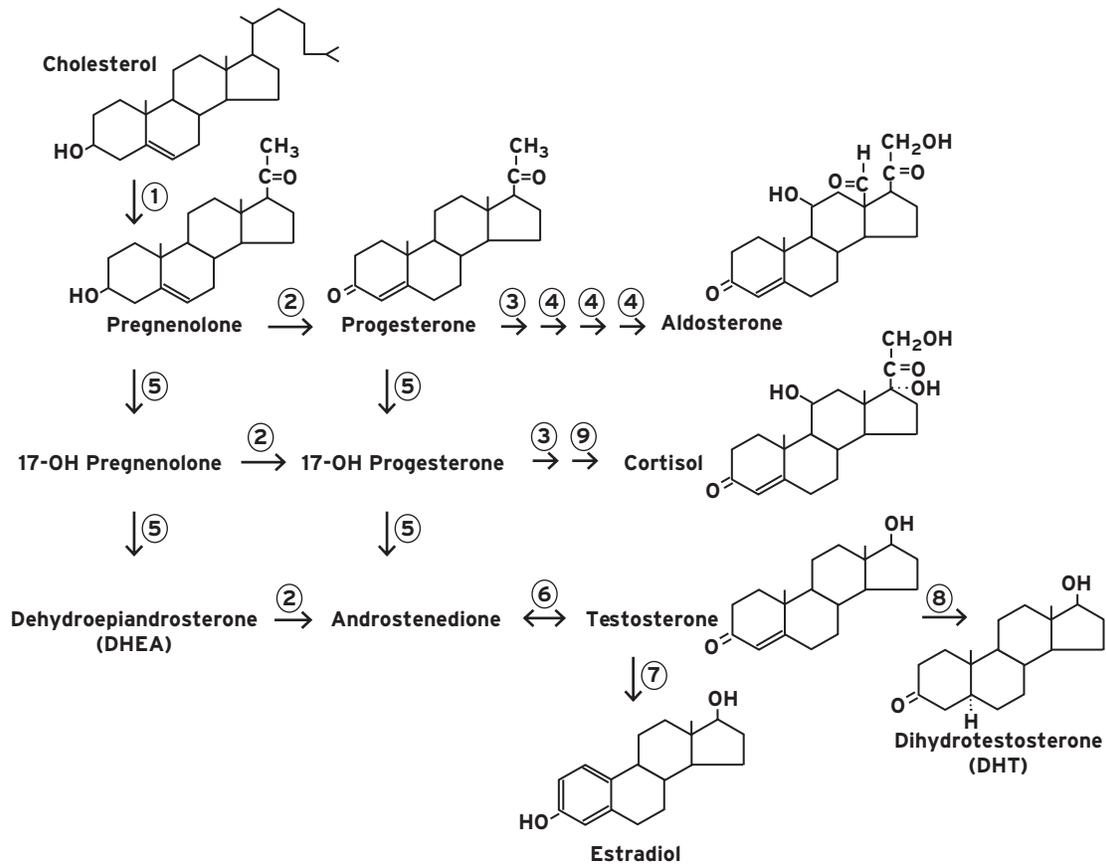

Figure 36.1 Synthetic pathways for steroid hormones. Circled numbers identify synthetic enzymes: 1 = cytochrome P450 (CYP) 11A (cholesterol desmolase); 2 = 3 β -hydroxysteroid dehydrogenase; 3 = CYP21 (21-hydroxylase); 4 = CYP11B2 (11 β -hydroxylase, 18-hydroxylase, 18-oxidase); 5 = CYP17 (17 α -hydroxylase, 17,20-lyase); 6 = 17 β -hydroxysteroid dehydrogenase (or oxidoreductase); 7 = aromatase; 8 = 5 α -reductase; 9 = CYP11B1 (11 β -hydroxylase).

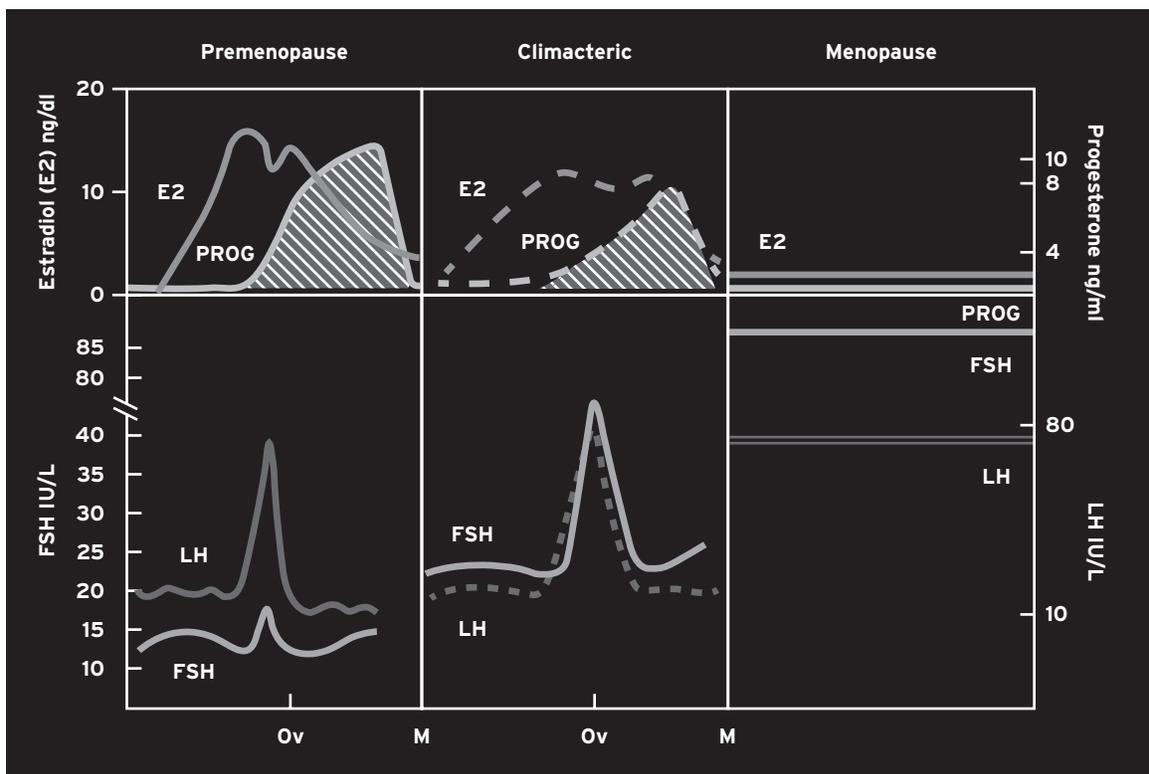

Figure 36.2 Hormonal changes during the menstrual cycle, the female climacteric (perimenopause), and the menopause.

have associated enzyme activity (e.g., histone acetylase activity, which facilitates chromatin remodeling and gene transcription). There are 300 or more of these coregulators, and the way in which specific amino acid residues are modified (e.g., phosphorylated) by cell signaling (e.g., hormone binding) determines which other coregulators and transcription factors they recruit, which in turn determines their effect on transcription (McDonnell and Wardell, 2010). Another group of intracellular proteins, the cointegrators, provide a means by which classical hormone receptors can bind to and regulate sites other than hormone response elements (e.g., estrogen receptor [ER] or glucocorticoid receptor [GR] binding cyclic AMP-response element binding [CREB] protein [CBP] and, subsequently, the AP1 binding site), and competition for cointegrator or other transcriptional regulatory proteins appears to be a mechanism by which even ligand-free hormone receptors can influence (e.g., squelch or interfere with) the transcriptional efficacy of other activated hormone receptors. Thus, the intracellular hormone receptor environment as well as the extracellular hormone environment may dictate the response to hormone receptor activation. The binding of a hormone agonist or antagonist in the binding pocket of the receptor alters the conformation of the receptor in such a way as to facilitate or interfere with the binding of coregulatory proteins. Recently, however, additional sites have been identified in the structure of nuclear hormone receptors where other molecules, called nuclear receptor alternate site modifiers (NRAMS), may bind to regulate the actions of hormones.

Second, the hormone receptors were found to exist in different forms. For example, isoforms of the progesterone receptor, PRA and PRB (the latter of which contains a 164 amino acid N-terminal extension), have different distributions and biological actions, and two separate forms of the estrogen receptor, ER α and ER β , are encoded on different chromosomes (6 and 14, respectively), have different patterns of distribution in the brain, different affinity patterns for certain ligands, and a range of different actions (including those created by ER heterodimers). Further, a variant of ER β , ER β 2, is expressed in the brain, where it can heterodimerize with the ER α or ER β receptors and inhibit their transcriptional actions (Thomas and Gustafsson, 2011). The clinical importance of these receptor isoforms is revealed by a variety of studies suggesting that ER β mediates the antidepressant effects of E2 in animal models as well as exerting proliferative effects in the hippocampus and antiproliferative effects in a variety of peripheral tumor models (e.g., breast, prostate, colon).

Third, a variety of substances (e.g., nerve growth factor, insulin) are capable of activating a steroid receptor even in the absence of ligand. This crosstalk is exemplified by the ability of dopamine to induce lordosis by activating the progesterone receptor.

Fourth, the relatively slow, genomic effects of gonadal steroids have been expanded in two dimensions: time, with a variety of rapid (seconds to minutes) effects observed; and targets, which now include ion channels and a variety of second-messenger systems. Several lines of evidence indicate that the rapid effects of E2 are not likely to be the consequence of nuclear events but rather must be related to events occurring at the cell surface. Both classical and unique ERs

(e.g., ER-X, GPR30) exist in the caveolae or caveolar-like microdomains of membranes where they link to scaffolding proteins (e.g., caveolin-1, flotillin) and multiple signaling molecules, particularly the G proteins, which then activate a wide array of signal transduction systems (reviewed in Zhang et al., 2005). Through alterations in signal transduction or by direct binding, E2 can also regulate ion channel activity (e.g., calcium and potassium channels) and hence, cellular activation (Zhang et al., 2005). The significance of these nongenomic effects is twofold. First, the nongenomic signal may serve to amplify the subsequent genomic effect of the hormone (Vasudevan and Pfaff, 2008). Second, the nongenomic effect on dendritic spines may similarly “prime” the neuron so that closely paired environmental signals are more effectively encoded and “learned” (Srivastava et al., 2011). Finally, the activity of neurotransmitter membrane receptors is acutely modulated by gonadal steroids (e.g., glutamate receptors by E2 and γ -aminobutyric acid [GABA] receptors by the neurosteroid allopregnanolone). Adding to the complexity of the effects described is their tissue- and even cell-specific nature (e.g., E2 increases MAPK in neurons but decreases it in astrocytes).

Fifth, gonadal steroids regulate cell survival. Neuroprotective effects of E2 have been described in neurons grown in serum-free media or those exposed to glutamate, amyloid- β , hydrogen peroxide, ischemia, or glucose deprivation (Dubal and Wise, 2002). Some of these effects appear to lack stereospecificity (i.e., are not classical receptor mediated) and may be attributable to the antioxidant properties of E2, although more recent data support receptor-mediated mechanisms of action. Gonadal steroids may also modulate cell survival through effects on cell survival proteins (e.g., Bcl-2, BAX), MAPK, Akt, or even amyloid precursor protein and A β metabolism or through enhancing mitochondrial respiratory efficiency).

Finally, the effects of gonadal steroids do not occur in isolation but, rather, in exquisite interaction with the environment. These environmental influences may include diet and medication, as short-chain fatty acids (including valproic acid) dramatically increase cellular sensitivity to gonadal steroids by amplifying their transcriptional potency through inhibition of histone deacetylase and stimulation of MAPK.

The vicissitudes of gonadal steroids and their receptors, therefore, direct neural architecture and provide the means by which the response of the CNS to incoming stimuli may be altered. The extent to which these effects underlie or contribute to differential pharmacologic efficacy or to behavioral differences observed across individuals is unclear but is of considerable potential relevance for reproductive endocrine-related mood disorders.

HOW DO THE NEUROBIOLOGICAL EFFECTS OF GONADAL STEROIDS OVERLAP THE PATHOPHYSIOLOGY OF DEPRESSION?

The simple answer is that virtually every system implicated in the pathophysiology of depression is regulated by gonadal steroids. For example, as described elsewhere (Rubinow and

Girdler, 2011), E2 “beneficially” modulates the following putative system disturbances in depression:

1. *Neurotransmitter deficiencies*—E2 regulates the synthesis, metabolism, and receptor concentration/trafficking of the classical neurotransmitters implicated in depression (i.e., serotonin, dopamine, and norepinephrine).
2. *Stress*—E2 regulates both basal and stress-induced ACTH and cortisol in animals through effects on GR and corticotropin-releasing hormone (CRH; although P may have more regulatory effects in humans).
3. *Neuroplasticity*—E2 has a significant impact on neuronal plasticity-related processes, acting like antidepressants (and opposite to stress) in stimulating BDNF, a critical growth factor observed to be deficient in depression; increasing activity of the transcription factor cAMP response element-binding protein (CREB) and trkA (neurotrophic tyrosine kinase receptor type 1); and decreasing glycogen synthase kinase (GSK)-3 β in rat brain, the same direction of effects as seen with mood stabilizers. Consistent with these effects, as mentioned previously, E2 is neuroprotective in a variety of models, including oxidative damage, glutamate excess, and β -amyloid toxicity.
4. *Cellular energetics*—E2 improves mitochondrial respiratory efficiency and prevents the oxygen free radicals that are believed to adversely affect mitochondrial energetics in depression.
5. *Inflammation*—At multiple levels, E2 prevents or counteracts the proinflammatory processes described as contributing to depression.
6. *Brain systems*—The ability of gonadal steroid hormones to regulate activation in brain regions implicated in depression can be inferred from imaging studies conducted over the menstrual cycle or after gonadal steroid administration.

MENSTRUAL CYCLE EFFECTS

Studies of response to negative visual stimuli have shown significant differences in the response of affective circuitry between menstrual cycle phases and provided clues to the modulatory roles of E2 and P. During the late follicular phase, when E2 levels are at their peak, activity in several limbic, frontal, and hypothalamic regions show a significantly reduced response to negative material compared with the early follicular phase, when E2 levels are low (Goldstein et al., 2005). E2 has been found to modulate affective processing in the dorsolateral prefrontal cortex (dlPFC), where there was significantly increased activation while inhibiting response to positive words during the mid-luteal (high E2) phase of the menstrual cycle.

Menstrual cycle-related differences can also be seen in the orbitofrontal cortex (OFC), which functions in inhibitory control and emotional regulation. In healthy women, OFC responses to negative linguistic stimuli show greater medial activation during the luteal phase than during the

follicular phase. Greater medial activation may signify an enhanced emotion-related visceromotor control circuit activity premenstrually, perhaps indicating a greater need for top-down regulation of a heightened excitability of limbic system premenstrually (Protopopescu et al., 2005).

Negative emotional images produce significantly greater activity in the amygdala and hippocampus during the mid-luteal phase, when P is elevated, than during the early follicular phase, when both E2 and P are at low levels. Similar findings were demonstrated in healthy women in their follicular phase who were administered exogenous P at levels similar to those seen during the mid-luteal phase. These findings suggest that P-mediated effects dominate during the luteal phase, and further suggest that E2 and P may play opposing roles in modulating the brain's arousal circuitry.

The reward circuitry varies in a menstrual cycle-dependent fashion. During reward anticipation, activity in the amygdala and OFC are increased in the follicular phase relative to the luteal phase. At reward delivery, increased follicular phase activity can be observed in the midbrain and striatal areas (Dreher et al., 2007). Additionally, not only does the menstrual cycle regulate cerebral blood flow in brain regions (e.g., amygdala, dlPFC) implicated in depression, but as well it regulates the valence of the stimulus to which brain regions like the OFC react (Protopopescu et al., 2005)

Hormone manipulation studies in humans have shown that normal cognitive-stimulated activation of the dlPFC and cerebral blood flow to that region are suppressed in premenopausal women during pharmacologically induced hypogonadism—an effect that is reversed when gonadal hormones are reintroduced (Berman et al., 1997). E2 also regulates in humans the mesolimbic reward circuitry that is believed disturbed in depression, and it serves to bias toward or against the activation of specific neurocircuitry in animals. For example, it has been demonstrated that stress-induced c-fos expression in various cortical HPA-axis related regions are differentially stress activated in female rats depending on the phase of the estrous cycle. Gonadal steroids may also regulate cognitive-stimulated activity in the subgenual cingulate region (Brodmann area 25; BA25), the region implicated in deep brain stimulation treatment of depression.

The relevance of gonadal steroids in depression is also inferred from the antidepressant effects of E2 in several animal models of depression. Given the well-established role of stress in triggering the onset or exacerbation of depression in humans, preclinical research has focused on behavioral and neuropathological effects of stress to model mechanisms involved in human depression. A number of studies have shown that E2 diminishes “depressive behaviors” in animal models of chronic stress and that the antianxiety and antidepressant effects of E2 are largely mediated through ER β , an isoform that is abundantly expressed in brain, including the limbic system, the hypothalamus, and the PFC. Additionally, E2 may also influence affective behavior by altering the activity of an extensive array of neuroregulatory proteins. For example, as noted previously, E2 attenuates chronic stress-induced increases in c-fos positive neurons in the paraventricular

nucleus of the hypothalamus, similar to the effects seen in rat brain after chronic antidepressant treatment. E2 also attenuates stress-induced sensitization in the limbic system.

The data reviewed in the preceding provide a strong basis for inferring a potential role of gonadal steroids in the etio-pathogenesis or treatment of mood disorders, particularly those linked to periods of reproductive endocrine change.

REPRODUCTIVE ENDOCRINE-RELATED MOOD DISORDERS

PREMENSTRUAL DYSPHORIC DISORDER

Premenstrual dysphoric disorder (PMDD) refers to the appearance of mood and behavioral symptoms in the luteal (postovulatory/premenstrual) phase of the menstrual cycle. This disorder is relatively common (about 5% prevalence in women) and is associated with a significant amount of morbidity, estimated at as many as 14.5 million disability-adjusted life years in the United States. Unlike other diagnoses in medicine, PMDD is a time-oriented and not a symptom-oriented diagnosis. The symptoms are relatively nonspecific; rather it is their exclusive appearance during the luteal phase that defines the disorder. As such, the diagnosis cannot be made based on history but instead requires a prospective demonstration that symptoms are confined to the luteal phase, disappearing at or soon after the onset of menses. Although many variations on this theme may potentially exist, use of a more restrictive definition has been necessary to ensure the homogeneity of samples across studies necessary for comparison and generalization of results obtained. Employment of standardized diagnostic guidelines has demonstrated the existence of PMDD and permitted resolution of many (but not all) of the controversies in the literature regarding the neurobiological basis of PMDD.

HORMONE STUDIES OF PMDD

Hormone studies in women with PMDD have employed several different strategies: (1) the measurement of basal hormone levels at selected points in the menstrual cycle; (2) evaluation of dynamic endocrine function employing endocrine challenge paradigms; and (3) the manipulation of menstrual cycle physiology in order to examine the plasticity of the linkage between the menstrual cycle and PMDD symptoms. The most frequently employed strategy has been the comparison of luteal phase basal hormone levels with those from the follicular phase in women with PMDD or with comparable values from a non-PMDD control group.

Comparisons of basal plasma hormone levels (E2, P, T, FSH, and LH) in women with PMDD and controls have revealed no consistent diagnosis-related differences (Rubinow and Schmidt, 2006), suggesting that PMDD is not characterized by abnormal circulating plasma levels of gonadal steroids or gonadotropins or by hypothalamic-pituitary-ovarian axis dysfunction. Several studies do, however, suggest that levels of E2, P, or neurosteroids (e.g., pregnenolone sulfate) may be correlated with symptom severity in women with PMDD.

Studies of a variety of other endocrine factors (e.g., thyroid or HPA axis hormones) in patients with PMDD have been similarly unrevealing. Although isolated significant differences have been reported, neither the diagnostic group-related differences nor their confinement to the luteal phase are consistently observed. Further, for the overwhelming majority of biologic factors for which diagnostic group-related differences have been suggested or demonstrated, the difference is not confined to the luteal phase but rather appears in follicular and luteal phases, thus arguing against their direct role in the expression of a disorder confined to the luteal phase (Rubinow and Schmidt, 2006). Three systems have received special attention for their possible role in PMDD.

SEROTONIN

A variety of observations implicate dysfunction of serotonergic neurons in PMDD. Although investigations utilizing pharmacologic probes to test 5-HT system function in women with PMDD have yielded inconsistent results, treatment studies consistently demonstrate the therapeutic efficacy of serotonin-enhancing agents (e.g., fluoxetine) for many women with PMDD. Additionally, we observed an acute therapeutic response in women with PMDD following oral administration of the 5-HT_{2C} agonist/5HT_{2A} antagonist, m-CPP, as well as a delayed (24 hours) reversal of the efficacy of fluoxetine by the serotonin receptor antagonist metergoline. These data converge to strongly suggest the role of the serotonin system in the pathophysiology of PMDD. As the majority of abnormalities in neuroendocrine response to serotonergic agents in PMDD are observed in both phases of the cycle (and because approximately 40% of women with PMDD do not respond to SSRIs), serotonergic dysfunction cannot be implicated as a direct cause of PMDD. It may, however, convey a vulnerability to mood destabilization in association with changes in gonadal steroids seen during the menstrual cycle.

NEUROSTEROIDS

The 5- α and 5- β reduced metabolites of progesterone (allopregnanolone and pregnanolone, respectively) rapidly and positively modulate the GABA-A receptor in brain and display anxiolytic effects in several animal models. These compounds, shown in Figure 36.3, are intriguing as potentially contributing to PMDD, as their withdrawal (as occurs in the late luteal phase) is associated with anxiety and insensitivity to benzodiazepines. Additionally, cerebral cortical inhibition increases during the luteal phase, a presumed effect of increased allopregnanolone levels and a finding absent in women with PMDD. Further, women with PMDD have blunted allopregnanolone responses to stress and evidence of altered metabolism of P to allopregnanolone (Klatzkin et al., 2006). Nonetheless, studies to date fail to demonstrate any consistent diagnosis-related differences in allopregnanolone or pregnanolone nor any difference in pregnanolone levels in women with PMDD before and after successful treatment with antidepressants.

HPA AXIS

Reports of HPA axis function in PMDD are inconsistent. Compared with controls, blunted HPA axis responses are

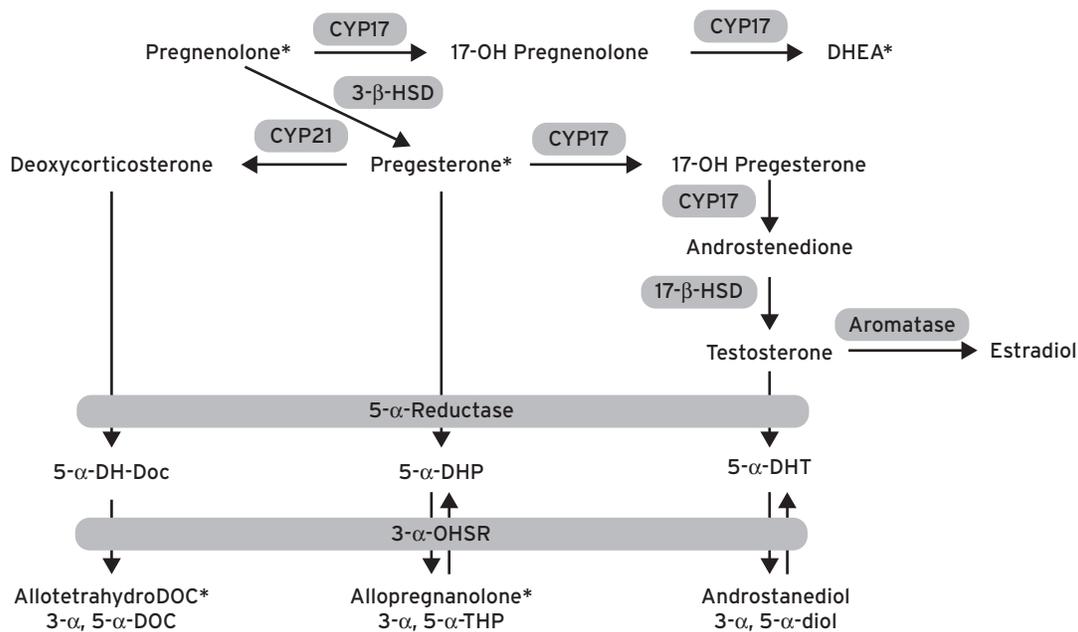

Figure 36.3 DHEA and progesterone-related neurosteroids. Neurosteroids are marked with *.

frequently observed, but both enhanced and normal HPA axis function are reported. Most studies employing either an endocrine challenge or serial plasma sampling suggest that the regulation of plasma cortisol and ACTH secretion at the levels of the hypothalamus, pituitary, and adrenal is normal in women with PMDD. Recently, we performed dexamethasone (Dex)/CRH challenge studies during GnRH agonist-induced hypogonadism with and without physiologic levels of E2 and P replacement in women with prospectively confirmed PMDD and in asymptomatic controls. In both women with PMDD and controls, we confirmed the previous findings by Roca and colleagues (2003), who employed an exercise challenge and showed that P but not E2 significantly increased HPA axis responsivity. However, we observed no significant differences between women with PMDD and asymptomatic controls in any measure of HPA axis function. Thus, in contrast to depression, PMDD is characterized by neither abnormal glucocorticoid feedback regulation nor increased central hypothalamic drive. Although stimulation of the HPA axis with psychological stress or with agents that increase serotonergic function has resulted in reported differences between women with PMDD and controls (e.g., blunted HPA response in PMDD), findings again are inconsistent across studies and permit no conclusion of disturbed HPA axis activity in women with PMDD (Lee et al., 2012). Presently, then, there is no clearly demonstrated luteal phase-specific physiologic abnormality in PMDD.

Given the absence of basal or stimulated reproductive endocrine abnormalities or luteal phase-specific biological abnormalities in PMDD, one could reasonably ask whether the luteal phase is required for the expression of PMDD. We answered this question by blinding women with PMDD to menstrual cycle phase with the progesterone antagonist mifepristone (RU-486) combined with either human chorionic gonadotropin (hCG) or placebo. We observed that women with

PMDD experienced their characteristic premenstrual mood state after the mifepristone-induced menses in both groups, despite the presence of an experimentally induced follicular phase in the women receiving mifepristone alone. The mid- to late luteal phase, then, is clearly not required for the appearance of PMDD symptoms. It, nonetheless, remained possible that symptoms could be triggered by hormonal events prior to the mid- to late luteal phase, consistent with reports that the suppression of ovulation results in a remission of PMDD symptoms.

We confirmed the efficacy shown by others of GnRH agonists (e.g., leuprolide acetate [Lupron]) in the treatment of PMDD. Consistent with earlier observations, a therapeutic response was not observed in all patients despite the consistent reduction of gonadal steroid levels to hypogonadal levels. Although the majority of study participants did show a therapeutic response, the mechanism of action remained unclear (e.g., low plasma gonadal steroid levels, consistent gonadal steroid levels, anovulation, suppression of follicular development). This uncertainty was in part addressed by the double-blind, placebo-controlled reintroduction of E2 or P in the study participants in whom Lupron displayed efficacy. The results unequivocally demonstrated the precipitation of a wide range of characteristic symptoms of PMDD during E2 and P addback but not during placebo addback (reviewed in Rubinow and Schmidt, 2006). The combined results from our study and those of earlier studies strongly suggest the role of gonadal steroids in the occurrence of PMDD symptoms despite the absence of evidence for abnormal levels of steroid hormones in this disorder. Particularly striking, however, is the observation that controls lacking a history of PMDD and going through the same protocol showed no perturbation of mood during hypogonadism and no mood disturbance during hormonal addback. It would appear, therefore, that women with a history

of PMDD are *differentially sensitive* to the mood-perturbing effects of gonadal steroids, as similar steroid manipulations in women without a history of PMDD are without effect.

TRIGGER AND SUSCEPTIBILITY

New neurobiological models: If gonadal steroids trigger PMDD in some women, how do they do so and why not in all women?

Trigger

To determine whether the steroid-induced mood disturbances in women with PMDD are caused by the change in hormone levels or by a permissive effect of elevated hormone levels on expression of an infradian driver, we recently administered Lupron followed by three months of continuous E2 and P replacement. This paradigm demonstrated that it is the change in gonadal steroids that triggers the mood disturbance; that is, reintroduction of gonadal steroids precipitated a self-limited episode with no subsequent dysphoria over the remainder of the three months. These findings suggest that continuous administration of oral contraceptives might, after the first precipitated episode, effectively prevent the recurrence of all other symptoms (due to the stable hormone levels). Possibly consistent with this hypothesis is the recent demonstration of the efficacy of oral contraceptives when administered with a reduced pill-free interval. Several examples exist of the ability of changes in hormones to convey important biological regulatory information. Particularly notable is the demonstration by Shen and colleagues (2005) that withdrawal of allopregnanolone reconfigures hippocampal GABA receptors (changes its subunits) to completely reverse the effects of allopregnanolone on chloride ion conductance, resulting in hippocampal excitability rather than suppression following subsequent exposure to allopregnanolone. The nature of the trigger aside, one must explain why changes in gonadal steroids provoke mood changes only in some women; that is, what is the source of the susceptibility to steroid-induced mood changes?

Susceptibility

There is precedent for inferring that polymorphisms in genes involved in the gonadal steroid signaling pathway or in gonadal steroid-regulated genes may alter the nature or strength of the steroid signal as well as the phenotype. Although some earlier candidate gene studies did not find significant associations with PMDD, we identified a region of the ER α gene (*ESR1*) containing multiple polymorphic alleles that are associated with PMDD (Huo et al., 2007). Further, this association was significant in only those women with the val/val genotype of the COMT Val158Met polymorphism, thus lending support to the idea that the effects of multiple genes may interact in creating a dysphoric behavioral response to normal gonadal steroid levels.

Demonstration of a relationship between genetic variations in *ESR1* and PMDD is very promising for several reasons. First, ER α plays a major role in arousal, the dysfunction of which could underlie somatic, cognitive, and affective symptoms of PMDD. Second, ER α regulates the signaling of neurotransmitter systems implicated in the etiopathogenesis and treatment

of PMDD. For example, extensive links exist between E2 and serotonin function, with the latter involved in mood regulation and the selective therapeutic effects of SSRIs in PMDD. At least some of the effects of E2 are mediated through serotonin 1A receptors, which are upregulated through nuclear factor-kappa B (NF- κ B) by ER α but not ER β (Wissink et al., 2001). Third, the ER has clear physiologic relevance in PMDD as the receptor for a hormone that can trigger the onset of symptoms of the disorder. Finally, a speculative model for PMDD can be created based on interactions between E2, ER α , and COMT: The variants in *ESR1* that associate with PMDD do so only in the presence of the COMT val/val polymorphism, which regulates PFC dopamine (as well as participating in the metabolism of E2). E2, which has been shown to provoke symptoms of PMDD, also regulates the activation in brain regions (e.g., PFC, OFC, amygdala, BA25) and brain networks (e.g., reward circuitry) critical to affect as well as the connectivity between the PFC and hippocampus. "Disordered" E2 signaling through ER α , then, could contribute to and combine with reduced PFC dopamine to compromise top-down cortical regulation of affect. Although speculative, this hypothesis receives indirect support from two observations: (1) the increased mOFC activation seen normally during the luteal phase is absent in women with PMDD (in association with greater amygdalar response to negative stimuli and less activation of the ventral striatum to positive stimuli); and (2) more recently, women with PMDD were found to demonstrate overactivation of the dlPFC on both PET and fMRI compared with control women, with the degree of overactivation significantly correlated with the degree of symptomatic impairment.

SUMMARY

To identify what the study of PMDD may contribute to our understanding of the effects of gonadal steroids on brain and behavior, several observations must be integrated. First, there does not appear to be a disturbance of reproductive endocrine function that underlies PMDD. Second, changes in levels of E2 and P appear to be capable of triggering mood disturbances in a susceptible population; that is, some preexisting vulnerability must explain the capacity of the same biologic stimulus (e.g., gonadal steroids) to elicit a differential behavioral response across groups of people. Third, perturbations of nonreproductive endocrine systems appear capable of precipitating PMDD. Menstrual cycle-related mood disorders may appear in the context of hypothyroidism (with symptoms responsive to thyroid hormone replacement), and provocative and especially treatment studies suggest the relevance of the serotonin system to PMDD. Menstrual cycle-related mood disorders, then, may represent a behavioral state that is triggered by a reproductive endocrine stimulus in those who may be rendered susceptible to behavioral state changes by antecedent experiential events (e.g., history of major depression) or physical or sexual abuse or biological conditions (e.g., hypothyroidism). Treatment can, therefore, be directed to either eliminating the trigger (e.g., ovarian suppression) or correcting the "vulnerability" (e.g., serotonergic antidepressants). Although the means by which alterations in gonadal steroids trigger changes in behavioral state in certain individuals are unclear, it is nonetheless

striking that, in contrast to the pathological function of other endocrine systems (e.g., adrenal, thyroid) seen in association with mood disorders, gonadal steroids may precipitate mood disturbances in the context of normal ovarian function. This suggests that further study of the interactions between gonadal steroids and other neuroactive systems may help elucidate general mechanisms underlying affective regulation as well as the physiologic substrate that predisposes certain people to experience reproductive endocrine-related mood disorders.

POSTPARTUM PSYCHIATRIC DISORDERS

Affective syndromes that occur during the postpartum period have traditionally been divided into three categories: (1) postpartum “blues,” (2) postpartum depression (PPD), and (3) puerperal psychosis. PPD is associated with more persistent symptoms and a higher rate of morbidity than the “blues” but is less severe (depressions of minor to moderate severity) than postpartum psychotic depressions. The two- to three-month prevalence rates of postpartum depression in studies using conventional diagnostic criteria (e.g., RDC, DSM-III) have been reported to be in the range of 8.2% to 19.2% (Gavin et al., 2005; Wisner et al., 2002). Some studies have reported that the incidence of depression is increased significantly during the first three months after birth as compared with during prepregnancy, pregnancy, or the period after the first postpartum year. Others have disputed this association, arguing that the prevalence of depression during the postpartum period is no greater than that in comparably aged non-puerperal women. In fact, recent epidemiologic studies observed that the last trimester of pregnancy also was associated with an increased prevalence of depression compared with the postpartum. Thus, the peripartum (last trimester and early postpartum) is not associated with an increased prevalence of major or minor depression. Nonetheless, it is not the increased prevalence of depression but the linkage of the onset of depression to a specific phase of reproductive change that distinguishes this condition.

HORMONE STUDIES OF POSTPARTUM DEPRESSION

A number of studies have attempted to determine the relationship between postpartum mood symptoms and gonadal steroid levels by examining basal levels, or changes in levels, during pregnancy and the postpartum period. As reviewed by Bloch and colleagues (2003), most studies of women with PPD showed that plasma E2 and P levels were indistinguishable from controls, although one found higher P in women who went on to develop PPD. In addition to levels of E2 and P, studies have focused on measures that may predict a woman's vulnerability to develop gonadal steroid-induced depression. Examples of such measures include apomorphine-induced growth hormone response and alterations in neurosteroid levels in postpartum psychiatric illness. Wieck and colleagues (1991) demonstrated that an increased growth hormone response to apomorphine on postpartum day four (before the usual onset of illness) was associated with an increased risk of a recurrent episode of depression. The authors speculated that these findings reflected increased sensitivity of central

dopamine receptors, which may be triggered by the sharp fall in circulating E2 concentrations after delivery (i.e., E2 uncouples D2 receptors, with an acute upregulation in D2 receptors possibly resulting in psychiatric disturbance following the sudden postpartum drop in E2 levels). As previously described, neurosteroid metabolites of gonadal steroids are known to have acute, nongenomic modulatory effects at GABA and glutamate receptors. Levels of one such potent P metabolite, allopregnanolone, rise progressively during pregnancy and drop relatively abruptly after parturition (as levels are closely correlated with plasma P levels). Preliminary data (Daly, unpublished data) suggest that women with a history of PPD show a significant correlation between decreasing levels of this anxiolytic neurosteroid and mood symptoms. Pearson-Murphy also has suggested a role for alterations in P metabolites in PPD, with higher levels of 5- α -dihydroprogesterone observed in depressed patients compared with controls during the last trimester of pregnancy (Pearson-Murphy et al., 2001). To summarize the preceding data, no consistent differences in gonadal steroid levels have been demonstrated, either in pregnancy or the postpartum, between women with and those without PPD, suggesting that the condition does not represent a simple gonadal steroid excess or deficiency state.

Higher cortisol levels at the end of pregnancy have been reported in association with more severe blues, and cortisol levels have been shown to correlate with postpartum mood in breastfeeding mothers during the first week postpartum. Most studies, however, have failed to show any association of blues or PPD with plasma or salivary cortisol or with urinary metabolites (reviewed in Bloch et al., 2003).

Abnormalities of CRH-stimulated ACTH (but not cortisol) have been reported in mixed samples of PPD and blues. Magiakou and colleagues (1996) showed that women with the blues or PPD had a more severe and longer-lasting suppression of hypothalamic CRH secretion in the postpartum period than euthymic mothers. Additionally, Bloch et al. (2005) observed greater CRH stimulated cortisol in euthymic women with a history of PPD compared with controls during a hormone add-back state simulating pregnancy. These dynamic abnormalities of the HPA axis suggest that adaptive response to stress may be compromised in women who experience or are susceptible to PPD.

Finally, no clear relationship between thyroid dysfunction and PPD exists, and although thyroid dysfunction may contribute to postpartum mood disorders, other factors would appear to play more defining roles in the development of the condition.

IMAGING STUDIES OF POSTPARTUM DEPRESSION

Differences in the neural processing of affective stimuli have also been reported in women with postpartum depression. When compared with healthy mothers, depressed mothers had significantly diminished dorsomedial prefrontal cortex activity and dorsomedial prefrontal cortical-amygdala connectivity in response to negative emotional faces. Reduced amygdala activity in response to negative emotional faces was associated with greater postpartum depression severity

(Moses-Kolko et al., 2010). This is consistent with a recent report of decreased right amygdala activation in response to threat-related linguistic stimuli in unmedicated women with postpartum depressive symptoms. This pattern is distinct from the cerebral activation associated with unipolar depression.

SUMMARY

Although basal reproductive hormone levels do not distinguish women with PPD from those without the disorder, a role of gonadal steroids in this disorder may nonetheless be inferred from a study that created a scaled-down model of the peripartum in euthymic women with a history of PPD compared with those lacking a history of depression. After suppressing ovarian function with leuprolide acetate, Bloch and colleagues (2000) blindly added back high-dose E2 and P for eight weeks followed by blinded and acute withdrawal of steroid addback. As shown in Figure 36.4, euthymic women with a history of PPD developed depression during high-dose addback, with greater depression demonstrated during the acute withdrawal phase. In contrast, no symptoms of depression were observed in the control group undergoing the same protocol. These findings suggest that, as is the case with PMDD, changes in reproductive steroid signaling can precipitate depression, but only in a susceptible subgroup of women.

It is unclear whether it is prolonged, high dose steroid exposure or steroid withdrawal that is the offending stimulus, perhaps mirroring the clinical observation that the onset of depressive symptoms in some women who develop PPD occurs during pregnancy rather than solely following parturition. Our data would, nonetheless, suggest that alterations in the levels of gonadal steroids are implicated in the development of perinatal depression, either during the period of elevated levels

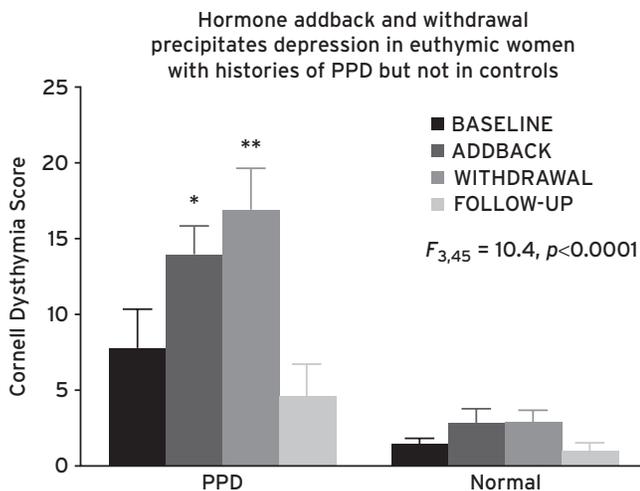

Figure 36.4 Mean Scores on the Cornell Dysthymia Scale before and after estradiol and progesterone replacement in women with a history of postpartum depression ($n = 8$) and normal controls ($n = 8$).^a

^aStudy phases: 8-week baseline, when no medications were administered; 12 weeks of leuprolide-induced ovarian suppression, with addback of estradiol (4–10 mg/day) and progesterone (400–900 mg/day) during the last 8 weeks; 4-week early withdrawal, when estradiol and progesterone were withdrawn but leuprolide continued; and 8-week follow-up, when no medications were administered. * Addback vs. baseline, $p < .05$. ** Withdrawal vs baseline, $p < .01$ (Bonferroni corrected t tests)

or during withdrawal from such levels. In summary, gonadal steroids appear to play a key role in the development of PPD, but the exact nature of this role has yet to be fully determined. Only a subgroup of women appear to have an underlying biological sensitivity that ultimately manifests as PPD.

PERIMENOPAUSAL DEPRESSION

As with PPD and PMDD, epidemiologic studies observe that only a subgroup of women are at risk for the development of depressive disorders during the menopause transition. Moreover, like PPD, it is unclear whether there is any increased prevalence of depression during the perimenopause compared with other stages of a woman's life. Thus, reproductive aging is not uniformly associated with affective disturbance. Nonetheless, several longitudinal community-based studies have documented an increased risk for depression during the menopause transition compared with the premenopause and the postmenopause, with odds ratios ranging from 1.8 to 2.9 compared with the premenopause (reviewed in Harsh et al., 2009). In particular, two studies (Cohen et al., 2006; Freeman et al., 2006) observed a 2- to 2.5-times greater risk for the first onset of depression during the late menopause transition compared with the premenopause. These data suggest that ovarian aging and the events surrounding the final menstrual period increase vulnerability to depression in some women.

Predictors of vulnerability to perimenopausal depression include longer duration of the menopause transition time, vasomotor symptoms, stressful life events proximate to the menopausal transition, and histories of depression, although none of the characteristics are uniform antecedents to perimenopausal depression. In a small clinic-based longitudinal study, we observed that most depressions appeared during the late stage of the menopause transition, which is characterized by more prolonged hypogonadism than the early perimenopause. Thus the timing suggests an endocrine mechanism related to the perimenopause (E2 withdrawal and/or recent-onset of prolonged hypogonadism) in the pathophysiology of perimenopausal depression. It is possible that fluctuating levels of gonadal steroid hormones interact with individual characteristics (e.g., sensitivity to stress, histories of depression) in some women to increase their vulnerability to develop perimenopausal depression. Individual physiologic or historical characteristics may indeed provide the context in which the response to a biological signal is determined (Rubinow et al., 2002). On the other hand, vulnerability to E2 withdrawal/fluctuations may have a genetic basis, as suggested by the heritability of the puerperal trigger in postpartum disorders (Jones and Craddock, 2007), the heritability of premenstrual symptomatology (Kendler et al., 1992), and the significant association of PMDD with intron 4 SNPs in ER α (Huo et al., 2007).

HORMONE STUDIES OF PERIMENOPAUSAL DEPRESSION

The relevance of changes in pituitary-ovarian function to depression during the perimenopause is suggested by evidence that mood symptoms may change coincidentally with FSH levels and that E2 therapy has acute mood-enhancing effects in

perimenopausal women with depression (Schmidt et al., 2000; Soares et al., 2001).

Despite a few studies identifying levels of one hormone or another (e.g., estrone, FSH) as different in perimenopausal depressed women compared with controls, subsequent studies have been unable to confirm any diagnosis-related differences in reproductive hormones. A possible exception are the levels of the adrenal androgen dehydroepiandrosterone (DHEA) and its sulfated metabolite, DHEA-S, both of which were observed to be lower in women with perimenopausal depression as well as inversely correlated (DHEA) with symptoms of depression in peri- and postmenopausal women (Rubinow et al., 2002). Limitations of basal hormonal measures notwithstanding, data suggest that depressed perimenopausal women are not distinguished from nondepressed perimenopausal women by being “more” estrogen deficient.

HORMONE THERAPIES FOR PERIMENOPAUSAL DEPRESSION

Multiple reports of increased mood symptoms and depressive disorders during the menopause date back more than 150 years and generated the belief that reversal of these symptoms could be achieved with ovarian hormone replacement. Controversy regarding the antidepressant efficacy of hormone replacement stems almost from its inception and reflects the same methodological inconsistencies that have compromised efforts to determine whether the perimenopause is accompanied by an increase in mood symptoms or depression. Methodological differences of note (other than study design) include menopausal state (perimenopause vs. postmenopause), determination of state (earlier studies used age as a proxy measure), baseline symptomatology (asymptomatic vs. depressive symptoms vs. syndromic depression), and symptom or syndrome measure.

A meta-analytic examination of 26 studies of the effects of HRT on depressed mood revealed a moderate to large effect size of 0.68, showing lower ratings of depressed mood in treated patients compared with controls (Zweifel and O'Brien, 1997). Baseline symptom rating scores were suggestive of syndromal depression in only two of these studies. Twenty-two additional studies have been published since this earlier meta-analysis, nine of which are double-blind and placebo-controlled.

Two general categories of randomized controlled trials have been performed and, as noted in the following, observed findings may differ as a function of the menopausal status of the samples (i.e., postmenopausal vs. perimenopausal):

Non-depressed patients

Among the double-blind, placebo-controlled studies, two had large sample sizes and showed no effect of HRT (conjugated equine estrogen plus medroxyprogesterone acetate) on affective symptoms in postmenopausal women, but subjects in both studies were affectively asymptomatic at baseline or discouraged from participating if menopausal symptoms were present. These studies then provide moderate-strong evidence for a statement of limited clinical value: HRT does not prevent symptoms of depression in an asymptomatic, postmenopausal population. Data from the HERS study suggested that among postmenopausal women, those with menopausal symptoms

showed lower depressive symptoms on HRT than those lacking menopausal symptoms.

Depressed patients

Two small randomized, placebo-controlled trials demonstrated the antidepressant efficacy of transdermal E2 in depressed, perimenopausal women. Subjects selected met diagnostic criteria for depression and were followed with standard syndrome rating scales. A study employing similar methodology failed to show antidepressant efficacy of transdermal E2 in a postmenopausal sample. One study did demonstrate antidepressant efficacy of a continuous combined HRT preparation in postmenopausal women selected with diagnostic criteria for the presence of mild-moderate depression. This study was performed by the makers of the HRT preparation and, while methodologically sound, showed a very high drop-out rate (Santen et al., 2010). An additional 14 studies are either observational, open-label, or methodologically compromised, thus providing less compelling evidence regarding the antidepressant efficacy of ERT or HRT. Notwithstanding the small sample sizes in the few well-designed trials in depressed perimenopausal women, there is evidence (low-moderate) for the antidepressant efficacy of E2 in perimenopausal but not postmenopausal women.

SUMMARY

Despite the antidepressant efficacy of E2 and the linkage of perimenopausal depression to a time of E2 withdrawal, we still do not have direct evidence that E2 withdrawal triggers the onset of depression in these women. Preliminary observations from a study of the effects on mood of E2 withdrawal suggest, however, that women with a history of depression during the perimenopause, but not those lacking such a history, experience a recurrence of depressive symptoms when E2 is withdrawn under blinded, placebo-controlled conditions (Schmidt et al., unpublished observation). The ability of fluctuations in hormones during the menopause transition to contribute to the development of depression in vulnerable women is supported by the work of Freeman and colleagues (Freeman et al., 2006). These authors showed that greater variability in E2 concentrations, and not E2 concentrations per se, was associated with both elevated depressive symptomatology as well as diagnosed major depressive disorder during the menopause transition. As with PMDD and PPD, therefore, a reproductive endocrine signal, in this case low or declining E2 levels, can be shown to trigger depression during the perimenopause, but only in a susceptible population.

MIDLIFE DEPRESSION

Midlife also may be associated with the onset of depression in both men and women. Indeed several epidemiologic studies report a recent increase in suicide rates in white men and women during midlife, despite overall stable or declining rates at other stages of life. Depressions that present at midlife can often reflect the onset of medical illness; however, depression at this stage in life also can increase the risk for several midlife-relevant medical illnesses, including heart disease and dementia. Further complicating the picture, the clinical presentation of midlife depression

often is focused on symptoms (e.g., low energy, decreased libido, and cognitive decline) that can obscure the underlying depressive illness. The fifth and sixth decades of life are accompanied by several endocrine events related to aging, including changes in growth and metabolism, alterations in HPA axis function, and age-related changes in both gonadal and adrenal androgen secretion. In addition to the precipitous changes in E2 and P in women during the perimenopause, androgen levels—T, DHT, DHEA, and androstenedione—also decrease during midlife in both men and women. However, in contrast to the relatively rapid declines in ovarian E2 and P secretion, androgen secretion declines more gradually in both men and women. Thus declining androgen secretion potentially could lead to a more insidious onset of depressive symptoms. Nonetheless, studies suggest that the age-related decline in androgen secretion occurs in the majority of midlife men and women in the absence of accompanying depression. Thus as with other reproductive endocrine-related depressions, midlife-onset depression could reflect the effects of declining androgen secretion in the context of other individual characteristics that increase a man or woman's risks for depression. However, in midlife depressions the effects of aging on several behaviorally relevant physiologic systems including the HPA axis, insulin-like growth factors, thyroid function, and other metabolic systems must be considered as potential contributors to the onset of depression at this time in life.

ANDROGENS AND MOOD IN MEN

Beginning in the third decade, there is a slow but continuous, age-dependent decline of T levels (1% decrease each year). This decline is more pronounced for free T than for total T, a consequence of the age-associated increase of sex hormone-binding globulin (SHBG) levels. At age 75, mean total T level in the morning is about two-thirds of the mean level at ages 20–30, whereas the mean FT and bioactive T (FT plus albumin bound T) level are only 40% of the mean levels in younger males. The circadian rhythm of plasma T levels, with higher levels in the morning than in the evening, is generally lost in elderly men as well (Kaufman and Vermeulen, 2005).

Plasma androstenedione levels vary between 2 and 8 nmol/liter in adult males aged 20 to 30 years and significantly decline with age. Serum concentrations of DHEA decline more rapidly and more profoundly than those of T—approximately 2% per year (Kaufman and Vermeulen, 2005).

There are three different aspects to the changes in serum testosterone levels in aging men:

1. *Primary testicular changes:* There is a diminished secretory capacity of the Leydig cells in the elderly compared with young men. This decrease in testicular secretory reserve appears to involve a reduction of the number of Leydig cells. Also in rats, all enzymes involved in the synthesis of T are decreased with aging, as is the steroidogenic acute regulatory protein, which is involved in the transport of cholesterol into mitochondria.
2. *Altered neuroendocrine regulation of Leydig cell function:* There is reduced hypothalamic secretion of GnRH,

resulting in inadequate stimulation of LH secretion by the pituitary gland.

3. *Increase of plasma SHBG binding capacity:* The decline of the serum levels of FT is accentuated relative to that of total serum T, as a consequence of an age-associated increase of serum SHBG (Kaufman and Vermeulen, 2005).

Findings from cross-sectional and longitudinal studies of testosterone and mood in men have been inconsistent. Studies are fairly equally divided between those that have demonstrated lower T in depressed men than in controls and those that have shown no difference in absolute levels. Inconsistencies in the literature may be due to small sample sizes and different diagnostic assessments of depression in different study samples. However, data are most consistent with the interpretation that if there is any functional effect of MDD on the male HPG-axis, it is likely to be small. Some clinical data suggest that low T, persisting over years, may lead to a chronic, low-grade, depressive illness such as dysthymic disorder rather than to MDD. Nonetheless, caution must be employed in interpreting low T values, in men or women, consequent to the unreliability of assay in the low range.

Early studies on the antidepressant effects of T suggested that a significant number of depressed men responded dramatically to T replacement therapy and relapsed when treatment was discontinued. Standardized psychiatric diagnoses were not used in these studies, however, and baseline hormone levels were not assessed. More recently, a double-blind, randomized trial of T replacement versus placebo in 30 men with MDD and hypogonadism found T replacement indistinguishable from placebo in antidepressant efficacy: 38% responded to T and 41% responded to placebo (Seidman et al., 2001). A study by Pope of 22 hypogonadal men with partial response to SSRIs found that those randomized to T gel had significantly greater improvement in depressive symptoms than subjects randomized to placebo. A subsequent study, also by Pope, of 100 hypogonadal men with partial SSRI response randomized to augmentation with T or placebo gel failed to show a significant difference between groups (Pope, 2010). Most clinical trials of T therapy for depression have included 30 or fewer subjects, too few to reliably detect small antidepressant effects. Overall, systematic trials do not support T as a broadly effective antidepressant. It may be more effective in certain populations, such as antidepressant-resistant men or HIV-infected men.

ANDROGENS AND MOOD IN WOMEN

Women experience an approximately 50% drop in T due to loss of ovarian function (the other 50% is adrenal in origin in women). A role for DHEA and DHEA-S in the regulation of mood state has been suggested by both its effects on neural physiology (Baulieu et al., 1998) and its potential synthesis within the central nervous system. Moreover, in clinical trials, DHEA administration has been reported to improve mood in some (Bloch et al., 1999; Wolkowitz et al., 1999), but not all, studies (Wolf et al., 1997). Finally, abnormalities of DHEA secretion have been observed in depressive disorders, with

both increased and decreased levels observed relative to non-depressed controls (Heuser et al., 1998). DHEA's potential role in the onset of depression may be particularly relevant at midlife given the declining levels of DHEA production with aging and the accelerated decrease in DHEA levels reported in women, but not men, during midlife (Laughlin and Barrett-Connor, 2000).

CONCLUSIONS

The differential sensitivity to gonadal steroids seen in women with histories of PMDD and PPD (and possibly perimenopausal depression) emphasizes that the response to a biological signal cannot be inferred absent an understanding of the context in which the signal occurs. This context includes current physiological and external environments, prior experience, past history of exposure to the stimulus, and genetic makeup. Data already exist from both animal and human studies in support of the importance of genetic context in determining the response to a reproductive steroid signal. Spearow and colleagues (1999) demonstrated greater than 16-fold differences in sensitivity to E2 (reproductive disruption) across six different mouse strains, with genotype accounting for more of the variation than the hormone dose. Similarly, we observed strain differences in the behavioral impact of E2: antidepressant-like effects in Long Evans but not Wistar rats, and depression-like effects of E2 withdrawal in Wistar but not Long Evans. Finn and colleagues (1997) observed strain/genetic (and task-dependent) differences in behavioral sensitivity to allopregnanolone. Several studies suggest that steroid receptor polymorphisms may alter the steroid signaling pathway (e.g., by increasing transcriptional efficiency) in such a way as to produce or contribute to a different behavioral/phenotypic response to a hormone signal. Indeed, possible genetic susceptibility loci for PMDD and puerperal psychosis have been identified (Huo et al., 2007; Jones and Craddock, 2007). More interesting and compelling, however, are the demonstrations that while both genetic and reproductive steroid effects on behavior exist, their interactions are the most relevant and powerful in determining phenotypic expression. Maguire and Mody (2008) showed that the behavioral effect of a mutation in the delta subunit of the GABA receptor was expressed only in the context of a specific reproductive state—postdelivery—at which time the dams displayed depressive-like behavior and killed their pups. Similarly, the effects of a COMT polymorphism on cognitive performance are entirely dependent on the presence or absence of E2 (Jacobs and D'Esposito, 2011). At the very least, it is time to recognize the importance of context, at the behavioral level no less than at the cellular level, in determining the response to a steroid signal. By understanding the mechanisms underlying the differential sensitivity to gonadal steroids exemplified by women with PMDD, PPD, and perimenopausal depression, we will be in a far better position to answer what is arguably the most important question in behavioral neuroscience: Why do different people respond differently to the same stimulus?

DISCLOSURES

Dr. Rubinow serves on the Editorial Board of *Dialogues in Clinical Neuroscience*, for which he receives compensation. He additionally has served on the Scientific Advisory Board of Azevan Pharmaceuticals, for which he has received stock options. Dr. Rubinow receives no other funding or material support other than his NIMH grant support (three ROIs and a T32 training grant).

Dr. Craft and Dr. Schmidt have no conflicts of interest to disclose.

37 | DEPRESSION AND MEDICAL ILLNESS

TAMI D. BENTON, JOSHUA BLUME, PAUL CRITS-CHRISTOPH, BENOIT DUBÉ,
AND DWIGHT L. EVANS

Increasing recognition of the impact of depression on physical health has prompted focused investigation on its diagnosis and treatment. The World Health Organization (WHO) projects that depression will be the leading cause of life lost to disability in 2030, imposing a greater health burden than ischemic heart disease (WHO, 2008). The report also emphasized depression's contribution to morbidity and mortality. Depression is a risk factor for the onset and progression of both physical and social disability (Prince et al., 2007; WHO, 2008). Additionally, individuals with depression and other mental illnesses may develop their health conditions earlier due to behavioral and biological factors related to their mental illnesses, and they may die earlier from comorbid medical illness (Sullivan et al., 2012).

Evidence that adverse health risk behaviors and the presence of depression increases risk for medical disorders, and that the presence of a medical disorder may increase risk for depression has prompted examination of the bidirectional relationship between depression and medical illness (Evans et al., 2005). Further support for these observations has been provided by recent research identifying a potential role for inflammatory responses in the pathophysiology of depression, finding higher levels of pro-inflammatory cytokines, acute phase proteins, chemokines, and cellular adhesion molecules in depression (Blume et al., 2011; Dantzer et al., 2008).

In this chapter, we will review the relevant recent research linking depression and medical illness. We will present an overview of the bidirectional relationship between depression and medical illness. We will review existing research on the possible mechanism for the connection between depression and medical illness, focusing on the connection between depression and several specific medical illnesses (cardiac disease, diabetes, HIV/AIDS, cancer). We then outline basics of the assessment of depression in the context of medical illness. We conclude with a presentation of treatment considerations for depression in specific medically ill populations.

PREVALENCE OF DEPRESSION IN THE MEDICALLY ILL

Depressive disorders are more prevalent among the medically ill when compared to the general population of the United States. The average lifetime prevalence of depression is about 16.6% of the US population and is two times more prevalent in

women when compared to men (Kessler et al., 2005). Those with chronic medical illnesses are two to three times more likely to be depressed than age- and gender-matched non-medically ill individuals in community-based primary care settings (Katon, 2011). The prevalence of depression among individuals who are medically ill ranges from 3% to 10% in community and primary care settings and up to 10–14% in inpatient medical settings (Katon, 2003). Prevalence estimates for depressive disorders among those populations with specific medical conditions are even higher, ranging from 20% to 55% (Evans et al., 2005) (Table 37.1).

MECHANISMS OF COMORBIDITY FOR DEPRESSION AND MEDICAL ILLNESS

Recent research examining depression among medically ill populations has sought to link the inflammatory processes underlying specific disorders such as cardiovascular disease, diabetes, and cancer, to those inflammatory processes underlying major depression. Emerging evidence suggests that depressive disorders may be conditions of immune dysregulation, specifically activation of the inflammatory response system (Dowlati et al., 2010; Raison et al., 2009). These theories gain support from the observation that the treatment of patients with cytokines can produce symptoms of depression, antidepressant treatments can reverse those symptoms, and immune system activation is present in some, but not all, individuals with depression. Additionally, cytokine mediated signaling to the brain can influence the production and metabolism of neurotransmitters relevant to mood disorders and its treatments including serotonin, dopamine, and catecholamines (Raison et al., 2009).

A decade of investigation has established the contribution of cytokines to the pathogenesis of depression. Cytokines are proteins and glycoproteins secreted by immune cells that function as signals among and between immune cells. Cytokines are the hormones of the immune system. They can be secreted by immune and nonimmune cells and can affect cells outside of the immune system. They function locally and systemically to modulate and regulate immune functions throughout the body, including those of the central nervous system.

The role of cytokines in the pathogenesis of depression has been confirmed by clinical and experimental observations. Several studies comparing cytokines in people with MDD have found increases in certain cytokines compared to people without MDD (Miller et al., 2009; Raison et al.,

TABLE 37.1. Depression in patients with comorbid medical illness

COMORBID MEDICAL ILLNESS	PREVALENCE RATE (%)
Cardiac disease	17–27
Cerebrovascular disease	14–19
Alzheimer’s disease	30–50
Parkinson’s disease	4–75
Epilepsy	
Recurrent	20–55
Controlled	3–9
Diabetes	
Self-reported	26
Diagnostic interview	9
Cancer	22–29
HIV/AIDS	5–20
Pain	30–54
Obesity	20–30
General population	10.3

Adapted from Evans et al., 2005, with permission.

2009). Although association does not imply causality, there are many reasons to believe that the abnormalities of inflammation found in depression may contribute to its pathology. Medically ill patients who exhibit immune activation or inflammation secondary to infections, autoimmune diseases, and neoplastic diseases demonstrate higher rates of depression (Nemeroff and Vale, 2005). Cytokines have also been shown to be effective in the treatment of certain cancers, hepatitis C, viral infections, and multiple sclerosis. However, a behavioral syndrome similar to major depression has been observed among these individuals treated with cytokines for the treatment of infectious diseases or cancer. This syndrome referred to as “sickness behavior” is characterized by anhedonia, cognitive dysfunction, anxiety, irritability, psychomotor slowing, anergia, fatigue, anorexia, sleep alterations, and increased sensitivity to pain (Dantzer et al., 2008). Although the exact prevalence is unknown, studies suggest that the incidence of depression associated with cytokine therapy ranges from 0% to 45%, depending on the medical conditions and study designs (Dantzer et al., 2008). Moreover, the behavioral syndrome induced by cytokine treatment has been shown to be responsive to treatment with standard antidepressant medications, suggesting that the behaviors described as the “sickness syndrome” are related to major depression. However, antidepressant treatment has been noted to be more effective on the mood symptoms than on neurovegetative symptoms (Capuron et al., 2002; Constant et al., 2005).

Furthermore, cytokines have been found to influence all of the pathophysiologic domains relevant to depression. Cytokines have been shown to cause alterations in the metabolism of monoamine neurotransmitters relevant to depression, specifically serotonin, dopamine (DA), and norepinephrine (NE); to have stimulatory effects on HPA axis functioning through activation of corticotropin-releasing hormone (CRH) in the amygdala and the hypothalamus; to induce resistance of nervous, endocrine, and immune system tissues to circulating glucocorticoid hormones stimulating the glucocorticoid resistance found in patients with depression; to induce enzymes that metabolize tryptophan the primary precursor of serotonin, and may inhibit pathways involved in thyroid hormone metabolism and to activate NF- κ B, a transcription factor that signals the inflammatory cascade in the brain (Dantzer et al., 2008; Irwin and Miller, 2007; Raison et al., 2009).

Despite growing evidence that dysregulation of the immune system may contribute to the pathogenesis of major depression, other studies have found conflicting results or no association between depression and immune parameters or inflammation (Blume et al., 2011; Whooley et al., 2007). One factor that might explain variations between studies is the type of immune system variable or inflammatory marker examined. Pike and Irwin found that, among patients with MDD relative to controls, there was evidence for decreases in NK cell activity (indicating impairment in the immune system) and higher levels of IL-6 (indicating immune activation) (Pike and Irwin, 2006). Furthermore, changes in NK cell activity were not correlated with levels of IL-6, suggesting that depression may have independent effects on these different aspects of the immune system. Alternatively, an emerging literature suggests that while acute inflammation boosts immune defenses, the chronic exposure of immune cells to proinflammatory cytokines may actually result in impaired cellular immunity (Medzhitov, 2008). Thus depression-associated chronic activation of the immune system may lead to immune deficiency resulting in increased vulnerability to cancer and infection (Blume et al., 2011). Miller points out that causality may also operate in the other direction: depression is associated with impaired regulatory T cells, which modulate innate immune responses (Miller, 2010). Thus, depression-associated cellular immune suppression may contribute to chronic inflammation, and the pathogenesis of diseases—such as atherosclerosis and cancer, in which inflammation has been implicated.

Further observations supporting the relationships between chronic inflammation and cellular immune suppression have been demonstrated among two of the most common rheumatologic disorders, rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE). SLE is an autoimmune disorder resulting in tissue and organ damage caused by abnormal immune complexes and T-lymphocytes as well as autoantibodies. RA is characterized by inflammation that primarily affects the synovial tissue of the joints. Both chronic inflammatory disorders have high rates of comorbid depression with prevalence estimates ranging from 13% to 42% in RA (Bruce, 2008) and 10.8% to 39.6% in SLE (Nery et al., 2007), depending on diagnostic methods. Both disorders are characterized by multiorgan systemic involvement affecting the cardiac, vascular,

respiratory, and nervous systems. Direct CNS involvement is rare in RA, however neuropsychiatric manifestations are frequent in SLE. The mainstay of treatments for both disorders include anti-inflammatory agents and other immunosuppressant agents.

Chronic inflammation is present in RA and SLE, and both conditions are characterized by a high frequency of infection, possibly related to impaired circulating T-cells leading to immune suppression (Doran et al., 2002; Gladman et al., 2002; Koetz et al., 2000; La Cava, 2008). In addition, impaired T-cell function has been observed in the synovial fluid of individuals with RA, when the T-cells were chronically exposed to TNF alpha (Cope, 2003), and etanercept, an anti TNF-alpha therapy, has been shown to restore T-cell reactivity in patients with RA (Berg et al., 2001; Blume et al., 2011). Dysregulation of immune T-cell tolerance, and decreased numbers and/or functioning of suppressive CD4CD25 T-regulatory cells have been observed in peripheral blood in human models of SLE (La Cava, 2008). Thus, depression associated cellular immune suppression might contribute to inflammation and the pathogenesis of both SLE and RA, as well as atherosclerosis and cancer.

CARDIAC DISEASE

The intimate and clinically relevant connection between depression and cardiovascular disease has been well established. Depression is prevalent across the spectrum of cardiac diseases including coronary artery disease (CAD), unstable angina, acute myocardial infarction, congestive heart failure, and coronary artery bypass graft surgery. Current estimates suggest rates of depression that are significantly higher than in the general population, ranging from 17% to 27% (Rudisch and Nemeroff, 2003). Depressive symptoms increase the risk for the onset of CAD by 1.64-fold. Furthermore, the occurrence of depression within three to four months of a myocardial infarction (MI), predicts a three times greater likelihood of dying in the next year, when compared to individuals without depression following MI (Lett et al., 2004).

Depression appears to be an independent risk factor in cardiac disease, as the connection between depression and cardiac disease does not appear to be due to the association between depression and other known risk factors (e.g., smoking, history of MI). Depression has been found to be a significant predictor of mortality 6 and 18 months following MI, even after adjusting for other risk factors such as left ventricular dysfunction and previous MI (Frasure-Smith et al., 1995).

MECHANISMS OF COMORBIDITY

Several possible mechanisms linking depression to cardiovascular diseases have been proposed. These include inflammation, hypothalamic-pituitary-adrenocortical dysregulation, sympathomedullary hyperactivity, increased platelet activity and aggregation, autonomic dysfunction causing reduced heart rate variability (HRV), and endothelial dysfunction (Celano and Huffman, 2011; Skala et al., 2006).

It is well known that HPA axis dysregulation occurs in depression and that administration of corticosteroids is associated with increases in cardiovascular disease risk factors,

including hypercholesterolemia, hypertriglyceridemia, and hypertension. Consistent with this potential mechanism, elevated plasma cortisol has been found to be associated with moderate to severe coronary atherosclerosis in young and middle aged men.

Sympathoadrenal hyperactivity may mediate the relationship between depression and cardiovascular disease through an effect on platelets. Individuals with depression show increased levels of plasma NE in response to cold or orthostatic challenge, which may enhance platelet activity. Some, but not all studies have found platelet hyperactivity in those with MDD. Recent studies of depressed patients with ischemic heart disease show elevated platelet factor 4 and plasma b-thromboglobulin levels (Celano and Huffman, 2011).

Inflammatory responses may partly underlie the relationship between depression and cardiovascular disease. The inflammatory markers IL-6, TNF-a, and C reactive protein (CRP) are associated with cardiovascular and cerebrovascular events, specifically CHD, congestive heart failure, and stroke (Cesari et al., 2003). Increases in circulating levels of IL-6 and CRP are also found in depression (Dowlati et al., 2010). Other studies examining the relationships between depression and inflammation in cardiac disease have found elevations in CRP and serum amyloid A (SAA) in women treated for major depression who are in remission, suggesting a sustained proinflammatory state in women who have clinically recovered and who no longer take antidepressant medications. The authors suggest that the persistence of a "proinflammatory state" might contribute to the increased CAD risk associated with MDD (Kling et al., 2007).

Statins are drugs routinely administered to patients post-MI for their lipid lowering and anti-inflammatory properties. Stafford and Berk investigated the effect of statins on the onset of depression in hospitalized cardiac patients, hypothesizing that the anti-inflammatory effect of statins would serve as prophylaxis against depression. In support of a link among depression, inflammation, and cardiovascular disease, they found that over nine months postdischarge, statins were associated with a 79% reduction in the likelihood of depression (Stafford and Berk, 2011). Recent findings from the Heart and Soul Study suggest that statin use was associated with a 38% decreased odds of developing depression in their sample, further confirming this association (Otte et al., 2012).

Frasure-Smith and colleagues (2007) assessed 702 individuals (602 men) for depression and inflammatory markers (CRP), IL-6, and soluble adhesion molecules at two months postdischarge for an acute coronary syndrome, and then followed them for two years for major adverse cardiac events defined as cardiac death, survived MI or cardiac arrest, and nonelective revascularization. Of this sample, 102 individuals (78 men) experienced at least one major adverse cardiac event. Elevated scores on the Beck Depression Inventory-II (BDI-II) and current major depression were significantly related to major adverse coronary events over two years, and this association was stronger in men than women. The study also found an association between elevated depressive symptoms, CRP, and soluble intercellular adhesion molecules (sICAM-1), but not IL-6, providing some support for the association between depression and inflammation (Frasure-Smith et al., 2007).

Abnormalities of the autonomic nervous system may be another mechanism linking depression and CAD. HRV, a measure of the balance between sympathetic and parasympathetic inputs to the cardiac conduction system, is often reduced in patients with severe CAD or heart failure. Reduced HRV is associated with ventricular arrhythmias and sudden cardiac death (Dekker et al., 2000). Studies that found diminished HRV in depression raised the possibility that HRV might be the link between depression and CAD (Nahshoni et al., 2004; Stein et al., 2000). One study found that HRV partially mediates the relation between depression and increased risk for mortality after acute myocardial infarction (Carney et al., 2005). HRV has also been found to be associated with increased markers of inflammation in patients with heart failure and acute coronary syndromes.

Depression is also associated with endothelial dysfunction, a putative mechanism of atherosclerotic disease. A study of men and women ages 40 to 84 years old concluded that depressed individuals had impaired flow-mediated dilation of the brachial artery—a measure of endothelial function—compared to non-depressed individuals. The use of antidepressant medication was associated with improved endothelial function. Subsequent investigations have corroborated these findings (Cooper et al., 2010; Pizzi et al., 2008, 2009).

Evidence further suggests that depression may worsen the impact of other cardiac factors. In a study examining risks for cardiac mortality following MI, the highest death rates (60%) for patients at 18 months post-MI were found in a subgroup of patients with elevated depressive symptoms and increased numbers of premature ventricular contractions per hour (PVCs) (Frasure-Smith et al., 1995).

Depression can also indirectly increase the risk of CAD. The pessimism and low energy often found in clinical depression can lead individuals to be less adherent to exercise programs, smoking cessation, dietary changes, and pharmacological interventions for CAD (Glazer et al., 2002; Skala et al., 2006; Wang et al., 2002). Failure to adequately address these risk factors may then put the individual with depression at even greater risk for a future cardiac event.

DIABETES MELLITUS

Depression is common among individuals with diabetes. Among the 23.6 million people in the United States diagnosed with diabetes mellitus (DM), 5–15% have type I diabetes (CDC 2008), with type II diabetes (T2DM) being much more prevalent; however, research suggests that rates of depression are elevated in both. People with diabetes are twice as likely to have depression compared with those without diabetes. Prevalence estimates suggest that 10–15% of individuals with DM are currently affected by depression and that 24–29% of individuals with diabetes will be affected by depression during their lifetimes. The presence of depression has been associated with higher symptom burden; poor adherence to medication, diet, and exercise; and higher hemoglobin A1C levels (Markowitz et al., 2011). Depression has also been associated with increased frequency and severity of diabetes complications including retinopathy, nephropathy, neuropathy, macrovascular

complications including coronary vascular diseases, and sexual dysfunction. Furthermore, depression has been associated with an increased risk of all cause mortality in diabetes, among individuals with and without previous cardiovascular disease (Sullivan et al., 2012). Depressive symptoms and heightened distress, absent a major depression diagnosis, have been found to adversely impact diabetes self-care and diabetes control (Markowitz et al., 2011). Depression with diabetes has been associated with increased health care costs (Katon, 2011).

MECHANISMS OF COMORBIDITY

The mechanisms underlying the well-established association between depression and diabetes remain unknown. Studies seeking to understand these associations have focused on the diagnosis and burden of disease management as a risk for the development of depression, suggesting that depression is a consequence of diabetes (Knol et al., 2007). Other studies have suggested that depression is a risk factor for diabetes (Campayo et al., 2010; Golden et al., 2008; Knol et al., 2007).

Studies examining the bidirectional associations between depression and diabetes have provided conflicting results. Longitudinal studies of clinically depressed older adults in the community found depression to be associated with a 65% increased risk for incident diabetes, and that this association was true for untreated depression and persistent and non-severe depression (Campayo et al., 2010). Golden and colleagues examined incident rates for T2DM in men and women with and without depressive symptoms over five years. They found incidence rates for T2DM of 22.0/1,000 person years for those with increased depression symptoms compared with 16.6/1000 person years for those without increased depressive symptoms. Incident rates for elevated depressive symptoms per 1,000 person years were 36.8 for those with normal fasting glucose; 27.9 for those with impaired fasting glucose; 31.2 for untreated T2DM and 61.9 for treated T2DM. They also found a modest association of baseline depressive symptoms with incident T2DM, which were partially attributed to lifestyle. Both untreated T2DM and impaired FG were inversely associated with incident depressive symptoms, but treated T2DM was positively associated with depressive symptoms (Golden et al., 2008).

The Vietnam experience study (Gale et al., 2010) explored the association between fasting glucose, T2DM (diagnosed and undiagnosed), and depression among middle aged men. Subjects with untreated diabetes had nearly double the odds (1.8 95% CI) of developing major depression compared with men with normal FBGs. Men with known diabetes had triple the odds of MDD (3.82 95% CI). Men with undiagnosed and diagnosed T2DM had higher depression scores, suggesting that there is a positive association between T2DM and depression, even for those who are unaware of their disease.

Several, but not all, studies support the hypothesis that increased depression is a consequence of diabetes. Some studies suggest that the psychosocial burden of diabetes may increase risk for depressive symptoms. Other investigators have found that the perceived disability and awareness of having a chronic illness may impose higher levels of psychologic burden for people with diabetes, particularly if they have low levels of social support (Knol et al., 2007). A meta-analysis by Mezuk and

colleagues found that people with diabetes have a modest (15%) increased risk for depression compared to those without diabetes, but that depression is associated with a 60% increased risk for T2DM (Mezuk et al., 2008). Another meta-analysis examining depression and diabetes, found a 24% increased risk for incident depression among those diagnosed with diabetes compared to people without diabetes, and that rates of incident diabetes were greater for those with previous depressive episodes (Nouwen et al., 2010). However, investigators discovered that patients with chronic illnesses overall who were frequent users of medical care had similar rates of new depression diagnosis.

Further support for depression as a consequence of diabetes is provided by the Utrecht health project, a longitudinal study of a population of adults in the Netherlands. Knoll and colleagues investigated subjects with impaired fasting glucose and undiagnosed diabetes finding no association with increased depressive symptoms, suggesting that depression results from the diagnosis of diabetes. In this study, those diagnosed with diabetes had a 1.7 times risk for depressive symptoms. After adjusting for the number of chronic diseases, risk for depression was no longer significant (Knol et al., 2007).

Although the biological mechanisms underlying the association between depression and diabetes remain unclear, the evidence strongly suggests a bidirectional relationship.

Depression related physiologic alterations have been associated with increased vulnerability of depressed patients to develop T2DM. Efforts to understand the biological relationships underlying the depression-diabetes link have focused on three potential mechanisms: The hypothalamic pituitary adrenal axis (HPA), counter-regulatory effects of the sympathetic and parasympathetic nervous systems, alterations in glucose transport, and immune activation and inflammation (Musselman et al., 2003).

Psychological stress and depression stimulate activation of the HPA axis and sympathetic nervous systems (SNS), resulting in the release of cortisol and increased catecholamine and cytokine production (Dantzer et al., 2008). The release of these hormones (glucocorticoids, catecholamines, growth hormone, glucagon) stimulating both anabolic and catabolic processes involved in glucose regulation may lead to increased insulin resistance, by counteracting insulin's hypoglycemic effects, thus raising blood glucose levels and increasing the risk for diabetes. Increasing levels of cortisol are associated with redistribution of fat from subcutaneous to increased visceral adipose tissue, which results in central adiposity and dyslipidemia (Champaneri et al., 2010).

Another potential mediator implicated in the relationship between depression and diabetes involves cellular glucose transporters. These transporters facilitate the entry of glucose, a necessary metabolic substrate for all mammalian cells, into cells. Entry of glucose into endothelial cells, astrocytes, and neurons are facilitated by GLUT1 and GLUT3 respectively (Musselman et al., 2003).

Studies using positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), both methods for quantifying neuronal activity in the brain by measuring glucose utilization, have shown decreased glucose utilization in the left lateral prefrontal cortex. PET has also shown a

correlation between reduction in LPFC function and depression severity. Further studies are needed to determine whether these alterations in neuronal activity are related to alterations in the glucose transporters. Additionally, since brain glucose consumption does not affect glucose transport, while alterations in plasma glucose does affect glucose transport, further studies will be needed to understand these relationships (Musselman et al., 2003).

Immune activation and cell mediated cytokine production have also been implicated in the relationship between depression and diabetes. Elevations in the proinflammatory cytokines, IL-1, IL-6, and TNF-alpha, have been found in some, but not all, depressed patients (Blume et al., 2011; Dowlati et al., 2010). Proinflammatory cytokine production is also increased in individuals with diabetes (Musselman et al., 2003). Cytokines IL1, IL6, TNF alpha, and IFN gamma, found to induce sickness, exert neural effects that mediate these symptoms.

HIV/AIDS

Meta-analyses of early prevalence studies revealed that those with HIV were nearly twice as likely to have a diagnosis of major depression compared to individuals who were HIV-negative (Ciesla and Roberts, 2001). Prevalence rates of major depression range from about 5% to 20% (Cruess et al., 2003). A number of studies have found that women who were HIV positive may be particularly susceptible to MDD, with rates of current MDD higher in women who are HIV-positive compared to women who were HIV-negative (Evans et al., 2005; Lewis et al., 2010). Large-scale studies of depressive disorders among pediatric patients who are HIV-positive are lacking, but a meta-analysis estimated the prevalence in this population at 25% (Scharko, 2006).

There is considerable evidence that depression impacts the clinical course and treatment of HIV/AIDS. Clinical depression, elevated levels of depressive symptoms, or general psychological stress are associated with poor adherence to antiretroviral treatment, deterioration in psychosocial functioning, more rapid progression of HIV/AIDS, and higher mortality in both men and women before and after the HAART era (Evans et al., 2005; Ickovics et al., 2001; Leserman et al., 2002; Leserman, 2008). One study of over 1,700 women who were HIV-positive followed for 7.5 years found that those with chronic depression had 1.7 times greater odds of dying compared to women without depression (Cook et al., 2004). The impact of depression on mortality remained even after controlling for antiretroviral therapy use, medication adherence, substance abuse, clinical indicators (baseline CD4 count, baseline viral load, baseline HIV symptoms), and demographic factors; the use of mental health services was associated with significantly less AIDS-related mortality.

MECHANISMS OF COMORBIDITY

Although there is now substantial evidence supporting a relationship between depression and HIV disease progression, less is known about the mechanisms underlying this relationship. It is possible that unhealthy lifestyle behaviors may play a mediating role in this relationship between depression and the course of HIV/AIDS, but support for this hypothesis is lacking (Ickovics et al., 2001; Leserman et al., 2002; Leserman, 2003).

Disruption of the HPA axis has been investigated as a possible mediator of the depression-immune relationship. Increased levels of cortisol have been linked to stress and depression in HIV (Gorman et al., 1991), and it is hypothesized that cortisol may adversely influence the immune response and thereby negatively impact HIV disease progression (Evans et al., 2005; Leserman, 2003). In addition, NE has been shown to affect HIV replication (Cole et al., 1998). Another possible mediator is the neuropeptide substance P, which upregulates HIV and is elevated in persons with HIV (Douglas et al., 2001; Ho et al., 1996). The diminished host defense against HIV infection that has been observed in depressed individuals, may result from depression associated alterations in the functioning of killer lymphocytes (NK and cytotoxic T-lymphocytes), thus hastening HIV disease progression (Evans et al., 2002; Ironson et al., 2001; Leserman, 2003). Consistent with this hypothesis, stressful life events, poor social support, and chronic depression have all been associated with more rapid declines in CD4 lymphocyte counts (Burack et al., 1993; Kemeny and Dean, 1995; Kemeny et al., 1995) and progression to AIDS (Ickovics et al., 2001; Leserman et al., 2002; Leserman, 2003, 2008). Recent evidence from *ex vivo* studies suggest that a SSRI or a substance P antagonist may enhance NK immunity in HIV/AIDS adding further evidence to the potential role for NK cells in the host defense against HIV and the role of depression and antidepressant treatment in HIV disease progression (Evans et al., 2008).

Depression also has an effect on adherence to treatment regimens. Patients with HIV and depressive disorders have greater difficulty in accessing antiretroviral therapy and adhering to treatment once accessed. (Rabkin, 2008).

CANCER

The prevalence of depression is higher among those with cancer than in the general population, and prevalence estimates vary across malignancy types and disease severity. Small sample sizes and non-standardized definitions of depression have also hindered research in this area. The general range of prevalence estimates for MDD among patients with cancer has been reported to be 1.5–50% across studies, with an overall rate of 22–29% (Evans et al., 2005; Raison and Miller, 2003).

The presence of depression in individuals with cancer has been associated with poorer prognosis and increased morbidity and mortality (Evans et al., 2005). A recent meta-analysis of 31 studies found that cancer patients with depressive symptoms had a 25% higher mortality and those with major depression had a 39% greater mortality (Satin et al., 2009). A more recent study by Giese-Davis et al. (2011) suggested that depression is an independent risk factor for survival in cancer and found that a decrease in depressive symptoms was associated with longer survival in a secondary analysis of women with metastatic breast cancer who were treated with supportive-expressive group therapy. An emerging preclinical and clinical literature suggests that immune suppression and immune activation in depression may help explain the effects of depression on cancer survival (Blume et al., 2011).

Recent evidence suggests that proinflammatory cytokines released during tissue damage and destruction resulting

from cancer and its treatments may be associated with the onset of depressive symptoms. The inflammatory changes precipitated by these cytokines can have a substantial impact on neurotransmitter function, neuroendocrine function, and behavior, resulting in the “sickness syndrome.”

The observation that a significant percentage of patients with cancer treated with the cytokine IFN- α develop a behavioral syndrome with similarities to major depression has been an impetus for the investigations in this area. Cytokine therapies are well known to cause neurobehavioral symptoms including major depression in up to 50% of patients with cancer undergoing cytokine treatment with IFN- α (Capuron et al., 2002; Musselman et al., 2001a) and IL-2 (Capuron et al., 2004). Among patients with cancer, patients with depression and cancer were found to have significantly higher levels of IL-6 compared to patients with cancer and no depression and healthy controls (Musselman et al., 2001b). More recent studies have found associations between specific depressive symptoms and elevated cytokines; for example, some investigators have found elevated IL-6 concentrations in patients with cancer presenting with fatigue and impaired executive functioning (Collado-Hidalgo et al., 2006). Capuron and colleagues (Capuron et al., 2002, 2004) and Musselman et al. (2001a) have described two distinct behavioral syndromes that occur in individuals who become depressed with cytokine therapies. One syndrome is characterized by depressed mood, anxiety, irritability, and memory and attentional disturbances. This syndrome is reported to occur within the first three months of therapy in susceptible individuals (Capuron et al., 2002, 2004; Musselman et al., 2001a). The other syndrome, characterized by the neurovegetative symptoms of fatigue, psychomotor slowing, anorexia, and altered sleep patterns, occurs within the first few weeks of IFN- α therapy and persists at later stages of therapy (Capuron et al., 2002). These two different syndromes are thought to have different responsiveness to antidepressant treatment. The mood and cognitive symptoms were responsive to pretreatment with paroxetine (Capuron et al., 2002) whereas the neurovegetative symptoms were not, suggesting that these systems may have different pathophysiologic pathways.

Although depressive symptoms are very responsive to antidepressant treatment, the neurovegetative symptoms described in the “sickness syndrome” have been less responsive to antidepressant treatments, perhaps requiring a different treatment approach (Capuron et al., 2002; Raison and Miller, 2003).

ASSESSMENT OF DEPRESSION IN MEDICAL ILLNESS

Many psychological and physical factors can make the diagnosis of depression among those with medical illness challenging for the clinician. The classic signs and symptoms such as depressed mood, dysphoric affect, fatigue, pain, psychomotor retardation, anorexia, weight loss, cognitive impairment, and insomnia can represent demoralization or the medical illness itself. Thoughts of death or desire for a hastened death is not a reliable sign for depressive disorders in this population but may represent demoralization. In several studies, demoralization

has been associated with lower quality of life and a desire for hastened death (Rackley and Bostwick, 2012). The loss of ability to experience pleasure in many activities may also be the result of physical suffering or disability and not a symptom of depression. Some acute medical conditions, such as hypoaffective delirium, or progressive conditions, such as cancers and neurological conditions, have depressive symptoms that may change over time due to the illness or its treatments. Currently, no standardized approach exists for diagnosing depression among individuals who are medically ill. We continue to rely on the mental status examinations and DSM-IV criteria for depression (Evans et al., 2005). Investigators have examined the utility of excluding symptoms that can occur as part of the medical condition and the depressive condition (exclusive approach) versus the more favored inclusive approach that counts all symptoms when making a diagnosis of depression, but the findings have been inconclusive (Newport and Nemeroff, 1998; Raison and Miller, 2003). Fortunately, several well-validated instruments are available to assist the clinician in making the diagnosis of depression in the presence of medical symptoms (Rackley and Bostwick, 2012) (Table 37.2).

TREATMENT OF DEPRESSION IN MEDICAL ILLNESS

Well-controlled trials examining the efficacy of antidepressant treatments among individuals who are medically ill provide strong support for the effective use of antidepressant

medications across many medical conditions (Evans et al., 2005). The challenge for the clinician is in choosing a medication that maximizes beneficial side effects while minimizing adverse effects. In the context of medical illness, identifying an effective agent and dosing regimen, whose mechanism of action and side-effect profile will not exacerbate the coexisting medical condition and minimizing polypharmacy can be challenging. The selective serotonin reuptake inhibitors (SSRIs) are widely used for treating depression in medical illness due to their safety and side-effect profiles. They may not only improve depressive symptoms but also result in positive effects on the co-occurring medical illness. For example, fluoxetine has been shown to improve glycemic control in patients with diabetes mellitus (Lustman et al., 2000). Caution in the use of SSRI or serotonin norepinephrine reuptake inhibitors (SNRIs) is warranted under certain circumstances to prevent exacerbation of the medical condition and to prevent the development of potentially serious side effects such as the syndrome of inappropriate antidiuretic hormone secretion (SIADH), platelet dysfunction that can lead to bleeding problems and serotonin syndrome (Turner et al., 2007).

Of greater concern is the potential for drug interactions. Patients with serious medical conditions, particularly the elderly, often receive multiple medications, increasing the risk of drug interactions. The presence of renal or hepatic disease with resulting fluid shifts and weight loss, for example, may affect metabolism and excretion of SSRIs and alter their pharmacokinetics (Beliles and Stoudemire, 1998). Tricyclic antidepressants (TCAs) are effective in the treatment of depression. Despite

TABLE 37.2. Screening tools used for depression in patients who are medically ill

INSTRUMENT	DESCRIPTION	ADVANTAGE/DISADVANTAGE
Center for Epidemiological Studies Depression Scale (CES-D; Radloff, 1977)	20-item self-report instrument of which only four are somatic; recommended cutoff score of 17	Wide use in patients who are medically ill High sensitivity and specificity Lack of consensus on optimal cut scores Positive predictive value low
The Hospital Anxiety and Depression Scale (HADS; Zigmond and Snaith, 1983)	14-item self-report with separate 7-item subscale for depression and anxiety Cutoff scores range from 7 to 21	Brief and highly acceptable to patients Not extensively validated as a screen Lack of consensus about utility of cutoff scores
Beck Depression Inventory-II (BDI-II; Beck et al., 1996)	21-item self-report measure Cutoff scores: 10—mild; 20—moderate; 30—severe	Validated as an accurate self-report measure in patients who are medically ill Less acceptable to patients due to forced-choice format and complex response alternatives Sensitivity and specificity high and positive predictive value high
The Patient Health Questionnaire-9 (PHQ-9; Kroenke and Spitzer, 2002)	9-item self-report depression module of the PHQ Cutoff scores: 5-mild; 10-moderate; 15-moderately severe; 20-severe	Full PHQ well-validated in primary care/medical specialty clinic in United States, Europe, and China Good sensitivity and specificity
Zung Self-Rating Scale for Depression (Zung, 1965)	20-item self report Likert-type scale scores 1–4 with highest possible score of 80 Cutoff scores: >50 for depression	Validated as an accurate self-report measure in patients who are medically ill Good sensitivity and specificity
Hamilton Depression Rating Scale (Hamilton, 1960)	17-item scale; Clinician-administered Cutoff: 10–13 mild; 14–17 moderate; >17 severe	Validated as an accurate measure in patients who are medically ill Good treatment change measure High specificity and sensitivity

evidence of their efficacy in the treatment of depression among patients with medical conditions (Evans et al., 2005), SSRIs and SNRIs have substantially reduced the clinical use of TCAs. SSRIs are more commonly used due to their efficacy, safety, and side-effect profiles. TCAs are strong antagonists of cholinergic, histaminic, and alpha-adrenergic receptors and can affect cardiac conduction, potentially exacerbating medical symptoms.

Like TCAs, monoamine oxidase inhibitors (MAOIs), while effective, are less commonly used due to their abilities to produce hypertensive reactions, drug-drug interactions with common agents such as over-the-counter sympathomimetics and stimulants, and need for tyramine restrictions. A potentially fatal serotonin syndrome, characterized by mental status changes, autonomic instability, and neurotransmitter hyperactivity, may occur when SSRIs or SNRIs are combined with MAOIs, and may be mistaken for disease in the medically ill (Rackley and Bostwick, 2012).

Psychostimulants (methylphenidate and amphetamine-based products) are used to treat depressed patients with medical conditions despite inconsistent data supporting efficacy. These agents have been used due to their ability to rapidly improve mood, motivation, and appetite, and diminish fatigue in patients who are debilitated (Hardy, 2009).

Emerging evidence suggests potential efficacy for other somatic therapies for depression in the medically ill. Neuromodulatory therapies such as electroconvulsive therapy (ECT) and transcranial magnetic stimulation (TMS) have shown promise for the treatment of depressive symptoms in medical illness. Recent preliminary data suggests IV ketamine, an *N*-methyl *D*-aspartate (NMDA) modulator, may rapidly ameliorate treatment-resistant depression in healthy, medically ill, and palliative care patients (Rackley and Bostwick, 2012).

ANTIDEPRESSANT TREATMENTS FOR DEPRESSION IN CARDIAC DISEASE, CANCER, AND HIV

CARDIAC DISEASE

The treatment of depression in the context of cardiac disease has been an area of great interest due to the well-established relationships between CAD, depression, and mortality. Several randomized controlled trials have been suggestive of efficacy and safety of antidepressants in the treatment of depressive disorders in patients with cardiac disease, though efficacy in regard to the progression of the cardiac disease has not been clearly established (Berkman et al., 2003; Glassman et al., 2002, 2009; Honig et al., 2007; Lesperance et al., 2007).

A Cochrane review and meta-analysis found that SSRIs and psychological approaches were effective for the treatment of depression in patients with coronary artery disease (Baumeister et al., 2011). There was no detectable difference in efficacy among various psychological treatments. Hospitalization rates and emergency room visits were reduced in patients treated with SSRIs compared to placebo, however this review was unable to conclude that there was any benefit in mortality, or cardiac events in active treatments compared to placebo. However, another recent meta-analysis did find

that treatment with SSRIs is associated with a decrease in the rate of readmission and in the rate of mortality in patients with coronary heart disease (Pizzi et al., 2011).

DIABETES

The known associations of depression and diabetes, and the evidence supporting poor outcomes, have prompted trials examining the efficacy of therapeutic interventions for depression in diabetes. A recent meta-analysis from fourteen RCTs evaluating psychotherapy, pharmacologic interventions, and collaborative care in 1,724 subjects with type 1 and 2 diabetes and depression demonstrated clear effects with moderate effect size for depression treatment. Despite heterogeneity of study settings and treatment outcomes, depression treatments were effective (Markowitz et al., 2011; van der Feltz-Cornelis et al., 2010) for all three interventions in depression and diabetes.

Randomized placebo-controlled trials for fluoxetine, sertraline, paroxetine, and *s*-citalopram have demonstrated efficacy for the treatment of depression in diabetes (Markowitz et al., 2011). In a fluoxetine trial, significant reductions in depression severity were found for fluoxetine compared to placebo; however, there were no statistically significant differences in HbA1c (Lustman et al., 2000). In another trial with sertraline examining resolution of depression and glycemic control, hazard ratios for the risk of recurrence of depression for the sertraline treated group were significantly lower than for the placebo treated groups, suggesting a greater protection from recurrence of depression. Subjects under 55 years benefited from this prophylactic effect, when compared with a placebo group, but not those over 55 years. There were also improvements in HbA1c levels, however, they did not differ significantly between groups (Markowitz et al., 2011; Williams et al., 2007).

Two studies have examined paroxetine treatment for diabetes. In both studies, investigators studied depressed women who had not achieved optimal control of their type 2 diabetes for changes in depression severity and HbA1c levels, permitting observations of change in glycemic control. One study randomized mildly depressed postmenopausal women to either 10 weeks of a paroxetine or placebo condition. Although no differences were observed between groups with regard to depression scores, there was a statistical trend toward improved HbA1c in the paroxetine treated group when compared with placebo (Paile-Hyvarinen et al., 2007). The second study randomized mildly depressed subjects to six months of treatment with either paroxetine or placebo. HbA1c levels were significantly lower when compared to baseline for the paroxetine treated group when compared to placebo at three months. However, these gains were not maintained at six months. For both studies, depression severity was very low, with small sample sizes limiting power to detect changes in depression severity (Markowitz et al., 2011). There has been one study comparing the efficacy of different SSRIs. In this trial, subjects with T2DM and depression were randomized to either fluoxetine or paroxetine for 12 weeks. Both groups showed significant improvement on depression scores, while the fluoxetine group demonstrated a non-significant decrease in HbA1c levels (Gulseren et al., 2005).

There has been one double blind RCT of a TCA for depression in diabetes. Subjects with T1DM or T2DM and poor glycemic control were randomized to nortriptyline (NT) or placebo for eight weeks. Reductions in depression for the NT group were significantly greater than the placebo group, but not for reductions in HbA1c. NT was discovered to have a direct hyperglycemic effect on further analysis. However, improvements in depression improved glycemic control in both conditions mitigating differences (Markowitz et al., 2011).

An open trial of bupropion for depression with diabetes found that HbA1c levels, BMI, and body fat decreased significantly from baseline. Additionally, reduced BMI and depression severity predicted lower HbA1c levels during maintenance, while only decreased depression severity predicted lower HbA1c. This study, also measured pre- and posttreatment self-care with subjects reporting improvements in self-care during acute and maintenance phases (Markowitz et al., 2011; Williams et al., 2007).

Evidence supporting efficacy of antidepressant medications for depression in diabetes has resulted in increased utilization of SSRIs. However, several studies, but not all, suggest a link between the use of antidepressant medications (SSRIs and TCAs) and the risk for developing T2DM (Andersohn et al., 2009; Pan et al., 2012) while other studies found no association between antidepressant use and DM (Knol et al., 2007). Differing study designs may account for the inconsistencies in these findings.

Recent meta-analysis of treatments for depression in type 1 and type 2 diabetes concluded that psychosocial interventions, particularly cognitive behavioral therapies, are effective in improving depression in patients with diabetes, and in some but not all studies, effective at improving HbA1c levels (Markowitz et al., 2011; van der Feltz-Cornelis et al., 2010).

Collaborative care, an approach utilizing antidepressant and psychosocial interventions using a stepped care algorithm, has been studied in primary care populations. The evidence supports its effectiveness for the treatment of depression in the primary care setting similar to CBT and antidepressant treatments. Additionally, improvements of HbA1c levels and LDL cholesterol levels, were seen with the collaborative care model (Katon et al., 2010; Markowitz et al., 2011; van der Feltz-Cornelis et al., 2010). This approach may be a promising intervention for alleviating depression, and improving self-care and adherence for individuals with diabetes (Katon et al., 2010).

HIV/AIDS

A number of studies have supported the effectiveness of TCAs and SSRIs for treating depression in adults with HIV (Cruess et al., 2003; Rabkin, 2008; Repetto and Petitto, 2008). The TCAs and SSRIs have both shown equal efficacy in head to head studies. In one placebo-controlled study comparing imipramine, paroxetine, and placebo in 75 individuals who were HIV-positive, both agents were equally effective when compared to placebo. However, anticholinergic side effects with imipramine resulted in high dropout rates (48%) for imipramine, compared with 20% for paroxetine and 24% for placebo respectively (Elliott et al., 1998). One small open label study evaluated

the efficacy of paroxetine, fluoxetine, and sertraline in HIV seropositive individuals. (Ferrando et al., 1997). Improvements were reported in depression and somatic symptoms related to HIV disease in most patients (83%), but the dropout rates were high (27%). Comparative effectiveness of the three SSRIs could not be evaluated due to the small sample size. One other small uncontrolled study found improvements among clinically depressed HIV seropositive individuals who were treated with paroxetine (Grassi et al., 1997). Preliminary data based on open trials suggests that sustained release bupropion (Theobald et al., 2002) and mirtazapine (Currier et al., 2003) may be effective. Although larger placebo-controlled studies are needed to confirm these findings, existing findings suggest the effectiveness of SSRIs in reducing symptoms of depression in HIV seropositive individuals. A protocol for a Cochrane review has recently been published (Lewis et al., 2010).

TCAs have been found to be ineffective in two studies of HIV-related neuropathy (Saarto and Wiffen, 2010). No data are available on the SNRIs venlafaxine and duloxetine in the treatments of HIV-related neuropathy.

Psychostimulants (methylphenidate and dextroamphetamine) have also been studied in placebo-controlled trials in patients with depression and HIV. There have been two small uncontrolled studies of psychostimulants in the treatment of depression in HIV/AIDS (Fernandez et al., 1995; Wagner et al., 1997), and one small, placebo-controlled study (Wagner and Rabkin, 2000) that showed efficacy. Reductions in depressive symptoms as early as two weeks after initiating treatment have been reported (Wagner et al., 1997). In another study, among patients who were HIV-positive who also had significant levels of fatigue, methylphenidate and pemoline were found to be significantly superior to placebo in decreasing fatigue, and improvement in fatigue was significantly associated with improved quality of life and decreased levels of depression (Breitbart et al., 2001).

Reductions in testosterone levels among individuals with HIV/AIDS can be associated with changes in mood, appetite, and sexual function. In one study enrolling symptomatic patients who were HIV-positive, testosterone treatment was significantly better than placebo at restoring libido and energy, alleviating depressed mood, and increasing muscle mass (Rabkin et al., 2000), and a recent meta-analysis found that testosterone was effective in treating depression in HIV/AIDS (Zarrouf et al., 2009). The adrenal steroid dehydroepiandrosterone (DHEA) has also been evaluated and was effective (Rabkin et al., 2006).

As with other medical and nonmedical populations, the choice of an antidepressant agent in patients with HIV must be guided by the potential for drug-drug interactions and a number of potential interactions have been noted for medications used to treat depression and HIV/AIDS (Watkins et al., 2011).

CANCER

The effectiveness of antidepressants agents, specifically SSRIs and TCAs, for the treatment of depression in individuals with cancer is supported by a number of clinical trials (Evans et al., 2005).

In a small study of major depression among women with breast cancer, comparing the efficacy of an SSRI (paroxetine) to a TCA (desipramine), no differences were found in efficacy compared to placebo (Musselman et al., 2006). In addition to the SSRIs and TCAs, mirtazapine and mianserin have shown promising results in open trials (Costa et al., 1985; Theobald et al., 2002; van Heeringen and Zivkov, 1996). Mirtazapine's potential to cause weight gain might be of benefit for anorexic-cachectic patients with cancer, but should be used cautiously in those already gaining weight from steroids or from chemotherapy (Theobald et al., 2002). SSRIs are generally preferred over TCAs in this population, because of fewer sedative and autonomic side effects. SSRIs and the SNRI venlafaxine have demonstrated positive effects for women without depression who become menopausal after chemotherapy for breast cancer or who have a recurrence of vasomotor symptoms when they discontinue hormone replacement therapy. They have been effective for reducing the number and intensity of hot flashes and night sweats. The potential for drug interactions must be considered in patients with cancer. Recent evidence indicates that antidepressants that inhibit CYP2D6 may adversely affect the metabolism of tamoxifen, and it is recommended that known CYP2D6 inhibitors such as fluoxetine, paroxetine, or bupropion, should be avoided in combination with tamoxifen (Desmarais and Loope, 2009).

As reviewed earlier, another consideration in patients with cancer is depression that can result from certain cancer treatments that activate the immune system. In particular, treatment with IFN- α can cause the onset of new depressive episodes or trigger a recurrence of a previous episode. In a placebo-controlled trial, the use of an antidepressant (paroxetine) at the time of IFN- α treatment was found to reduce the incidence of depressive episodes and reduce the rate of discontinuation of IFN- α treatment (Musselman et al., 2001a). Currently, prophylactic use of antidepressants for patients with cancer is not recommended.

Although studies supporting antidepressant efficacy for psychostimulants (methylphenidate, dextroamphetamine) are lacking, they have been used with patients with cancer to promote a sense of well-being, improve symptoms of depression, increase energy, and improve cognitive function (Rozans et al., 2002). Psychostimulants have also been used to potentiate the analgesic effects of opioids and to counteract their sedative effects (Rozans et al., 2002).

CONCLUSIONS

Depressive disorders are prevalent among those with chronic medical conditions and may increase symptom burden and functional disability, adversely affect self-care and adherence to treatment, and decrease quality of life. Depression is also associated with immune suppression and immune activation. Depression associated cellular immune suppression may be a mechanism whereby depression may adversely effect immune-based diseases such as cancer and AIDS. On the other hand, depression-associated immune activation may be a mechanism whereby depression may have an adverse effect on diseases such as cardiovascular disease and diabetes.

Antidepressant treatments and psychotherapies are effective in the treatment of many of the symptoms of depression in individuals who are medically ill. High rates of depression among the medically ill call for heightened attention to this comorbidity. Depression should be actively identified and targeted for intervention. A number of studies suggest that the treatment of depression in individuals who are medically ill might improve overall medical outcomes or disease progression. Further large-scale studies will be needed to confirm these findings. Future investigation should focus on understanding the immune mechanisms as well as other mechanisms underlying depression and comorbid medical illness. Understanding the mechanisms underlying the associations between depression and medical illness may stimulate the development of novel therapies that provide effective interventions for this complex patient population.

DISCLOSURES

The work of Drs. Benton, Crits-Christoph, Dubé, and Evans, and the training of Dr. Blume, has been funded, in part, by the National Institutes of Health. Dr. Dubé was on the Speaker Bureau of Boehringer Ingelheim in 2009, 2010, and 2011, and has received compensation.

INTRODUCTION

Depression encompasses a large number of psychobiological syndromes with the core features of depressed mood and/or loss of interest associated with cognitive and somatic disturbances, which causes significant functional impairment. Clinical depression is distinguished from normal sadness by the severity of associated symptoms and its impact on functional status. Major depressive disorder (MDD) is characterized by one or more episodes of depressed mood, or a loss of interest or pleasure, for a minimum of two weeks, associated with four or more of the following symptoms: appetite disturbance, sleep disturbance, psychomotor agitation or retardation, fatigue or loss of energy, feelings of guilt or worthlessness, poor concentration, suicide attempts, or thoughts of death (American Psychiatric Association, 2000). Frequently, depressed patients present with a chief complaint of chronic pain, fatigue, gastrointestinal problems, anxiety, irritability, or sleep disturbance. The lack of a medical cause for these symptoms should raise the index of suspicion for clinical depression. A full discussion of the diagnosis and symptoms of depression is presented in Chapter 29.

Large epidemiological studies suggest that major depressive disorder is common, with a lifetime prevalence of 16.6%, occurring with approximately twofold higher frequency in women compared to men (Kessler et al., 2005).

Given the high prevalence and morbidity of depression, research efforts for discovery of effective antidepressant treatments span many decades. The first antidepressant agents, iproniazid (Crane, 1956) and imipramine (Kuhn, 1958), were discovered by serendipity, as they had been initially developed for other indications (tuberculosis and psychosis, respectively). Empiric observations about these agents' activity on mood and psychomotor function led to more systematic clinical trials in depressed patients, where they demonstrated clinical efficacy. In further investigations iproniazid was found to inhibit the monoamine oxidase enzyme (involved in the catabolism of serotonin, norepinephrine, and dopamine) while imipramine was shown to inhibit the reuptake of serotonin and norepinephrine (Gershon et al., 1962; Glowinski and Axelrod, 1964). Such insights led directly to the discovery of additional molecules with antidepressant properties—the monoamine oxidase inhibitors (MAOIs) and the tricyclic antidepressants (TCAs)—and to a number of key observations linking the monoamines (serotonin, norepinephrine, and dopamine) to mood, perception, and cognition. This became the basis of the monoamine hypothesis of depression, postulating that basic

neurotransmitter imbalances within the brain are the main causes of depression and that medication correcting these imbalances can lead to clinical improvement (Schildkraut, 1965). The support for the monoamine hypothesis came from several observations. The locus coeruleus (the major source of the brain's adrenergic innervations), and the brainstem raphe nuclei (origin of serotonin neurons) have modulatory roles, regulating global functions such as arousal, vigilance, attention, mood, and appetite. Certain drugs, such as reserpine, which deplete the monoamine neurotransmitters, induce a clinical state indistinguishable from depression, thus providing an animal model for the disease. Also, antidepressants such as MAOIs and TCAs increased by different mechanisms the amounts of monoamine neurotransmitters, resulting in clinical relief from depression.

In its most simplistic form, the monoamine hypothesis proved to be an inadequate theory on the biology of depression and the mechanisms of antidepressant drug action. There is a lack of evidence to prove globally diminished levels of noradrenergic or serotonergic neurotransmission characterize depression. Moreover, the effect of most antidepressants in raising the levels of neurotransmitters occurs very fast, in a matter of hours, while the latency for onset of clinical benefit is typically two to four weeks, and for the full clinical effect six to eight weeks. According to more recent understanding of the neurobiological effects of antidepressants, it is possible that changes in monoaminergic neurotransmitters are at the origin of a chain of intracellular second-messenger systems that promote gene regulation and synthesis of neuroprotective factors such as brain-derived neurotrophic factor (BDNF), thereby gradually restoring network function and ultimately mood (Kozisek et al., 2008). By regulating the phosphorylation of the DA- and cAMP-regulated phosphoprotein DARPP-32, antidepressants such as SSRIs also have indirect effects on α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) glutamate receptors, which represent a novel therapeutic target in depression (Alt et al., 2006).

However, the monoamine theory had an important role in guiding subsequent efforts for the discovery of novel antidepressants. The understanding that serotonin plays a major role in depression led to focused research for drugs with activity on serotonergic receptors, although antidepressant efficacy has been associated with opposing mechanisms of action (e.g., selective serotonin reuptake inhibitors, SSRIs, versus tianeptine, a selective serotonin reuptake enhancer). SSRIs were the first class of antidepressants specifically researched based on a putative mechanism of action. After the first SSRI, zimelidine,

was withdrawn due to side effects, fluvoxamine (first marketed in 1984 in Switzerland) and fluoxetine (marketed in the United States since 1987) became the precursors of a series of other antidepressants with similar monoaminergic mechanisms.

The development of novel antidepressants has been limited by imperfect understanding of the neurobiological mechanisms causing depression and by the biological and clinical heterogeneity of patients with the same diagnosis and by imperfect clinical research methods (e.g., variability in rating scores and limited sensitivity to change in some research instruments, inflation of placebo response rates).

The rational selection of antidepressant treatments requires an understanding of their pharmacological and biological properties (Montgomery, 2007). Partial or inadequate response to antidepressant treatment is common in MDD; only about 30% to 40% of the patients who receive adequate pharmacotherapy will achieve full remission (absence or near absence of symptoms) (Rush et al., 2006). In the Sequenced Treatment Alternatives to Relieve Depression (STAR*D) study only 29% of 2,876 MDD subjects treated with the maximum tolerated dose of citalopram (up to 60 mg) for up to 14 weeks achieved remission (Trivedi et al., 2006). Several clinical variables such as comorbid anxiety disorders (Fava et al., 2008), substance use disorders (Nunes and Levin, 2004), and medical illness (Iosifescu, 2007), have been associated with lower rates of improvement with antidepressant treatments. Non-response to antidepressants is associated with disability and higher medical costs (Simon et al, 2006), and partial response is associated with higher relapse and recurrence rates (Judd et al, 1998). Moreover, it takes 6–12 weeks to fully evaluate the efficacy of an antidepressant treatment. As each new pharmacotherapy is tried, patients are exposed to additional cost, side effect burden, and the potential for loss of function and suicide.

We will focus in this chapter on the pharmacological treatments for major depressive disorder (MDD), while also reviewing somatic treatments, psychotherapies, and natural remedies with proven efficacy in MDD. We will also focus on strategies to use these treatments, alone or in combination, in MDD patients. Finally we will review treatment of depression in special populations such as melancholic, atypical depression, bipolar depression, or psychotic depression.

PHARMACOLOGICAL TREATMENTS (THE ANTIDEPRESSANTS)

Most antidepressants currently available have mechanisms of action involving monoaminergic neurotransmitters. A useful classification is based on their known receptor affinities, despite the fact that significant chemical structural diversity may be present within each class, which in turn may explain significant differences in pharmacokinetics, metabolism, tolerability, or toxicity (see Table 38.1). We will discuss separately major classes of antidepressants (e.g., TCAs, MAOIs, SSRIs, SNRIs), and specific antidepressants not fitting into these classes (e.g., bupropion, mirtazapine). We will then discuss strategies to address treatment non-response, including combinations of antidepressants and other medications used to

augment antidepressants (such as lithium, thyroid hormones, atypical antipsychotics).

TRICYCLIC ANTIDEPRESSANTS

Tricyclic antidepressants (TCAs) have been in use for more than 50 years. They are named after their core chemical structure consisting of three rings (two joined benzene rings). The initial TCA, imipramine, with a chemical structure similar to phenothiazines, was discovered in the 1950s and found to be associated with robust clinical improvements in depressed subjects (Kuhn, 1958). The class includes *tertiary amine TCAs*, which inhibit the reuptake of both norepinephrine and serotonin (members of this class include amitriptyline [Elavil], imipramine [Tofranil], trimipramine [Surmontil], clomipramine [Anafranil], doxepin [Sinequan]), and their demethylated *secondary amine derivatives TCAs*, with more selective norepinephrine reuptake inhibition (nortriptyline [Pamelor], desipramine [Norpramin], protriptyline [Vivactil], amoxapine [Ascendin]). In addition, maprotiline (Ludiomil) is classified as a tetracyclic.

With the exception of clomipramine, where serotonin reuptake inhibition predominates, all other TCAs inhibit the reuptake of norepinephrine more potently than the reuptake of serotonin (Richelson, 2003). TCAs are also active at multiple other monoamine receptors: to varying degrees TCAs also block histamine H-1 receptors, serotonin 5-HT₂ receptors, muscarinic acetylcholine receptors, and α -1 adrenergic receptors (Richelson and Nelson, 1984). This explains their side-effect profile, as described later, and may also explain potential secondary mechanisms of antidepressant effect. Amoxapine is also a dopamine D₂ receptor antagonist (which confers both antipsychotic properties and a risk of extrapyramidal side effects (Richelson, 2003).

Although TCAs are generally as effective as the more modern selective serotonin reuptake inhibitors (SSRIs) for depression (Anderson, 2000) and some evidence favors the use of TCAs in severe melancholic depression (Perry, 1996), they are rarely used as first-line treatments due to their inferior side-effect and safety profile in comparison with newer antidepressants. In addition, TCAs have a more established track record than SSRIs in treating a variety of chronic pain conditions, including neuropathies, fibromyalgia, and migraine (Sindrup et al., 2005).

Typical TCA antidepressant doses are 100–300 mg/day (nortriptyline and protriptyline require lower doses). TCA treatment should be initiated with lower doses (e.g., 10 mg/day for imipramine) due to poor tolerability at higher doses. The relationship between serum levels and clinical response varies: while desipramine was reported to have a linear relationship between increasing levels and effectiveness, most other TCAs appear to exhibit an inverse “U” shaped curve, with decreasing efficacy at blood levels above therapeutic range (Perry et al., 1994). Blood levels may be useful in establishing compliance, higher than usual dose requirements (as in chronic smokers), or toxicity due to overdose or drug interactions.

The adverse effect profile of TCAs accounts for the high dropout rate (30–70%) in published studies. Blockade of

TABLE 38.1. Antidepressant blockade of several monoamine transporters and receptors in the human brain. Potency (affinity) data is expressed as the inverse of the equilibrium dissociation constant K_d , multiplied by 10^{-7} . (Data are adapted from Richelson, 2003.)

muscarinic acetylcholine receptors causes dry mouth, blurred vision, constipation, urinary hesitancy, tachycardia, and ejaculatory difficulties. Secondary amine TCAs tend to cause fewer anticholinergic effects than tertiary amine TCAs. TCAs should be avoided in patients with narrow angle glaucoma and prostatic hypertrophy as symptoms related to these conditions may worsen because of anticholinergic effects. Blockade of histamine H-1 receptors may cause sedation, carbohydrate craving, and weight gain. Weight gain with TCAs can be substantial, averaging 1–3 lb per month of treatment. Secondary amine TCAs tend to cause less sedation than tertiary amine TCAs. Alpha-1 adrenergic receptor antagonism may lead to orthostatic hypotension, which can be severe. Nortriptyline is generally thought to be less likely to cause orthostatic hypotension than tertiary amine TCAs. TCAs can block sodium and potassium channels, which can lead to arrhythmogenic and epileptogenic effects, especially in overdose. Cardiac toxicity may occur in susceptible individuals and following TCA overdose. TCAs should be avoided in patients with bifascicular heart block, left bundle branch block, or a prolonged QT interval. TCAs also decrease heart rate variability, which is a risk factor for cardiovascular disease. Baseline and follow-up electrocardiograms should be monitored, especially in older patients or those with cardiac conduction disorders, as well as in pediatric patients.

TCAs have a low threshold for toxicity; overdose of even a one-week supply may be lethal. Due to the lethality after overdose, it may be safer to treat acutely suicidal depressed patients with non-TCA antidepressants or to prescribe limited quantities of TCAs. Cytochrome P450 2D6 inhibitors (such as certain SSRIs) can lead to potentially dangerous increases in TCA blood levels. Manifestations of anticholinergic toxicity may include dilated pupils, blurred vision, dry skin, hyperpyrexia, ileus, urinary retention, confusion, delirium, and seizures. Additionally, arrhythmias, hypotension, and coma may develop. Although TCAs are highly plasma-bound and are not removed by hemodialysis, they are metabolized by hepatic microsomal enzymes. Patients who have overdosed on TCAs may require alkalization of their serum, pressors, or ventilatory support to maintain survival.

While no longer used as first-line treatment for depression due to their unfavorable side-effect and safety profile, TCAs are effective antidepressants and are commonly used in patients with chronic pain (Sindrup et al., 2005).

MONOAMINE OXIDASE INHIBITORS (MAOIS)

MAOIs act by inhibiting the monoamine oxidase (MAO), an enzyme found on the outer membrane of cellular mitochondria, where it catabolizes intracellular monoamines, including the CNS monoamines: dopamine, norepinephrine, serotonin, and tyramine. In the GI tract and the liver, MAO catabolizes dietary pressor amines, such as dopamine, tyramine, tryptamine, and phenylethylamine. MAO has two forms (MAO-A and MAO-B), with differences in substrate preference, inhibitor specificity, and tissue distribution. MAO-A, which preferentially oxidizes norepinephrine and serotonin, appears in positron emission tomography (PET) studies to be

elevated in multiple brain areas in MDD subjects (Meyer et al., 2009), and was considered the therapeutic target of MAOIs in depression.

Older MAOIs such as phenelzine (Nardil), tranylcypromine (Parnate), and isocarboxazid (Marplan), are irreversible inhibitors of both MAO-A and MAO-B. Their chemical structures relate either to the hydrazine class (phenelzine and isocarboxid) or are related to CNS stimulants (tranylcypromine). Moclobemide is a selective and reversible inhibitor of MAO-A available in Europe. The antiparkinsonian agent, selegiline (Eldepryl), is a more selective MAO-B inhibitor, particularly at low doses (<10 mg/day), but is not effective as an antidepressant at those doses. A newer formulation of transdermal selegiline was shown to minimize the inhibition of MAO-A in the GI tract (30% inhibition) at doses producing maximal MAO-A and MAO-B inhibition in the brain (Wecker et al., 2003). Transdermal selegiline (EmSam) is an effective antidepressant and relatively safer than other orally available MAOIs.

The overall efficacy of MAOIs appears to not differ from that of other antidepressant classes such as SSRIs (Papakostas and Fava, 2006) or TCAs (Thase et al., 1995). In atypical depression (characterized by mood reactivity plus hypersomnia, hyperphagia, extreme fatigue when depressed, and/or rejection sensitivity), MAOIs do appear to be more effective than TCAs (Thase et al., 1995), but it is unclear whether they are more effective than SSRIs.

The older MAOIs are rarely used in clinical practice due to their adverse effects profile (orthostatic hypotension, weight gain, and sexual dysfunction), particularly the need for dietary restrictions (to prevent hypertensive crisis), potentially fatal drug interactions (due to the interaction with sympathomimetic drugs or serotonergic drugs), and toxicity in overdose. Currently the MAOIs are used in individuals with treatment resistant depression, after successive treatment failures with more recent antidepressants.

The most common side effects include postural hypotension, insomnia, agitation, sedation, impotence, delayed ejaculation, or anorgasmia. Others include weight change, dry mouth, constipation, and urinary hesitancy. Peripheral neuropathies have been reported and may be avoided by concomitant therapy with vitamin B6.

When patients on MAOIs ingest dietary amines, rather than being catabolized in the intestines and the liver they are taken up in sympathetic nerve terminals and may cause the release of endogenous catecholamines with resulting adrenergic crises. This is characterized by hypertension, hyperpyrexia, and other adrenergic symptoms such as tachycardia, tremulousness, and cardiac arrhythmias. The amine most commonly associated with these symptoms is tyramine, but others, such as phenylethylamine and dopamine may be involved. Dietary amines can be avoided by adherence to dietary restrictions and avoiding tyramine-containing foods. The diet must be strictly followed. Patients must be instructed to avoid all matured or aged cheese, fermented or dried meats, such as pepperoni and salami, fava and broad bean pods (not the beans themselves), tap beers, marmite yeast extract, sauerkraut, soy sauce and other soy products, such as tofu and tempe. All meats and cheese must be fresh and must have been

stored and refrigerated or frozen properly. Up to two bottles of beer or glasses of wine may be consumed safely; this restriction includes non-alcoholic beers (Walker et al., 1996).

Since endogenous MAO activity does not return to baseline immediately upon MAOI discontinuation, two weeks should transpire before discontinuing the MAOI diet after MAOI discontinuation, or before beginning a contraindicated medication.

Reversible MAOIs such as moclobemide were pursued as a safer alternative to older MAOIs with a lower risk for hypertensive crises, but their antidepressant efficacy was not superior to SSRIs (Papakostas and Fava, 2006). Transdermal selegiline is associated with a lower risk for hypertensive crises although the FDA requires a tyramine-free diet at the higher doses of the patch.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS

Inhibition of the reuptake of serotonin at neuronal synaptic clefts is the immediate mechanism of selective serotonin reuptake inhibitors (SSRIs), which occurs within hours of initiation of SSRI treatment. SSRIs also have effects at other monoamine receptors (such as norepinephrine and dopamine), but their affinity is one to two orders of magnitude higher for the serotonin transporter (Table 38.1) (Richelson, 2003). By blocking serotonin reuptake SSRIs increase the amount of available serotonin in the synaptic cleft, stimulating a large number of serotonin receptors subtypes. However, the immediate effect on serotonin receptors cannot account by itself for antidepressant efficacy; the typical time to clinical improvement in depression for all antidepressant medications, including the SSRIs, is four to eight weeks.

More than 60 double blind placebo-controlled studies support the efficacy of SSRIs in MDD (Papakostas et al., 2006). Available SSRIs include fluoxetine, paroxetine, sertraline, fluvoxamine (in the United States only approved for OCD), citalopram, and escitalopram (the *S*-enantiomer of citalopram). Vilazodone, approved by the FDA in 2011, is a serotonin reuptake inhibitor and a partial agonist of the 5-HT_{1A} receptor. The common dosage regimens of SSRIs are presented in Table 38.2. Although dose-response curves have not been definitively established for the SSRIs, some patients who do not respond at a lower dose may benefit by having their dosage increased. SSRIs are hepatically metabolized and renally excreted; therefore, dose adjustments may be required in patients with reduced liver or renal function.

For reasons of tolerability and their relatively benign side-effect profile (as discussed later), the SSRIs have become the first-line treatment for depressive disorder spectrum illnesses, ranging from dysthymia to major depression. SSRIs are very rarely associated with fatalities even in the presence of large overdoses, unless they are combined with other agents. Several SSRIs may be relatively safe during pregnancy; fluoxetine and sertraline have a larger number of observational studies confirming low rates of fetal malformations or complications, while paroxetine has been associated with an increased risk of congenital heart malformations (Patil et al., 2011). Advantages of SSRIs include a favorable side-effect

profile, a broad spectrum of efficacy for comorbid disorders, a low potential for abuse and dependence, safety in overdose, and single daily dosing (with the exception of fluvoxamine).

Disadvantages of SSRIs include side effects and drug–drug interactions by inhibiting the activity of cytochrome P450 isoenzymes. The most common side effects of SSRIs are increased anxiety or “jitteriness” on initial dosing, headaches, agitation, insomnia, nausea (which tends to be worst during early treatment), diarrhea, reduced appetite, weight loss or gain, excessive sweating, headache, insomnia, sedation, dizziness, and sexual dysfunction—including decreased libido, delayed ejaculation, impotence, and anorgasmia. Other side effects include rash, dry mouth, and prolonged bleeding time. SSRIs have been associated with an increased risk of treatment-emergent suicidal ideation in children, adolescents, and young adults (under the age of 25), a side effect shared with other classes of antidepressants.

All currently available SSRIs appear to be equally efficacious for depression. The most significant differences between molecules in this family involve their half-lives and interactions with the cytochrome P 450 isoenzymes. Half-lives vary greatly among the SSRIs. Although an antidepressant’s half-life is not relevant to its treatment efficacy or its onset of action, it may be significant in terms of its side effects, its interactions with other agents, and its discontinuation-emergent symptoms. Medications with shorter half-lives may be useful when abrupt discontinuation is desired due to intolerable side effects or to medication interactions, however medications with shorter half-lives are more likely to cause the discontinuation-emergent symptoms (e.g., tachycardia, flu-like symptoms, dizziness, myalgias, anxiety, irritability, worsening of mood, jitteriness, and nausea). An SSRI with a longer half-life is more likely to “self-taper,” and may be beneficial for a patient who is apt to miss occasional dosages. Fluoxetine has the longest half-life (two days, while its active metabolite norfluoxetine has a half-life of 7–10 days). Fluoxetine is dosed daily, but due to its long half-life a once-weekly formulation of this drug is also available. Fluvoxamine has the shortest half-life (16 hours) and is the only SSRI requiring twice daily dosing.

Drug interactions: In rare cases, a serotonin syndrome can also occur when SSRIs are combined with monoamine oxidase inhibitors or with relatively serotonergic agents. More commonly, SSRIs may inhibit cytochrome P450 isoenzymes (Manolopoulos et al., 2012). Cytochrome P-450 isoenzymes, including the isoenzymes 1A2, 2C, 2D6, 3A3/4, are a family of heme-thiolate proteins located on microsomal membranes throughout the body. Their mechanism is best known in the liver and bowel wall, where they oxidatively metabolize medications as well as prostaglandins, fatty acids, and steroids. Alteration in function of these isoenzymes may cause clinically significant pharmacokinetic drug–drug interactions, via changes in drug levels. CYP450 2D6 inhibition by several SSRI antidepressants (primarily fluoxetine and paroxetine, but also clinically relevant for sertraline) and by bupropion may lead to increased levels of TCAs, beta-blockers, antiarrhythmics, and several narcotic analgesics (codeine, hydroxycodone, oxycodone, tramadol, dextromethorphan), which are all substrates for this enzyme. Also a potential consequence is inhibition of

* Not FDA approved for the treatment of depression

the conversion of codeine to its active form (morphine) with subsequent reduction of its efficacy. CYP450 3A4 inhibition by fluvoxamine (and the non-SSRI nefazodone) has potential consequences in increased levels of numerous commonly prescribed substrates including carbamazepine, cyclosporine, alprazolam, midazolam, zolpidem, zaleplon, calcium channel blockers, statins, sildenafil, oral contraceptives, and pimozide (arrhythmia risk). CYP450 1A2 inhibition by fluvoxamine may lead to toxicity on clozapine, theophylline, and other 1A2 substrates. CYP450 2C inhibition by fluoxetine, fluvoxamine, or

sertraline has a potential for increased levels of anticoagulant (warfarin) and diazepam.

TRAZODONE AND NEFAZODONE

The phenylpiperazine nefazodone and the triazolopyridine trazodone are 5-HT_{2A} antagonists. Both inhibit serotonin 5-HT_{2A} receptors; they are also weak inhibitors of serotonin reuptake. Inhibition of postsynaptic 5-HT_{2A} receptors has a synergistic effect with serotonin reuptake inhibition (explaining the antidepressant effects of these molecules as monotherapy and in

combination with SSRIs). Trazodone may also act as a serotonin agonist through an active metabolite and it is an antagonist of alpha-1 adrenergic receptors (associated with side effects).

Their antidepressant efficacy appears similar to that of SSRIs in a meta-analysis (Papakostas and Fava, 2007). Usual effective doses for both are 200–600 mg/day. The FDA approved an extended-release version of trazodone in 2010. Both medications have sedative properties and improve sleep continuity (5-HT₂ receptor blockers increase slow-wave sleep). Adrenergic effects of trazodone are associated with orthostatic hypotension. Priapism is a rare side effect of trazodone that requires immediate medical attention. Trazodone may also induce arrhythmias in those with preexisting heart disease. Nefazodone has fewer side effects than trazodone due to lower alpha-1 blockade. It is less likely to cause sexual dysfunction than SSRIs or TCAs, and is less anticholinergic and histaminergic. Common side effects include somnolence, dizziness, dry mouth, nausea, constipation, headache, and amblyopia and blurred vision. Nefazodone has been associated with rare but fatal hepatotoxicity, but remains an effective treatment for depression associated with anxiety.

MIRTAZAPINE (REMERON)

Mirtazapine has a tetracyclic chemical structure (unrelated to the TCAs). It is an antagonist at inhibitory alpha-2 adrenergic auto- and hetero-receptors, leading to increased release of both serotonin and norepinephrine at the synaptic level and increased tonic activation of postsynaptic 5-HT receptors. Mirtazapine also blocks 5HT₂ and 5HT₃ receptors, it is also a relatively potent histaminergic H-1 receptor antagonist. It does not have significant affinity for cholinergic or postsynaptic adrenergic receptors. Its antidepressant efficacy is comparable with that of SSRIs in a meta-analysis of head-to-head studies (Papakostas et al., 2008b). Histaminergic receptor antagonism may be related to common side effects including somnolence, weight gain, dizziness, dry mouth, and constipation. Weight gain can be significantly larger compared to other antidepressants. Due to blockade of 5HT₂ and 5HT₃ receptors, mirtazapine may reduce SSRI-related sexual dysfunction and nausea when administered concomitantly. The drug appears to have no known cardiac toxicity and to be relatively safe in overdose. Mirtazapine is an effective antidepressant, particularly useful in subjects where its effects on increasing sleep and increasing appetite are desirable; it is also preferable due to reduced rate of sexual side effects.

BUPROPION (WELLBUTRIN, WELLBUTRIN SR, XL)

The mechanism of action of bupropion has not been fully elucidated, although it appears to block the reuptake of both dopamine and norepinephrine. Bupropion inhibits the striatal uptake of the selective dopamine transporter (DAT)-binding radioligand (Meyer et al., 2002), but the lack of decrease in cerebrospinal fluid (CSF) levels of homovanilic acid (the primary dopamine metabolite) suggests the activity of bupropion is not primarily related to dopamine reuptake inhibition. Bupropion also has weak affinity for the norepinephrine transporter and increases presynaptic norepinephrine release

(Dong and Blier, 2001). The overall effect appears to be related to an increase in the brain extracellular dopamine and norepinephrine concentrations. Clinically, bupropion has sympathomimetic, stimulant-like effects.

Bupropion appears to be as effective as SSRIs in the treatment of depression (Thase et al., 2005). Its stimulant-like effects suggest it is more effective than SSRIs in treating fatigue associated with depression, while SSRIs appear more effective than bupropion in the treatment of anxious depression. Clinical efficacy was also demonstrated for seasonal affective disorder.

Effective doses range between 200 and 450 mg/day. Common side effects include agitation, insomnia, weight loss, dry mouth, headache, constipation, and tremor. Doses below 450 mg/day are associated with a rate of seizures of 0.4% for its immediate release form and lower for sustained release preparations. However, the risk of seizure markedly increases (2.4%) at doses > 450 mg/day and > 200 mg/dose. Bupropion may be more likely to induce seizures in patients with bulimia nervosa and histories of head trauma. It is generally safe in overdose, though fatalities have been reported. Bupropion is usually safe for patients with cardiac disease, although it may participate in drug interactions. It rarely induces sexual dysfunction and can even be beneficial as an adjunct in SSRI-induced sexual dysfunction. Bupropion is particularly useful for depressed subjects benefiting from its energizing effects (decreasing fatigue, increasing concentration) or from its reduced rate of sexual side effects.

SELECTIVE SEROTONIN NOREPINEPHRINE REUPTAKE INHIBITORS

Selective serotonin norepinephrine reuptake inhibitors (SNRIs) are potent reuptake inhibitors of both serotonin and norepinephrine, neurotransmitters associated with important symptom domains involved in MDD. While this is a simplification, norepinephrine may be related to energy, alertness, attention, and interest, while serotonin to anxiety, obsessions, and compulsions (Nutt, 2008). The SNRI group includes venlafaxine, desvenlafaxine, duloxetine, and milnacipran. Venlafaxine (Effexor, Effexor XR) is a phenylethylamine; it inhibits both serotonin and norepinephrine reuptake at doses above 150 mg, while lower doses only have a clinically significant inhibitory effect on serotonin reuptake. It has very low affinity for histaminergic, cholinergic, and adrenergic receptors. Desvenlafaxine, the major metabolite of venlafaxine, is a more potent reuptake inhibitor of norepinephrine. Duloxetine is a relatively more potent norepinephrine reuptake inhibitor than venlafaxine; it has little affinity for cholinergic or histaminergic receptors. Milnacipran has the highest relative norepinephrine reuptake inhibition in the class. Milnacipran is only approved by the FDA for the treatment of fibromyalgia but is available as an antidepressant in Europe.

Venlafaxine and desvenlafaxine are only 30% protein bound and thus have low likelihood of displacing tightly bound drugs, such as warfarin and phenytoin. Also, both venlafaxine and desvenlafaxine are not potent inhibitors of any cytochrome P450 hepatic enzymes, which results in low risk for pharmacokinetic drug interactions. Desvenlafaxine is

also not a substrate for CYP 2D6; therefore it is not subject to drug-drug interactions (its metabolism is not affected by inhibitors or inducers of CYP2D6). Similar to desvenlafaxine, milnacipran undergoes very little hepatic metabolism.

Several meta-analyses have suggested that in aggregate SNRIs are associated with higher rates of remission compared to SSRIs, but the difference appears modest or insignificant from a clinical perspective (Machado and Einarson, 2010). An earlier meta-analysis using the number needed to treat (NNT) statistic suggests nearly 24 patients would need to be treated with SNRIs instead of SSRIs in order to obtain one additional responder (well short of the NNT = 10 suggested as a mark of significant clinical difference between alternate therapies) (Papakostas et al., 2007c). The dual effects of venlafaxine on serotonin and norepinephrine have been used to explain the small increase in remission rates compared to SSRIs (Nemeroff et al., 2008). Duloxetine was shown to be additionally efficacious in the treatment of painful symptoms associated with depression. The dual effect on serotonin and norepinephrine is associated, just as in the case of TCAs, with SNRI efficacy in chronic pain conditions; both duloxetine and milnacipran are effective in the treatment of fibromyalgia.

As a class the SNRIs share many of their side effects. Similar with SSRIs, SNRIs are associated with GI side effects (nausea, diarrhea), insomnia, sedation, sexual dysfunction, headaches, sweating, tremors, dizziness, and weight gain. In contrast to SSRIs, the noradrenergic effects of SNRIs are associated with treatment-emergent hypertension (which is more prominent with venlafaxine and at higher doses), palpitations, and tachycardia. The more potent noradrenergic effects of duloxetine and milnacipran are also associated with dry mouth, constipation, and urinary retention. Abrupt discontinuation of any SNRI may result in withdrawal-related adverse events similar to SSRIs, but the syndrome is most intense with venlafaxine. Hepatotoxicity has been reported with duloxetine and with milnacipran.

As a group of efficacious and relatively well-tolerated antidepressants, SNRIs are frequently used in patients having failed treatment with an SSRI, or even as first-line treatments.

NOREPINEPHRINE REUPTAKE INHIBITORS

Norepinephrine reuptake inhibitors (NRIs) have primary activity by inhibiting the transport (as in the case of reboxetine) or the reuptake of norepinephrine (e.g., atomoxetine). Reboxetine also increases prefrontal cortex dopamine activity. Reboxetine is available as an antidepressant in Europe but not in the United States; its overall antidepressant efficacy appears similar to SSRIs in a meta-analysis (Papakostas et al., 2008a), although in the US phase III trials reboxetine did not separate from placebo. Atomoxetine (Strattera), which is FDA approved for the treatment of attention deficit disorder, has minimal data supporting efficacy in MDD. Both medications share side effects related to noradrenergic effects: dry mouth, nausea, sedation, urinary hesitancy, and tachycardia. At this point the majority of available data appears to favor SSRIs versus NRIs in the treatment of depression.

AGOMELATINE

Agomelatine is an antidepressant with a novel mechanism of action, with melatonin MT1 and MT2 agonist and serotonin 5-HT_{2C} antagonist effects. The 5-HT_{2C} effects appear to be related to increase in prefrontal dopaminergic and noradrenergic activity. Its melatonergic effects appear to be related to improved sleep quality, with no reported daytime drowsiness. It appears to have no affinity for adrenergic, histaminergic, cholinergic, dopaminergic, or other serotonergic receptors. In European studies agomelatine was found to be effective in the treatment of MDD; three out of six placebo-controlled trials have supported the short-term efficacy of agomelatine in MDD. Other studies have shown agomelatine to be as effective as the SSRI paroxetine or the SNRI venlafaxine (Carney and Shelton, 2011). Agomelatine is marketed as an antidepressant in Europe since 2009. Its development in the United States was discontinued in 2011. The phase III US trials provided inconsistent results: in one study the 25 mg dose but not the 50 mg separated from placebo, while in the other study only the 50 mg dose achieved efficacy (Stahl et al., 2010). Agomelatine has a favorable side-effect profile but has been associated with elevated liver transaminases in up to 4% of subjects.

ANTIDEPRESSANT STRATEGIES FOR TREATMENT-RESISTANT DEPRESSION

Given the large variety of available antidepressants and the lack of overwhelming evidence of superior efficacy for any one class, the choice of an initial antidepressant treatment is primarily related to tolerability, safety, and economic factors (cost, insurance formulary). Although many patients with MDD achieve clinical response (defined as 50% improvement of symptoms) to their initial antidepressant treatment, one third to one half of depressed patients fail to respond to antidepressant treatments of adequate dose and duration (Rush et al., 2006a). Treatment-resistant depression (TRD) is generally defined as lack of adequate improvement after two antidepressant treatments used at adequate doses (see Table 38.2) and duration (minimum six weeks). Remission (defined as resolution of symptoms) is an even more important goal; it is associated with improved long-term outcomes and lower relapse rates. The initial evaluation of a subject with TRD should start with a reevaluation of the diagnosis and comorbid illnesses. Bipolar depression would require different pharmacological approaches, as outlined later in this chapter. The presence of comorbid medical (e.g., cardiovascular, diabetes, etc.) and psychiatric illness (e.g., substance abuse, psychosis) has been associated with increased levels of treatment resistance; such comorbidities need to be treated to improve clinical outcomes. Patients who have already failed to respond to two treatments (TRD) experience very low (10–20%) remission rates with their next treatments (defined as near complete resolution of symptoms); for this group of patients there is no single pharmacotherapy showing significant superiority (Rush et al., 2006b, 2009).

Common pharmacological strategies for TRD include antidepressant dose increases/optimization, switches to other antidepressants, combinations of antidepressants, and

augmentation of antidepressants with other pharmacological agents. Non-pharmacological strategies include switch or combination treatment with ECT, TMS, or psychotherapy, as discussed later in this chapter. Gradual **dose increases/optimization** to the maximum FDA-recommended doses can be efficacious especially in subjects responding partially to the initial treatment. A **switch to another antidepressant** after the first therapy has been proven ineffective (with discontinuation of the first treatment) has the advantage of maintaining the lower side effect profile associated with monotherapy. The switch can be to another antidepressant in the same class or to a different class. A switch to the same class may be associated with rates of response and remission similar to out of class switches after a single antidepressant failure in the class. In STAR*D Level 2 subjects failing to improve after 12 weeks with the SSRI citalopram had near-identical response rates after switching to the SSRI sertraline compared to switching to the SNRI venlafaxine or to bupropion (Rush et al., 2006b). However, rates of response tend to be lower after failing two antidepressants in the same class, which justifies at that point switching to a different antidepressant class. The disadvantage of switching involves the loss of any benefits of the initial antidepressant treatment; clinical improvement would typically occur only after an adequate duration of treatment with the new antidepressant.

Combination therapy involves the addition of a second antidepressant; the advantages are related to potential pharmacological synergy in mechanisms of action (which may translate in clinical efficacy) and not losing partial benefits associated with the first treatment. The disadvantages relate to an increased side-effect profile (combining side effects of both agents). Commonly used pharmacological combinations are SSRI/SNRI plus bupropion, SNRI/SNRI plus mirtazapine, SSRI plus TCA, and SSRI plus NRI (e.g., reboxetine). While each of these strategies has been associated with adequate rates of success in some studies, a recent study comparing the efficacy of escitalopram monotherapy to the combinations of escitalopram plus bupropion or venlafaxine plus mirtazapine reported no significant differences in the acute (12 weeks) or the longer term (7 months) outcomes (Rush et al., 2011).

Augmentation therapy involves the addition of pharmacological agents (with no proven antidepressant properties as monotherapy) to boost the antidepressant response. Effective augmenting agents include lithium, thyroid hormones, atypical antipsychotics, agents with serotonin 1A activity, and hormonal strategies.

Lithium augmentation was initially proposed after the observation of rapid antidepressant effects after the addition of lithium to TCAs. A meta-analysis of the older studies involving lithium augmentation of TCAs suggested lithium was more efficacious than placebo (Bauer and Dopfmer, 1999), but only 3 studies (with 110 subjects) were determined to involve adequate lithium doses, and lithium effects were assessed after only 2 weeks. More recently, STAR*D level 3 compared lithium or T3 augmentation of antidepressants (sertraline, venlafaxine, or bupropion); numerically lower remission rates were reported for lithium (15.9%) compared to T3 augmentation (24.7%), but the difference was not

statistically significant (Nierenberg et al., 2006). Therefore the evidence for the efficacy of lithium as an augmentation is not conclusive. Lithium augmentation of TCAs remains a validated strategy. Adjunctive lithium may be associated with side effects such as tremor, somnolence, sedation, gastrointestinal symptoms (nausea, anorexia, abdominal pain, diarrhea), polyuria, edema, hypothyroidism, weight gain, and cardiac conduction abnormalities.

Atypical antipsychotics are the most extensively researched augmentation strategy in TRD. Given the receptor affinities of atypical antipsychotics, augmentation of SSRIs may increase levels of norepinephrine and/or dopamine in the prefrontal cortex, leading to improved antidepressant response. Randomized controlled studies have been reported with olanzapine, risperidone, quetiapine, and aripiprazole; a meta-analysis of 10 of these studies reported higher response and remission rates among patients who received augmentation with atypical antipsychotics compared to antidepressant monotherapy (Papakostas et al., 2007b). The rate of discontinuation for side effects was 3.5 times higher for patients treated with atypical antipsychotics. Currently three atypical antipsychotics have received FDA approval as augmentation treatments in TRD (aripiprazole, quetiapine XR, and the combination of olanzapine plus fluoxetine). Despite proven efficacy atypical antipsychotic augmentation should be considered in the context of the significant side effect burden of this class of medications, which includes sedation, somnolence, nausea, hyperprolactinemia, dyslipidemia, glucose dysregulation, weight gain, extrapyramidal side effects, neuroleptic malignant syndrome, and tardive dyskinesia.

Selective 5HT_{1A} agonists: initial clinical reports of augmentation of SSRIs with clomipramine or buspirone have led to theories suggesting that increased postsynaptic 5HT_{1A} activity and desensitization of presynaptic 5HT_{1A} autoreceptors play a significant role in the antidepressant mechanisms of multiple monoaminergic antidepressants, particularly SSRIs. Buspirone, a partial agonist at this receptor, appeared as efficacious as bupropion when added to the SSRI citalopram in STAR*D Level 2 (Rush et al., 2009). Pindolol, a beta-adrenergic antagonist and a 5HT_{1A} antagonist, was believed to have augmentation efficacy via effects on presynaptic autoreceptors, but pindolol did not separate from placebo in large randomized studies, possibly due to the low receptor occupancy achieved at the doses tested.

Hormonal strategies as augmentation in TRD:

a) *Thyroid hormones*: Most of the data supporting the efficacy of thyroid hormones as augmentation treatment was derived from studies of TCAs. A meta-analysis of four placebo-controlled studies of triiodothyronine (T₃) augmentation of TCAs revealed a non-statistically significant increase in efficacy of T₃ versus placebo (Aronson et al., 1996). Limited open data supports the efficacy of T₃ augmentation of SSRIs, remission rates with T₃ augmentation in STAR*D level 3 were 24.7% and numerically larger than those of lithium (Nierenberg et al., 2006). Side effects include tremors, sweating, nausea, headaches, palpitations, and dry mouth.

b) *Estrogens*: The role of estrogen receptors has been invoked in the neurobiology of depression, but clinically estrogen augmentation is associated with mixed results. One of two double blind placebo-controlled studies of estrogens in perimenopausal women with TRD reported greater resolution of depressive symptoms with adjunctive estrogens (Ng et al., 2010). Side effects include headache, somnolence, constipation, nausea, and sweating. In a randomized controlled trial the efficacy of adjunctive raloxifene (a selective estrogen receptor modulator) as augmentation in TRD did not differ significantly from placebo.

THE ROLE OF BIOMARKERS IN GUIDING ANTIDEPRESSANT SELECTION AND PREDICTING RESPONSE

Advances in our understanding of genetic, cellular, and brain mechanisms involved in the pathology of mood disorders hold the promise to not only advance our understanding of the pathology of MDD but also to result in specific measures (“biomarkers”) to help guide clinical treatment, both generally, by suggesting new molecular and neuroanatomical targets to guide the development of new therapies, and specifically, by guiding clinicians in the selection of existing therapies (i.e., personalized medicine). Over the past few decades, increased capability and availability of genetic, endocrine, neuroimaging, and electrophysiology (EEG) technology has supported efforts to use these as biomarkers of treatment response (e.g., distinguish likely treatment responders from nonresponders with a specific intervention).

The search for such predictors of treatment outcome has cast a very wide net, but while many studies report correlations between specific clinical and/or biological parameters and clinical response to antidepressant treatment, such correlations are not sufficient to define a “predictor of treatment response.” An ideal predictor of treatment outcome would be present in many or all patients and would have high (close to 100%) positive and negative predictive values; that is, if the predictor is present, all patients with the predictor would have the outcome of interest, and if the predictor is absent, none would have the outcome (Iosifescu, 2011). To be of clinical utility, the predictor would have to be relatively easy to measure (including cost considerations) and be present either at baseline, before the onset of antidepressant treatment, or early during the treatment (during the first week). Also importantly, research supporting putative predictors would have to report not merely significant statistical associations, but a detailed description of predictor behavior at different cutoff points, such as the area under the receiver-operator characteristic curve, AUROC, a common summary statistic for the goodness of a predictor in a binary classification (see Perlis, 2011, for a discussion of methodological problems in biomarker research).

A large number of studies have explored *genetic markers* as predictors of clinical response to antidepressants in MDD. Many candidate gene studies have been conducted on antidepressant use in MDD, but the results are not yet readily usable in clinical practice, as most of the pharmacogenetic findings

for antidepressants have been inconclusive and/or controversial (Narasimhan and Lohoff, 2012). With respect to antidepressant metabolism and drug-drug interaction, the ability to measure CYP450 genes and the known effect of CYP450 enzymes on pharmacokinetics of antidepressants has led to a validated, FDA-approved pharmacogenetic clinical test (AmpliChip CYP450, Roche Diagnostic, Basel, Switzerland). It provides genotypes for the two CYP450 genes CYP2D6 and CYP2C19, allowing clinicians to predict the metabolizer status of a patient, which might influence antidepressant choice and dosing. However, the effect of such metabolic changes on clinical response is inconclusive, and the use of this genotyping test in clinical practice is limited.

Neuroimaging tests have also been studied extensively as potential markers of antidepressant response. Mayberg and colleagues (2000) have reported specific changes in metabolism in subgenual anterior cingulate gyrus in relation to treatment response; such changes were later replicated but found to be present across a variety of antidepressant modalities (and therefore not potentially useful in driving treatment selection). Many other imaging measures proposed have not yet been replicated. Moreover, due to the small size of these studies it is generally difficult to assess the predictive ability of these putative biomarkers (Iosifescu and Lapidus, 2011).

Electrophysiology: Several measures derived from prefrontal analysis of spontaneous electroencephalograms (EEG), evoked potentials, and EEG source localization have been associated with antidepressant response (Iosifescu, 2011). The best developed at this point are spontaneous EEG measures such as the antidepressant treatment response (ATR) index, whose predictive abilities have been replicated in large-scale studies (Iosifescu et al., 2009; Leuchter et al., 2009). EEG-based technologies have considerable advantages as potential clinical predictors. Since EEG is more widely available and cheaper than neuroimaging, it lends itself to studies with larger numbers of subjects (which are required for the validation of any biomarker of treatment response). The translation to clinical practice is also easier with a cheaper, ubiquitous technology (Iosifescu and Lapidus, 2011).

The current development of biomarkers appears to involve large studies where combining a variety of biomarkers (deriving, e.g., from genetics, imaging, or cognition) and clinical characteristics is attempted for improving predictions of a multifactorial process such as treatment response in MDD. Several large-scale clinical trials coupled with biomarker assessments are currently underway, and offer an example of new approaches for biomarker identification and development. One such example is the Emory study “Predictors of Antidepressant Treatment Response,” which is assessing genetic and PET imaging predictors of response to antidepressants and behavioral therapy (<http://www.ClinicalTrials.gov>: NCT00360399).

Another biomarker trial currently underway is the International Study to Predict Optimized Treatment in Depression (iSPOT-D) (<http://www.ClinicalTrials.gov>: NCT00693849). The study aims to recruit more than 2,000 MDD participants, which will be evaluated clinically, with behavioral tests of cognition and emotion, physiological measures taken during corresponding cognitive and emotional

tasks (EEG, event-related potentials, autonomic measures of heart rate, skin, and electromyography), structural and functional imaging (at least 10% of participants), and genotyping. These assessments will be integrated in a standardized assessment battery taken before and eight weeks after randomization to one of three antidepressants (escitalopram, sertraline, or venlafaxine XR).

Another large-scale biomarker study recently started is the Establishing Moderators and Biosignatures of Antidepressant Response for Clinical Care for Depression (EMBARC) study (<http://www.ClinicalTrials.gov: NCT01407094>), a randomized double blind trial across several US academic centers which will enroll 400 MDD participants, each to be assessed using clinical evaluations, self-report, behavioral tests of cognition, EEG, imaging measures, and genotyping. The study attempts to assess clinical and biological moderators and mediators of treatment response to sertraline versus placebo; non-responders in the first phase will be randomized to sertraline or bupropion.

In summary, there is a high unmet need for objective biomarkers to direct efficient selection of antidepressant treatments, to replace the current “trial and error” process. While no such biomarkers have been currently validated, current large-scale studies offer the promise of analyzing several simultaneously multiple putative biomarkers to detect the most accurate predictors and the relationships between them.

SOMATIC TREATMENTS

Somatic treatments include a large variety of methods of delivering energy directly to the brain (Table 38.3). While

electroconvulsive therapy (ECT) is one of the earliest antidepressant treatments, the last decade has seen an important expansion of the somatic treatments used as antidepressant treatments.

ELECTROCONVULSIVE THERAPY

Electroconvulsive therapy (ECT) is a long-standing psychiatric intervention that was introduced as a treatment for schizophrenia in 1938 and became a common treatment for depression in the 1980s. It has been proven effective as an acute treatment option for hard to treat patients, such as those with TRD, psychotic depression, and acute suicidality (Prudic et al., 2004). More than half of patients who receive ECT respond within the first four weeks of treatment (Husain et al., 2004). ECT involves the placement of either one electrode (unilaterally) or two electrodes (bilaterally) on the skull to induce cerebral seizures in anesthetized patients. There has been much debate over the efficacy and safety of different variations of electrode placement and voltage dosage. Evidence has shown that high dosage right unilateral and bilateral ECT seem to be similarly effective, and twice as efficacious as low or moderate dose unilateral ECT; however bilateral electrode placement, most specifically bitemporally, appears to produce increased and more sustained cognitive impairments than unilateral ECT (Kellner et al., 2010). Studies have generally shown response rates of 70–90% in patients across the spectrum of depression severity and with varying treatment history, however, response rates have been lower in patients with severe treatment-resistant depression (Prudic et al., 2004). The majority of patients who do not receive active maintenance treatment will generally relapse in six months to a year following a course of ECT

TABLE 38.3. Somatic treatments for MDD

TREATMENT	FDA APPROVED FOR MDD?	SETTING	INVASIVE	ANESTHESIA REQUIRED?	AREA OF STIMULATION	FORM OF ENERGY
Electroconvulsive therapy (ECT)	Yes (grandfathered)	Inpatient or outpatient procedure	No	Yes	Generalized	Electrical
Repetitive transcranial magnetic stimulation (rTMS)	Yes	Outpatient (office) procedure	No	No	Focal	Magnetic
Vagus nerve stimulation (VNS)	Yes	Surgical implantation followed by outpatient office adjustments	Yes	Yes (for surgery)	Generalized	Electrical
Deep brain stimulation (DBS)	No	Surgical implantation followed by outpatient adjustments	Yes	Yes (for surgery)	Focal	Electrical
Low field magnetic stimulation (LFMS)	No	Outpatient (office) procedure	No	No	Generalized	Magnetic
Magnetic seizure therapy (MST)	No	Inpatient or outpatient procedure	No	Yes	Focal	Magnetic
Transcranial direct current stimulation (tDCS)	No	Office	No	No	Focal	Electrical

(Sackeim et al., 2001). Antidepressant medication therapy reduces the rate of relapse but maintenance ECT is associated with the lowest levels of relapse (approximately 10%; Gagne et al., 2000). ECT is generally considered to be a safe procedure with a low risk of serious medical adverse events, but it is associated in the development of cognitive impairments, specifically memory loss. Cognitive side effects include acute confusion, anterograde amnesia, and retrograde amnesia. While these cognitive side effects are generally considered to be moderate, tolerable, and time-limited, more significant and extensive impairment can result. Continued research is being conducted to examine the possibility of various different dosage and electrode placement combinations having decreased cognitive side effects (Kellner et al., 2010).

A modern variation of ECT is **magnetic seizure therapy (MST)**, which involves cortical seizure induction via a magnetic field rather than direct application of electrodes. The goal of MST is to allow a more localized and precise induction of seizures, which may reduce side effects (e.g., cognitive effects) compared to ECT. However small studies so far suggest clinical effects are not different from ECT (Kayser et al., 2011). As in ECT, this technique requires anesthesia and muscle relaxation.

TRANSCRANIAL MAGNETIC STIMULATION

Transcranial magnetic stimulation (TMS) is a brain stimulation technique using electromagnetic induction and a rapidly changing magnetic field to induce weak electric currents, which cause depolarization or hyperpolarization of neurons in specific parts of the brain. The main advantage of TMS is its non-invasiveness and the possibility to stimulate relatively small brain volumes. A variant of TMS, repetitive transcranial magnetic stimulation (rTMS), has been tested as an antidepressant treatment and it is approved in the United States for the treatment of unipolar depression in adults who failed to respond to a single medication trial (O'Reardon et al., 2007). The largest sham-controlled study showed TMS had remission rate superior to sham, but relatively low (14.1% versus 5.1%), with almost 30% of patients achieving remission in the later open-label phase (George et al., 2010). rTMS has moderate effect sizes (0.39) in TRD, similar to those seen with standard pharmacotherapy (Schutter, 2009) and less effective than ECT. In general, rTMS appears to be safe and well tolerated (O'Reardon et al., 2007). Common side effects include headache and scalp pain. Seizures can occur with rTMS, although in less than 0.5% of subjects. More research is needed to determine the optimal stimulation parameters. High frequency (5–20 Hz) stimulation of the left DLPFC has been the technique most studied, while data from low frequency stimulation (1Hz) of right DLPFC are limited.

Other variations of TMS currently researched include techniques with increased brain penetration (*deep TMS*, which can stimulate subcortical brain structures below the 2 cm area accessible with rTMS, or *synchronized TMS*, which allows individualized stimulation at the intrinsic alpha frequency of the subject; for both the efficacy results are still pending).

Low field magnetic stimulation (LFMS) is another investigational method of brain stimulation by an alternating magnetic field. LFMS is based on empirical observations

of echo-planar magnetic spectroscopic imaging (EP-MRSI) sequences inducing mood effects, possibly through stimulating effects of weak electromagnetic fields. Pilot studies have shown rapid mood elevating effects in both unipolar and bipolar depressed patients (Rohan et al., 2004). Larger studies, including a multi-site NIMH-sponsored trial (NCT01654796), are ongoing.

SURGICALLY IMPLANTED DEVICES

VAGUS NERVE STIMULATION

Vagus nerve stimulation (VNS) includes a surgical implant that stimulates electrically the ascending branch of left vagus nerve and stimulates the vagal nucleus of the solitary tract, which has widespread projections within the central nervous system, including to the forebrain. In animal models VNS was associated with GABA and noradrenergic effects in the frontal cortex. VNS has been used as an anticonvulsant and was adapted as an antidepressant treatment after positive effects on mood were noticed in patients receiving the treatment for epilepsy. In the pivotal study VNS did not separate from sham in the acute (12-week) period but open continuation for up to 12 months yielded a 27% response rate in highly treatment-resistant patients (George et al., 2005). VNS is FDA approved since 2005 for the treatment of chronic and treatment resistant depression in patients who failed to respond to at least four trials of antidepressants, but the rate of implantations appears low given challenges related to efficacy, surgery, and financial considerations (insurance reimbursement). Side effects for VNS include complications of surgery, neck or jaw pain, hoarseness, or cough.

DEEP BRAIN STIMULATION

Deep brain stimulation (DBS) is an investigational treatment for depression involving direct stimulation of specific subcortical brain areas to affect the brain neurocircuitry of emotional regulation. DBS (which is currently FDA approved for the treatment of essential tremor, Parkinson's, and dystonia) requires surgical implantation of an electrode stimulating the target brain area and connected to an electrical pulse generator. The largest studies investigating DBS in MDD have targeted the subgenual cingulate; a recent report suggests long-term efficacy in a 17 MDD subjects receiving open stimulation (Holtzheimer et al., 2012). Other smaller studies have targeted the ventral anterior internal capsule and the nucleus accumbens; larger controlled studies in several target areas are ongoing.

PSYCHOTHERAPIES

While the space of this chapter does not allow a detailed discussion of psychotherapies, we need to highlight that they represent a first-line treatment for MDD, with cognitive and behavioral therapies (CBT) and interpersonal therapies (IPT) having the most evidence in support of their efficacy in randomized clinical trials (Hollon and Ponniah, 2010). Some data supports the effectiveness of these therapies for prevention of depressive relapse after an initial acute treatment.

COGNITIVE AND BEHAVIORAL THERAPIES

Cognitive and Behavioral Therapies (CBT) includes a family of related treatments involving cognitive and behavioral interventions for MDD. Older meta-analyses have shown a slight advantage for CBT over medications in treating depression; however, methodological limitations in some of these older studies may have favored CBT (Butler et al., 2006). In the large, multisite Treatment of Depression Collaborative Research Program (TDCRP), CBT and medication (imipramine) showed similar efficacy; however, among patients with severe MDD, imipramine was found to be superior to CBT (Elkin et al., 1995). However, in more recent research, CBT and medication were comparable in treating severe depression. CBT and paroxetine were equally effective after 16 weeks of treatment in the treatment of moderate and severe MDD (DeRubeis et al., 2005). Thase and coworkers (2007) reported the results of the second level of the Sequenced Treatment Alternatives to Relieve Depression (STAR*D) study, where MDD subjects received CBT (either alone or as augmentation) after failing an initial trial of citalopram. Patients receiving CBT had similar response and remission rates to patients randomized to medication strategies, but patients receiving drug augmentation had more rapid response than those receiving antidepressant augmentation, while patients receiving CBT monotherapy experienced fewer side effects compared to those assigned to antidepressant monotherapy.

Acute outcomes of CBT and antidepressant medication appear largely comparable, and relapse rates after CBT are comparable to those of individuals maintained on antidepressants after one year and superior to placebo (Hollon et al., 2005). Combining antidepressants and CBT generally yields an advantage over either of the two treatments alone, and may be especially advantageous in more chronic forms of depression (Keller et al., 2000).

INTERPERSONAL THERAPIES

Interpersonal therapy (IPT) is a short-term, manual-based treatment for depression. IPT focuses on interpersonal issues, emphasizing on the way depressive symptoms are related to a person's relationships, including family and peers. The immediate goals of treatment are symptom reduction and improved social adjustment.

Two decades ago a large controlled study suggested that IPT and imipramine were more efficacious than placebo for the more severely depressed individuals, while CBT was not; the entire study sample did not show efficacy differences between treatment modalities (Elkin et al., 1989, 1995). However, in a more recent study CBT was more effective than IPT for the more severely depressed individuals, while the rates of response were comparable between therapies for the entire group and for the subgroups with mild and moderate depression (Luty et al., 2007). IPT was also shown to be more effective than placebo (but less effective than imipramine) in maintaining a group of MDD patients in long-term recovery (Frank et al., 1990). In elderly MDD subjects maintenance with paroxetine was more effective than IPT or placebo for prevention of relapse (Reynolds et al., 2006).

In summary, CBT may be comparable to medication for acute treatment and it provides durable benefits. Combining CBT and pharmacological treatments may be most effective in chronic depression. The efficacy of IPT for acute and maintenance treatment is also supported by several studies (Hollon and Ponniah, 2010).

NATURAL REMEDIES AS ANTIDEPRESSANTS

While the use of natural or "alternative" remedies is popular and increasing in the United States and worldwide, the data supporting their efficacy as antidepressants is limited. The best-studied natural medications for mood disorders are St. John's Wort (hypericum), omega-3 fatty acids, and S-adenosylmethionine (SAME).

ST. JOHN'S WORT (HYPERICUM)

The extract of the flower of St. John's Wort (*Hypericum perforatum L.*) is widely used for the treatment of depression. Although the extract contains a large number of molecules, the main active components in hypericum are considered to be hypericin and hyperforin. Hypericin does not cross the blood-brain barrier but may have modulatory effects on inflammatory cytokine production (interleukin-6 and interleukin-1 β), resulting in a decrease in corticotrophin-releasing hormone. Hyperforin appears to be associated with serotonin reuptake inhibition and norepinephrine and acetylcholine reuptake inhibition (Mischoulon, 2009). Large meta-analyses support the efficacy of St. John's Wort in MDD in comparison with placebo and relatively equivalent efficacy with suboptimal doses of antidepressants, with the most favorable studies all performed in German-speaking countries (Linde et al., 2008). In several large US studies St. John's Wort did not separate from placebo (Freeman et al., 2010). In monotherapy St. John's Wort has a favorable side effect profile; side effects include dry mouth, dizziness, constipation, other gastrointestinal symptoms, confusion, and phototoxicity. St. John's Wort appears to induce cytochrome P450 3A4, resulting in decreased levels of substrates (antiretrovirals, cyclosporines). Other components of hypericum, including flavonoids, are irreversible monoamine oxidase-A inhibitors and cases of serotonin syndrome have been described when St. John's Wort was combined with SSRIs.

OMEGA-3 FATTY ACIDS

Omega-3 fatty acids are polyunsaturated fatty acids with a double bond (C=C), commonly found in marine and nut oils. Their presence in modern diet is decreased due to substitution with omega-6 fatty acids present in vegetable oils. Eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) are the two fatty acids with evidence for an antidepressant effect. Proposed mechanisms for the antidepressant effects include their interaction with catecholamine metabolism and inhibition of inflammatory cytokines secretion (prostaglandin E2), leading to decreased corticosteroid release

(Mischoulon, 2009). A recent meta-analysis of 35 randomized controlled trials supports the efficacy of omega-3 fatty acids (in doses ranging from 0.5 to 9.6 g/d) compared to placebo in MDD, but finds the published literature to show significant heterogeneity, likely generated by publication bias (Appleton et al., 2010). There was no clear difference in efficacy between EPA and DHA. The omega-3s appear to be well tolerated and safe. Side effects include gastrointestinal upset, fishy aftertaste, and a small risk of bleeding.

S-ADENOSYLMETHIONINE

S-adenosylmethionine (SAMe) is present in all human cells, including the brain, acting as a methyl donor to membrane phospholipids, myelin, choline, catecholamines, and other molecules important for brain function. It is synthesized from the amino acid L-methionine through the one-carbon cycle; the vitamins folate and B12 are catalysts of this process (folate and B12 deficits have been associated with depression). The mechanism of SAMe's antidepressant effect has been associated with its role as an intermediate for the synthesis of norepinephrine, dopamine, and serotonin (Mischoulon, 2009). A recent systematic review reported that in 7 of 7 controlled trials that parenteral SAMe was more efficacious in MDD than placebo and equal in efficacy to the tricyclic antidepressants (Papakostas, 2009). Four out of 5 controlled trials also support the efficacy of oral SAMe (1600 mg/day). A recent RCT reported SAMe augmentation of SSRIs was more efficacious than placebo (Papakostas et al., 2010). Side effects are uncommon, but occasionally nausea, gastrointestinal upset, and anxiety can occur.

In conclusion, St. John's Wort is supported by evidence of efficacy as monotherapy, but the data is very heterogeneous and the risk of drug interactions should be considered. Limited evidence supports the efficacy of omega-3 fatty acids and SAM-e. Other natural remedies including L-methylfolate and N-acetyl cysteine (NAC) are associated with even more limited evidence of efficacy in MDD.

TREATMENT OF DEPRESSION IN SPECIAL POPULATIONS

Depression has a heterogeneous clinical presentation, and several subtypes of depression have been described. While a complete discussion of these subtypes is beyond the scope of this chapter, we will mention the most significant subtypes of depression: psychotic, melancholic, atypical, postpartum, seasonal, and bipolar. The presence of such variations in clinical presentation probably underlies a significant variability in the etiology of depression and does influence treatment decisions, as discussed in the following. Specific treatment strategies for geriatric depression and of depression with comorbid medical illness are addressed in Chapters 35 and 37 of this book.

PSYCHOTIC DEPRESSION

The presence of psychotic symptoms during a major depressive episode is considered a marker of increased severity, even

when depressive symptoms are moderate. Psychotic depression is associated with increased rates of recurrence, poor response to antidepressant treatment, and poor outcomes (Rothschild, 2003). Some studies suggest psychotic depression is biologically distinct from non-psychotic MDD, with more significant HPA axis abnormalities (increased cortisol levels, higher rates of non-suppression on the dexamethasone suppression test) and an activation of the dopaminergic system (higher levels of cerebrospinal fluid 5-hydroxyindoleacetic acid and lower serum dopamine-beta-hydroxylase (which converts dopamine to norepinephrine) (Rothschild, 2003). Recent meta-analyses suggest that while antidepressant or antipsychotic monotherapies are associated with lower rates of response, combined antipsychotic-antidepressant treatment can be more efficacious (Farahani and Correll, 2012). ECT is associated with high rates of treatment response but with relatively rapid loss of response (Prudic et al, 2004) in patients with psychotic depression.

MELANCHOLIC DEPRESSION

Melancholic depression is characterized by severe anhedonia with lack of mood reactivity, severe weight loss or loss of appetite, psychomotor agitation or retardation, early morning awakening, guilt that is excessive, and worse mood in the morning. Biologically, melancholic depression has been associated with enhanced activity of the hypothalamic-pituitary-adrenal (HPA) axis, involving elevated secretion of corticotropin-releasing hormone (CRH), which in turn contributes to sleep abnormalities (Gold and Chrousos, 2002). Clinically, melancholic depression appears associated with higher severity, increased anxiety, and higher rates of suicidality. Cognitive impairments (attention shifting, mental flexibility, decreased memory) are consistently associated with melancholia. Several antidepressants including SSRI and SNRIs appear effective for treating melancholia; ECT is particularly effective in melancholic and severe presentations.

ATYPICAL DEPRESSION

Atypical depression is characterized by persistent mood reactivity, hypersomnia, hyperphagia, leaden paralysis, and rejection sensitivity, although correlation analyses reveal only modest associations between several of the atypical symptoms (Posternak and Zimmerman, 2002). There is a significant degree of overlap with symptoms of bipolar depression. Biologically, several studies suggest reduced activity of the HPA axis and reduced noradrenergic activity in the locus coeruleus. Clinically, atypical depression is associated with a reported preferential response to monoamine oxidase inhibitors compared to TCAs; other studies suggest SSRIs are more efficacious than TCAs in such patients (Stewart et al., 2009). The SSRIs are a preferred first-line therapy in such patients.

POSTPARTUM DEPRESSION

Postpartum depression represents moderate to severe depression experienced by women after giving birth. It occurs in up to 10% of healthy women (but up to 50% in women with previous

history of depression) and it is different from the much milder postpartum “blues,” a self-limited, non-pathological condition which can occur in 50% to 85% of women in the first 10 days following delivery. The symptoms of postpartum depression appear most often within three months post delivery and are similar to other forms of MDD. Severe forms of postpartum depression are associated with psychosis and represent a psychiatric emergency.

Meta-analyses support the efficacy of psychotherapy (especially IPT and CBT) and of conventional antidepressants (fluoxetine, sertraline, venlafaxine) in the treatment of postpartum depression (Sockol et al., 2011). Postpartum depression has been associated with the significant hormonal fluctuations after delivery, especially the significant decrease in estrogen and progesterone levels. Several studies suggest a role for exogenous estrogen in the treatment of women with postpartum depression (Dennis et al., 2008), but treatment with estrogen has been associated with changes in breast-milk production and with thromboembolic events. Treatment with progesterone is not supported by current evidence.

SEASONAL AFFECTIVE DISORDER

Seasonal affective disorder (SAD, “winter blues”) represents a form of recurrent depression with a clear seasonal pattern. Decreased levels of DA transporter in the striatum have been reported in SAD (Neumeister et al., 2001). Bupropion, a dopaminergic antidepressant, appears efficacious as a treatment and for the prevention of seasonal depression episodes (Modell et al., 2005). Studies also support the efficacy of bright light therapy (10,000 lux 30 minutes/day for 8 weeks) and of fluoxetine for the seasonal depression (Lam et al., 2006), while other second-generation antidepressants have only minimal evidence of efficacy (Thaler et al., 2011).

BIPOLAR DEPRESSION

In patients with bipolar disorder, depression is the most frequent clinical problem and the most significant cause of morbidity and dysfunction. Quetiapine (Calabrese et al., 2005) and the olanzapine-fluoxetine combination (OFC) (Tohen et al., 2003) are FDA-approved for the treatment of acute bipolar depression. Lamotrigine is FDA-approved only for prophylaxis of bipolar mood episodes since only one of four controlled studies of lamotrigine for acute bipolar depression has achieved the primary endpoint. Other studies suggest lithium might be an efficacious antidepressant, and that lithium and lamotrigine might be equally efficacious for bipolar depression (Suppes et al., 2008). The usefulness of traditional antidepressants in bipolar patients is more controversial. Most treatment guidelines advocate against using antidepressant monotherapy in bipolar disorder, mainly due to the risk of manic switches and mood cycling. Despite such expert consensus, 50% of bipolar patients receive antidepressant monotherapy as their initial treatment (Baldessarini et al., 2007). While some studies have suggested that antidepressants added to mood stabilizers might have some benefit, in the NIH-funded STEP-BD study ($N = 366$) adding an antidepressant (paroxetine or bupropion)

or placebo to a mood stabilizer in bipolar depressed subjects resulted in equally low rates of improvement (23.5% versus 27.3% of subjects achieved recovery on antidepressant versus placebo, respectively) and similar rates of switch to mania (Sachs et al., 2007).

For patients who failed a first-line treatment, lamotrigine appeared to achieve numerically superior efficacy compared to risperidone or inositol, but the differences were not statistically significant due to the low number of patients in the study (Nierenberg et al., 2006b). Only a few small studies support the efficacy of pramipexole (Goldberg et al., 2004), MAOIs (Himmelhoch et al., 1991), or modafinil (Frye et al., 2007) when added to mood stabilizers for the treatment of bipolar depression. Ziprasidone and aripiprazole have failed to demonstrate efficacy in bipolar depression. There is also significant evidence in support of the efficacy of focused psychotherapies (cognitive behavioral therapy, family-focused therapy, and interpersonal and social rhythm therapy) in patients with bipolar disorder (Miklowitz et al., 2007).

NEW AVENUES IN ANTIDEPRESSANT TREATMENT

Given the large disease burden of MDD and the limitations in current treatments, the major goal of current neuropharmacology research is to identify safe and more effective antidepressant treatments. Several such agents currently in development can be broadly classified as monoaminergic, according to their primary mechanism of action. These include triple-reuptake inhibitors (TRIs), which bind to and inhibit all three primary monoamine synaptic reuptake proteins: the serotonin transporter (SERT), the norepinephrine transporter (NET), and the dopamine transporter (DAT). TRIs can be seen as the next logical step in an effort to broaden engagement of the monoamine systems, following the development of serotonin norepinephrine reuptake inhibitors (SNRIs). It remains to be seen, however, if TRIs will confer enhanced efficacy over currently available monoaminergic agents.

Innovative antidepressant drug discovery efforts focus however outside of the monoaminergic by targeting a variety of neural systems and chemical messengers, including the glutamate system, the HPA axis, the galanin and other neuropeptide systems, the melatonin system, inflammatory mediators, and neurogenesis (see Murrough and Charney, 2012, in press, for a recent review of the antidepressant horizon). Recognition of the role of stress-related neuropeptides in preclinical models of depression has prompted investigation into the clinical utility of small-molecule neuropeptide modulators, including corticotropin-releasing hormone (CRH) antagonists and neurokinin (NK) receptor antagonists. However, to date phase II and III RCTs of molecules from both classes of neuropeptide modulators have been disappointing.

The glutamate system in particular may be a fruitful avenue for novel treatment development. In this section we will briefly review the rationale for targeting the glutamate system in mood disorders and highlight the example of the glutamate

N-methyl-D-aspartate (NMDA) receptor (NMDAR) antagonist ketamine as an example of a potentially novel glutamatergic antidepressant (Murrough, 2012). Glutamate is the ubiquitous excitatory neurotransmitter in the brain and is a critical mediator of neuroplasticity and learning and memory. Cortical and limbic brain circuits crucial for cognitive and emotional regulation largely utilize glutamate as the primary neurotransmitter, and maladaptive alterations in synaptic structure and function observed in animal models of stress and depression are seen within glutamatergic pathways (Duman and Voleti, 2012). The extensive plasticity of the glutamate synapse in response to environmental influences suggests a key physiological substrate for the well-known link between environmental stress and depression and the neurotoxic effects of abnormally high levels of glutamate—which may result from stress—is a candidate mechanism for regional reductions in brain volume observed in MDD. These and other data point toward the glutamate system as a principal candidate to target for therapeutic modulation in MDD.

Ketamine is a high-affinity, non-competitive NMDAR antagonist that is currently FDA-approved as an anesthetic agent and is used off-label in the management of chronic pain. The potential antidepressant properties of ketamine were initially highlighted by a series of two small studies (Berman et al., 2000; Zarate et al., 2006), while several controlled and open-label studies conducted subsequently provide support for the rapid antidepressant effects of ketamine (reviewed in Murrough et al., 2012). Acute response rates as high as 70% are observed within 24 hours of a single intravenous infusion, even in patients with TRD. A series of recent basic science studies in animal models highlight alterations of synaptic structure and function as essential aspects of ketamine's antidepressant mechanism of action (Duman and Voleti, 2012). Larger controlled studies of ketamine in depression will be required before a firm conclusion can be drawn regarding the antidepressant efficacy of ketamine. A treatment schedule of repeated administrations of ketamine and relapse prevention strategies following a response to ketamine are currently active areas of investigation.

Non-pharmacological treatments are also an active area of antidepressant research. Those include novel methods utilizing magnetic stimulation (synchronized TMS, deep TMS, LFMS), other forms of non-invasive brain stimulation (e.g., magnetic seizure therapy, transcranial direct current stimulation, near infrared radiation), as well as invasive deep brain stimulation (DBS) with several brain targets. Several of these treatments have shown promise in early studies and are currently undergoing more definitive evaluation.

In conclusion, over the last four decades clinical observations and research have led to the validation of a large number of effective monoaminergic antidepressants, several structured psychotherapies (CBT, IPT), and ECT. However, limitations of current treatments and advances in our understanding of the biology of mood disorders represent the impetus for the major search for new treatments currently underway. A significant number of novel agents, including pharmaceuticals and natural remedies, as well as somatic treatments are currently in development. Potential biomarkers of treatment

outcome could also revolutionize current treatment strategies in depression.

DISCLOSURES

Dr. Iosifescu has been for the last three years a consultant to CNS Response, Inc., and Servier. Lifetime he has received research support from Aspect Medical Systems, Forest and Janssen Pharmaceutica, and he has received consulting and speaking honoraria from Cephalon, Eli Lilly, Forest, and Pfizer.

Dr. Murrough has no conflicts of interest to disclose.

Dr. Charney has been named as an inventor on a pending use-patent of ketamine for the treatment of depression. If ketamine were shown to be effective in the treatment of depression and received approval from the Food and Drug Administration for this indication, Dr. Charney and Mount Sinai School of Medicine could benefit financially.

SECTION V | ANXIETY DISORDERS

KERRY J. RESSLER

Anxiety disorders affect up to 30% of the population in their lifetime, and a large portion of suicides involve comorbid anxiety. Despite these statistics, anxiety disorders are often underappreciated and understudied. However, beyond the morbidity, mortality, and impairment associated with anxiety is the increasing awareness that these disorders are quite tractable from the perspective of neuroscience. Recent work on the basic neurobiology of fear and fear-related disorders has combined with over 100 years of psychological understanding of conditioned emotional responses and tremendous new tools to dissect the neural circuitry of fear. Together, these approaches have led to very exciting progress into the molecular genetics; cellular and systems neural circuitry; and neural processing, behavioral, and diagnostic implications for the class of mental disorders we call anxiety.

The section begins with an overview of current diagnostic nosology combined with progress in our understanding of etiology, at bio-psycho-social levels, of the shared and different underpinnings of some of these disorders (Chapter 39). This is followed by an update on state-of-the-art genetics of anxiety disorders, ranging from heritability studies in large twin samples to recent candidate and hypothesis-neutral-based gene association studies (Chapter 40). Although the genetics of anxiety has somewhat lagged behind other mental disorders, it is widely felt that because of the terrific models to circuitry-level understanding, as genetics catches up, it will be integrated into a scaffold of neural understanding of fear and anxiety, leading to rapid advances.

Progress in the neurobiology of behavior has no greater models of success than work in the area of neurobiology of fear. The central role of amygdala and of other associated brain regions involved in modulating amygdala function are clearly outlined in Chapter 41, which serves as a substrate for many of the subsequent chapters focused on further dissecting the emotion of fear regulation in mammalian systems. Chapter 42 examines the differential roles of the inhibitory GABA receptor population in regulating emotion, fear, and anxiety-like behavior. The inhibitory neuronal population and its accompanying GABA receptors are enormously heterogeneous and complex, and yet the multiple methods of controlling activity, with temporal, spatial, and regional specificity, provide much of the richness of brain function. The most classic anxiolytics

such as benzodiazepines, as well as some of the most novel hypnotics and cognitive enhancers, rely on specific targeting of differential GABA subunits. Chapter 43 further dissects regulation of the fear and anxiety modulatory systems by reviewing very recent updates in our understanding of prefrontal cortex control over emotion and anxiety. This chapter, primarily focused on animal models, is complemented by Chapter 45, which updates our understanding of human functional neurocircuitry from the perspective of recent neuroimaging studies of anxiety disorders.

Most anxiety disorders have their antecedent in development. Fascinating new studies in animal models have demonstrated that there are emotional “critical periods” of fear development and inhibition that may be akin to the types of critical periods that the field of neuroscience is familiar with in sensory system development. Chapter 44 outlines some of these new approaches detailing exciting advances in circuit and behavioral systems development.

The final chapters within this section focus on novel and developing treatments for anxiety disorders, including both psychological and cognitive (Chapter 46) and pharmacological approaches (Chapter 47), many of which have been rationally developed based on the preceding understanding of the neurobiology of the circuitry and pharmacology of fear and anxiety-like behaviors. The final two chapters examine the neurobiology and treatment of obsessive-compulsive disorder (Chapter 48) and posttraumatic stress disorder (Chapter 49), two of the most debilitating and refractory anxiety disorders. However, as these chapters illustrate, an enormous amount of progress has been made in recent years related to the neural underpinnings of these disorders, and this advanced understanding is leading to promising new approaches to treatment and prevention. Together, we hope that this entirely new section on anxiety disorders helps the reader appreciate the enormous progress in this area over the last few years. We are very excited that rapid advances in the neurobiology of fear- and anxiety-related behaviors have translated remarkably well to humans. This progress suggests that these disorders may be particularly tractable as affective neuroscience continues to improve, providing a model for other mental illnesses in the translation of basic neuroscience to novel and more powerful treatment and prevention efforts.

39 | DIAGNOSIS OF ANXIETY DISORDERS

MEGHAN E. KEOUGH, MURRAY B. STEIN, AND PETER P. ROY-BYRNE

THE CURRENT NOSOLOGICAL MODEL

Over the past 60 years, the conceptualization and diagnosis of psychiatric disorders has experienced substantial growth and transformation. Unlike the recent DSMs (*Diagnostic and Statistical Manuals*), the first two editions in 1952 and 1968 did not provide explicit categorical criteria sets and were rooted in the psychodynamic perspective that psychiatric symptoms reflect disguised psychological conflicts rather than disease states (American Psychiatric Association, 1952, 1968). The lack of standardized classification resulted in professionals operating largely based on their own personal beliefs and training, which resulted in substantial variability across individuals and institutions (Mayes and Horowitz, 2005). The publication of the DSM-III (1980) drew from work initiated in 1972 by a group of Washington University researchers (Feighner et al., 1972) and expanded in 1978 as the Research Diagnostic Criteria (RDC) by Spitzer and colleagues (1978). It emphasized an atheoretically derived group of symptom criteria designed to yield reliable diagnoses that, whenever possible, would also predict course of illness, family history, and treatment response (i.e., “predictive validity”). At the time, these investigators also hoped that biological variables might someday be included as diagnostic validators.

While these changes were built upon expanding scientific knowledge, the DSM-III changes also reflected political viewpoints within the mental health field, increased government involvement in mental health research, and pressure from insurance and pharmaceutical companies (Mayes and Horowitz, 2005). Subsequent revisions to the DSM-III and DSM-IV have further attempted to enhance both the reliability and the validity of the diagnostic criteria. One major revision in the DSM-III-R was the removal of the DSM-III hierarchical structure, which among other things, dictated that an individual could not be diagnosed with an anxiety disorder if depressed (American Psychiatric Association, 1980, 1987).

The current nosological model of the modern DSMs, while not without fault, has facilitated significant research growth in the anxiety disorders field over the past three decades, spurring scientific progress in our understanding of pathophysiology and the identification of effective treatments. It has allowed researchers to more reliably conceptualize a population of interest and clinicians to more reliably identify their patients’ diagnoses. The DSM is now extensively used around the world by clinicians, researchers, health insurance companies, pharmaceutical companies, funding agencies, and policymakers. This has created a shared language regarding psychiatric illness within and across these different professional stakeholders.

While the modern DSMs have bolstered the conceptualization and treatment of anxiety disorders, the current system continues to fall short of its fundamental goals of establishing a reliable and valid classification of mental disorders. While reliability has been largely achieved with the DSM-III and DSM-IV, a number of issues suggest that the validity of the diagnostic system has yet to be achieved. Among these issues are criticisms that the high rate of comorbidity among the disorders indicates an unwarranted splitting of underlying entities. The polythetic criterion, the requirement that only some criteria be present for diagnostic threshold to be met, has been criticized as resulting in widely disparate symptom presentations for the same diagnosis (i.e., two patients could meet criteria for the same disorder while having few, if any, overlapping symptoms). Others note that many clinically distressed individuals do not meet diagnostic criteria for any of the specific diagnoses, and subsequently, this results in an overreliance on not-otherwise-specified (NOS) diagnoses. Finally, and perhaps most importantly, because the current diagnoses developed apart from genetic and neuroimaging research that seeks to clarify the causes and mechanisms of psychiatric illness, the results of this emerging research do not necessarily align with current diagnostic conceptualizations. The DSM-5, currently in its final stages of development, hopes to address some of these criticisms.

PROPOSED REVISIONS IN DSM-5

BACKGROUND

The American Psychiatric Association is currently in the process of revising the DSM-IV to yield the DSM-5. The revisions are intended to incorporate the wealth of research that the field has generated in the past two decades, to maintain continuity with DSM-IV where possible, and to place the highest priority on clinical utility (American Psychiatric Association 2012a). The process has included preplanning white papers, a series of 13 planning conferences, and appointment of chair, vice-chair, and Work Group members. The DSM-5 development process has made use of systematic literature reviews, several rounds of public feedback, and extensive input from professional and consumer stakeholders. The release and publication of the DSM-5 is projected to coincide with the APA’s annual conference in May 2013.

Whereas this chapter is focused on anxiety disorders and the specific changes to these disorders as outlined in what follows, there are a number of general changes that will affect this category. First, the diagnoses previously included in the chapter “Disorders Usually First Diagnosed in Infancy, Childhood, or

Adolescence” are now incorporated into other chapters by noting their developmental continuity with adult disorders. Thus, separation anxiety disorder is now listed first in the anxiety disorders chapter. Second, the current revisions have also placed an emphasis on the additional dimensional assessment of psychiatric disorders. The categorical diagnostic system utilized in the previous DSMs is not being replaced by a dimensional system; however, there is an acknowledgment that measurement-based care that utilizes dimensional measures is feasible and would be of benefit to routine clinical care (Regier et al., 2012). Adding these measures will potentially allow for both a more nuanced conceptualization of patients’ psychiatric disorders and a more objective monitoring of patients’ progress throughout therapy. Thus, accompanying the proposed revisions of each anxiety disorder is a note of whether a psychometrically sound measure currently exists. In addition, each anxiety disorder includes two newly developed measures that are being tested for these purposes (the first designed to assess the severity of the specific anxiety disorder and the second designed to assess severity across all anxiety disorders).

Revisions to the anxiety disorders chapter were the responsibility of the Anxiety, Obsessive-Compulsive Spectrum, Posttraumatic, and Dissociative Disorders Work Group (referred from this point on in the chapter as the Anxiety Work Group). The Anxiety Work Group commissioned a series of literature reviews that were published in the peer-reviewed journal *Depression and Anxiety*. Proposed recommendations were informed by these reviews as well as secondary data analyses of existing datasets, collection of new data, surveys of experts and input and data provided by advisors and liaisons, DSM-5 Task Force members, other members of the research community, and other stakeholders (Phillips et al., 2010). The overarching approach continues to emphasize a search for associated factors that might “validate” these diagnostic categories, but has expanded beyond symptom measures, course of illness, family history and treatment response, to include, wherever possible, medical and psychiatric illness comorbidities, genetic and environmental risk factors, temperamental and personality antecedents, cognitive and emotional processing response measures, and neurocircuitry.

ANXIETY-RELATED DISORDERS ON THE MOVE

OBSESSIVE-COMPULSIVE DISORDER

Obsessive-compulsive disorder (OCD) is characterized by anxiety-provoking obsessions and/or compulsions that are intended to ameliorate anxiety. This disorder is equally common in men and women, yet due to its earlier onset in males, is seen more often in boys than girls. It typically follows a chronic course, and studies indicate a familial risk, with first-degree relatives at higher risk for OCD (American Psychiatric Association 2000).

Much of the discussion regarding OCD and the DSM-5 has surrounded its appropriate placement within the manual. This discussion has considered whether to leave OCD as an anxiety disorder, place it in its own chapter with other disorders from the OC spectrum, or include both anxiety disorders and OCD under the same umbrella category, as is done in the ICD-10,

which places both anxiety disorders and OCD under *neurotic, stress-related, and somatoform disorders* (World Health Organization, 1993). This last option was the favorite of the majority of authors in both the Phillips et al. (2010) and Stein et al. (2010) reviews. However, OCD researchers were mixed regarding their approval (60%) of the removal of OCD from the supraordinate anxiety category (Mataix-Cols et al., 2007), and clinical psychiatrists and “other professionals,” largely psychologists, showed a significant difference in opinion (75% agreed versus 40%–45%, respectively). Stein et al. (2010) outlined the research from a series of validators (e.g., neurocircuitry; course of illness; treatment response; and genetic, familial, and environmental risk factors) regarding OCD’s appropriate placement. While there are some uniquely distinctive aspects to OCD (involvement of fronto-striatal neurocircuitry and related deficits, a narrower range of effective medications and a clear dose–response pattern to SRI medication response, and a unique association with basal ganglia neurologic disorders), there is still much overlap with anxiety disorders in multiple other domains (e.g., comorbidity, family history). Generally, these results present a mixed picture providing both support for the inclusion of OCD within the anxiety disorders and its removal. Nevertheless, DSM-5 will move OCD to the *Obsessive-Compulsive and Related Disorders* category along with several other disorders including body dysmorphic disorder, hoarding, hair pulling (trichotillomania), and skin picking. These disorders are all characterized by repetitive, anxiety- or dysphoria-inducing thoughts and/or behaviors (designed at reducing the discomfort). While genetic, neural, and biomarker validators that support this new category are few, several other validators link these disorders with OCD or one another, including high comorbidity, similar psychopharmacology and psychotherapy response, and evidence of familial transmission (Phillips et al., 2010).

Proposed changes to the OCD criteria have been made and include moving the two items from the obsessions definition that sought to distinguish obsessions from GAD (generalized anxiety disorder; obsessions are not simply excessive worries regarding life problems) and psychosis (the individual recognized that the obsessional thoughts, impulses, or images are not created by an external force but rather are a product of his or her own mind) and placing them in Criterion D among the other diagnostic hierarchy issues (Leckman et al., 2010). Additionally, the requirement that individuals recognize that their symptoms are excessive was removed, and the poor insight specifier was replaced with specifiers indicating a range of insight (i.e., good or fair insight, poor insight, or absent insight). Finally, suggestions are made for dimensional measures. Previously validated measures include the Yale-Brown Obsessive-Compulsive Scale (Y-BOCS; Goodman et al., 1989), the Florida Obsessive-Compulsive Inventory (FOCI; Storch et al., 2007), and the Brown Assessment of Beliefs Scale (BABS; Eisen et al., 1998). A newly developed five-item questionnaire is also included and currently being tested.

POSTTRAUMATIC STRESS DISORDER

Posttraumatic stress disorder (PTSD) can develop following exposure to a traumatic event and is characterized by

reexperiencing the trauma, avoidance of traumatic cues, and increased symptomatic arousal. Evidence suggests that the development of PTSD following trauma is affected by social supports, childhood experiences, personality variables, type of trauma, and preexisting mental disorders (American Psychiatric Association, 2000). Additionally, genetic factors appear to affect the likelihood of developing the disorder (Stein et al., 2002).

Like OCD, much of the DSM-5 focus on PTSD has surrounded its most appropriate placement within the DSM. Stress-related fear circuitry findings from neuroimaging and fear conditioning studies, among other findings, support the retention of PTSD within the anxiety disorders (Friedman et al., 2011a). But PTSD frequently encompasses a broader range of emotions (e.g., numbing, guilt, alienation) than other anxiety disorders and shares a unique precipitating event (all cases are trauma induced). Emphasizing common etiology over symptom similarity, it has been concluded that PTSD should be placed in a newly formed category that includes disorders that are precipitated by a “serious life event” (the *Trauma-and Stressor-Related Disorders*). PTSD’s anticipated departure from the anxiety disorders has met strong criticism. Zoellner et al. (2011) note that the “rationale for this shift is unclear, underdeveloped, and unsupported” (p. 853) and delineate four main points that support retaining PTSD as an anxiety disorder: (1) fear is a critical component of PTSD, (2) the treatment of fear and avoidance is central to PTSD as it is with other anxiety disorders, (3) the evidence base does not support a separate category, and (4) reclassification moves the PTSD field away from its well-developed knowledge base.

The diagnostic criteria for PTSD are lengthier than most other diagnoses, and efforts at their improvement have been a frequent focus in previous revisions of the DSM. DSM-5, alas, will do nothing to simplify or shorten the diagnostic criteria. However, several of the proposed revisions to the PTSD criteria within the DSM-5 reflect substantial changes. Criterion A1, defining the nature of the traumatic event, has been retained, but the description of what constitutes an index traumatic event has been articulated in greater detail. Criterion A2, requiring an emotional response of fear, helplessness, or horror in response to the trauma, has been eliminated. One reason for its removal is that some individuals (e.g., military personnel, who in deployment situations are trained *not* to have a response like this) lack this type of emotional response at the time of the event but, nonetheless, can develop PTSD (Friedman et al., 2011b). Because of confirmatory factor analyses that indicate strongest support for a four-factor model (Friedman et al., 2011b), the DSM-5 is proposing splitting the current three-factor model (Criterion B—intrusion, C—avoidance, and D—heightened arousal) into a four-factor model by splitting Criterion C and adding symptoms to the newly formed Criterion D (negative cognitions and mood). There are also a number of other specific changes to the individual criteria. In an effort to enhance cross-cultural applicability of the criteria, the intrusion symptom regarding dreams about the trauma has been revised to include both trauma content or affect about the trauma (Hinton and Lewis-Fernandez, 2011). As the previous C category has been split in two with only two types of avoidance retained, the

criteria now require only one to be endorsed. The new category D has two new symptoms, blame and negative emotional state (which, on the face of it, will overlap tremendously with major depressive symptoms), and the previous symptom of a fore-shortened future has been expanded to encompass exaggerated negative beliefs and expectations to help expand the applicability to other cultures. Category E also has a new symptom that focuses on reckless and destructive behavior.

Friedman et al. (2011b) also conclude that there is insufficient research to support the acute versus chronic specifier and thus it has been eliminated. However, they conclude that there is support for both a dissociative subtype and a preschool subtype. There is evidence to suggest that individuals whose PTSD is characterized by dissociative symptoms demonstrate distinct prefrontal responses and a decrease in heart rate and skin conductance to trauma cues/memories (Friedman et al., 2011b). Traumatized preschool age children do develop PTSD but at lower rates than other age groups, which likely reflect, at least in part, that the current diagnostic criteria do not accurately capture the disorder among preschoolers. Thus, the revised diagnostic criteria for the preschool subtype is meant to more readily identify PTSD in these young people by being more developmentally sensitive and behaviorally anchored (Scheeringa et al., 2011). For a dimensional measure of PTSD, the Web site suggests the unpublished nine-item National Stressful Events Survey PTSD Short Scale (American Psychiatric Association, 2011).

MIXED ANXIETY/DEPRESSION DISORDER

Mixed anxiety/depression disorder (MADD) is characterized by dysphoric mood that is accompanied by symptoms of both anxiety and depression and is considered to be subordinate to anxiety and mood disorders (not considered if diagnostic criteria for one of these disorders has been met). Empirical work on this disorder and its validators is sparse.

While included as an official diagnosis in the ICD-10, MADD was relegated in DSM-IV to *Criteria Sets and Axes Provided for Further Study* (American Psychiatric Association 2000). Initial versions of the DSM-5 revisions moved MADD to mood disorders. This proposed move was met with intense criticism from a variety of standpoints, including MADD’s remarkably poor reliability as well as the paucity of validating data (e.g., First, 2011; Frances, 2012; Wakefield, 2012). On the heels of this criticism, the most recent DSM-5 revisions have moved MADD back to the section reserved for conditions requiring further study (where it had been placed in DSM-IV). This is, admittedly, an unorthodox move on the part of the DSM-5 framers. If the past 20 years was not enough time to study MADD, it seems unlikely that more specific criteria will result in a boon of research. A more judicious approach would have been to delete MADD altogether.

SEPARATION ANXIETY DISORDER

This disorder is expressed as developmentally excessive anxiety in the face of separation from the home or an attachment figure. While it is more common among females, representation among the sexes is equal in clinical samples. The risk of

developing separation anxiety disorder is elevated for children of mothers with panic disorder.

Despite clinically significant impairment as children, those with this disorder often do not have a disproportionate rate of anxiety disorders as adults (American Psychiatric Association, 2000).

Because of the redistribution of disorders previously included in the *Disorder Usually First Diagnosed in Infancy, Childhood or Adolescence*, separation anxiety disorder will be included in the *Anxiety Disorders* section of the DSM-5. The literature that the Anxiety Work Group relied upon to make the DSM-5 proposed changes to separation anxiety disorder is not publicly available at this time. But the proposed changes to the diagnosis are available and include removal of the criterion that onset occurs prior to age 18, further differentiating the DSM from the ICD-10 criteria that requires an age of onset prior to 6 (World Health Organization, 1993). The specifier “early-onset” has also been removed.

ANXIETY DISORDERS

AGORAPHOBIA

Agoraphobia (AG) is characterized by a fear of being in situations in which escape may be difficult or in which help may not be readily available. While not *on the move* to a different chapter as are the diagnoses in the previous section, the revisions to the DSM-5 have moved AG from subordinate to panic (i.e., necessarily attributing the avoidance of situations to a fear of panic-related symptoms) to an independent disorder, a status it originally held in the DSM-III. This will be consistent with how agoraphobia is treated by DSM’s international counterpart, the ICD (International Classification of Diseases; World Health Organization, 1993).

This decision was made despite remaining questions and controversy, as the authors of the literature review indicate that they reached a consensus in their recommendations but that the consensus was not unanimous (Wittchen et al., 2010). However, the decision was supported by familial genetic data, psychiatric history, patterns of comorbidity, course of illness, treatment response, and reliability (American Psychiatric Association, 2012b). This evidence, reviewed by Wittchen et al. (2010), highlights that AG without panic-like symptoms does occur (in epidemiologic studies) and is associated with significant disability and a persistent course with low rates of spontaneous recovery. Thus, while the majority of AG cases *do* occur in the presence of panic disorder, panic attacks, or panic-like symptoms, that does not uniformly demonstrate that AG is a function of panic.

The proposed criteria for AG are more specific than in DSM-IV to improve differential diagnosis. Criteria A lists five different groups of agoraphobic situations, provides several examples of each group, and requires the endorsement of one situation from two or more groups. Additionally, the new criteria include a six-month duration requirement to avoid unnecessarily pathologizing transient fear. In addition to the two newly developed dimensional measures, The Fear Questionnaire-Agoraphobia Subscale (Marks and Mathews, 1979) is listed as a previously validated dimensional measure, but specific recommendations regarding its use are not included at this time.

PANIC DISORDER

Panic disorder (PD) is characterized by discrete periods of sudden and intense physiological symptoms and fear (i.e., panic attacks [PAs]) that result in persistent concern about additional PAs or a change in behavior (avoidance, emergency department visits, seeking medical diagnostic tests). Age of onset for this disorder varies but is generally between late adolescence and mid-30s. Twin studies suggest a genetic contribution to the disorder, and studies indicated that familial risk is particularly elevated for first-degree relatives of those who developed PD prior to age 20 (American Psychiatric Association, 2000). Early suggestions that PD exhibited a unique pharmacological treatment response are untrue, and notions of unique psychosocial treatment response have been called into question by transdiagnostic cognitive behavioral therapy approaches (e.g., Norton and Philipp, 2008).

As PAs are a crucial piece of PD, the Anxiety Work Group-commissioned review of evidence focused on questions related both to PAs and PD (Craske et al., 2010). It suggested that the symptom “hot flushes” be changed to “heat sensations” to better capture cultural variants in this experience and recommended that culture-specific symptoms be included in the description of PAs but not counted as one of the four required symptoms. The extant evidence did not suggest that a change in the number of symptoms required for a PA is warranted at this time. To reinforce the paroxysmal temporal profile of panic, the wording was changed to indicate that a panic attack reaches “a peak within minutes” and “can occur from a calm state or an anxious state.” There was no new evidence exploring validators of panic attack frequency to suggest that the criteria of “recurrent” PAs be modified. Due to the empirical evidence that panic attacks are associated with an increase in symptom severity, comorbidity, suicidality, and treatment resistance of comorbid disorders, a note was added indicating that PAs can serve as a specifier for both anxiety and nonanxiety disorders (e.g., schizophrenia, panic attack specifier). As noted in the previous section, agoraphobia is now a codable disorder, and thus, PD is no longer listed as PD with agoraphobia or PD without agoraphobia.

The DSM-5 Web site identifies the Panic Disorder Severity Scale-Self-Report (Houck et al., 2002) as a dimensional measure that can be utilized to assess PD severity.

SPECIFIC PHOBIA

Specific phobia (SP) is characterized by clinically significant distress or anxiety in response to a specific feared object or situation. While it is more commonly found among women, the sex difference varies by type (e.g., animal and situational). Evidence indicates that familial risk seems to aggregate by type and that blood injection injury-type fears have a particularly strong family link. The symptoms of SP usually first emerge in childhood or midadolescence, and for those that persist into adulthood, remission is infrequent (American Psychiatric Association, 2000). There is some research suggesting neural differences between SP types, but this research remains at a nascent stage (LeBeau et al., 2010).

The diagnostic criteria for SP, which was referred to as simple phobia prior to the DSM-IV, have seen several modifications

in preparation for the DSM-5 revisions. The review by LeBeau and colleagues (2010) focused on four main areas: the accuracy and utility of the specific phobia type classification, the validity of test anxiety as a type of SP, the boundary between agoraphobia and SP, and the reliability and utility of the specific phobia criteria. The general conclusion of the review is that the extant literature does support the retention of the specific phobia types as a descriptive option; that little evidence exists either for or against the inclusion of test anxiety as a type of SP; and similarly, that there is insufficient evidence to reclassify agoraphobia as a type of SP. Finally, LeBeau and colleagues (2010) reviewed the SP criteria and made recommendations about rewording and reordering the specific criteria in order to enhance consistency across anxiety disorders and improve clinical utility and ease of use. The criterion that one recognize that his or her fear is excessive or unreasonable has been removed, as it is common for adults to deny that their fear is excessive or unreasonable (LeBeau et al., 2010). Due to research indicating that transient fears and phobias occur among adults (LeBeau et al., 2010), the duration criterion of six months for those under the age of 18 has been extended to all age groups. Currently, the Web site does not recommend any specific dimensional scales for measurement-based care, since most measures assess one specific type of SP; however, two newly developed alternative scales focusing on severity of SP and of anxiety in general are now being tested.

SOCIAL ANXIETY DISORDER

Social anxiety disorder (SAD) is characterized by a marked fear of social and performance situations that often results in avoidance of those situations. Epidemiological data suggest that it is more common among women than men but that the sexes are equally represented in clinical populations. Onset typically occurs by late teens and can be either insidious or abrupt. The course of SAD is typically continuous and lifelong. Increased familial risk among first-degree relatives is particularly strong for the generalized type (American Psychiatric Association, 2000).

Social phobia is currently the official name for this diagnosis, but the term *social anxiety disorder* was added in parentheses following this title in the DSM-IV-TR to reflect that this is a broader diagnosis rather than just a circumscribed phobia (Bogels et al., 2010). Much of the Work Group review focused on the SAD specifiers. The DSM-5 framers have elected to delete the “generalized” specifier for SAD, arguing that there was considerable heterogeneity within this category. Instead, a performance-only specifier was introduced, supported by evidence that there are qualitative differences these individuals demonstrate from others with SAD (later onset, not characterized by childhood factors of shyness or behavioral inhibition, not familial, a stronger physiological response, and more likely to respond to beta blockers). In theory, if an individual with SAD does not meet the performance-only specifier, then he or she would be highly likely to have what had been called *generalized SAD* in DSM-IV. The merits of this change remain to be determined, whereas the disadvantages of disconnecting from two decades of research and over a thousand PubMed references to generalized SAD are obvious.

Selective mutism, listed in DSM-IV as a separate diagnosis in *Disorders Usually First Diagnosed in Infancy, Childhood, or Adolescence*, had tentatively been proposed as a SAD specifier since the majority of those with selective mutism have SAD, there are very high rates of SAD among parents of children with selective mutism, and preliminary treatment evidence suggests that psychological and pharmacological treatments that are effective for SAD are also effective for selective mutism. It was ultimately decided, however, to situate selective mutism as a separate diagnosis within the Anxiety Disorders section, apparently to encourage further attention to factors which may distinguish selective mutism from SAD (e.g., developmental language or speech problems).

Revisions to the SAD criteria also evaluated the comorbidity between SAD and avoidant personality disorder (AVPD), thought by some to be a more severe version of SAD rather than a qualitatively distinct disorder. Alden, Laposa et al. (2002) report that AVPD studies investigating the comorbidity of SAD note an average comorbidity of 42% with SAD, which is considerably lower than one would anticipate if AVPD were synonymous with severe SAD. Genetic studies indicate a link between SAD and AVPD, but this link does not appear to be specific to these two disorders (Bogels et al., 2010). Similarly, psychological and pharmacological treatment studies indicate a similar response style between the two disorders; however, numerous other disorders also respond to these treatments. In addition, there are some indications that AVPD shares links with the schizophrenia spectrum (Bogels et al., 2010). Based in part on these findings, it was concluded that while these two have a high degree of overlap, it is too simplistic to consider AVPD a severe form of SAD (Bogels et al., 2010). Thus, the DSM-5 revisions will not collapse these two disorders.

Additional revisions to the SAD criteria include the expansion of the types of social situations that are avoided to include social interaction, observation, and performance with examples of each provided. To increase the cultural sensitivity of the diagnosis, the feared consequence of offending others has been added to the previously listed fear of negative evaluation. The criteria no longer require the individual to recognize that his or her fear is excessive but does require the fear to be out of proportion to the actual threat posed. This acknowledges that some patients do not see their fear as excessive, but they are clearly not psychotic, and it is sufficient for the clinician to assess the excessiveness of the fear. Finally, the duration criterion of six months has been extended beyond those under the age of 18 to now apply across all age ranges, as it was noted that adults can also experience transient social anxiety, which might result in overdiagnosis.

In addition to the two newly developed dimensional measures, the Web site lists two previously published measures, the Social Phobia Inventory (Connor et al., 2000) and Mini-Social Phobia Inventory (Connor et al., 2001), along with a brief description of each.

GENERALIZED ANXIETY DISORDER

Generalized anxiety disorder (GAD) is characterized by clinically significant worry and anxiety that is disproportionate to the circumstances and persists for at least six months. While

adult onset is not uncommon, approximately half of the individuals who present for treatment report childhood or adolescent onset. Course of this disorder is generally chronic but often worsens in times of stress. Twin studies indicate a genetic contribution to the development of GAD (American Psychiatric Association, 2000).

The diagnosis of GAD has been encumbered by poor reliability and substantial comorbidity with mood and anxiety disorders since its first inclusion in DSM-III. Revisions to subsequent versions have attempted to remedy this situation. Likewise, the proposed revisions by Andrews et al. (2010) are meant to further clarify the diagnosis and enhance its reliability. Included in these recommendations was reducing the duration criterion from six to three months as this would substantially increase test–retest reliability and not impact the type of patient included in terms of distress and impairment (Andrews et al., 2010). The criterion that worry is difficult to control has been removed because of a lack of validating support to indicate that it added anything to the criteria (Andrews et al., 2010). Four of the six associated symptoms of worry listed in Criterion C (being easily fatigued, difficulty concentrating or mind going blank, irritability, and sleep disturbance), are nonspecific to GAD and are being proposed for removal, retaining only the two associated symptoms that are specific to the diagnosis (restlessness or feeling keyed up or on edge and muscle tension) to enhance the GAD’s discriminant validity, especially from major depressive disorder, which greatly overlaps with these nonspecific symptoms. A list of four behaviors commonly employed by individuals with GAD in an attempt to decrease their worry or ameliorate distressing affect are now proposed for inclusion (e.g., repeatedly seeking reassurance due to worries), one of which needs to be endorsed to meet the diagnostic criteria. When the specific combination of the currently proposed changes was investigated, the prevalence of the disorder increased by 9%. However, these changes did not significantly affect the distress or impairment, indicating that the severity was retained and lending support to these changes (Andrews and Hobbs, 2010). At the time of this writing, it is unclear whether the preceding changes to GAD will be accepted or not. As with the other disorders, a previously published self-report measure of severity, the GAD-7 (Spitzer et al., 2006), is included among the DSM-5 revisions for GAD.

NEED FOR A NEW NOSOLOGICAL FRAMEWORK?

As noted, the central goal of the DSM has been to create a reliable and valid diagnostic system for mental illness that has concurrent and predictive validity. The past several decades have witnessed an increase in the reliability of psychiatric diagnoses and an accumulation of knowledge surrounding associated factors, both clinical and experimental, that might serve as validators. However, much work remains as diagnoses fail to align with recent findings from neuroscience and genetics, the diagnostic boundaries are not consistent with treatment response, and current validators remain relatively limited and lacking specificity.

A recent review nicely outlines the difficulty in identifying consistent validating data to support even the broad distinction

of an “anxiety” disorder from other disorders of emotional distress and misery (Craske et al., 2009). Extant evidence does suggest there is some consistency in unique, anxiety-specific findings of distinct self-report measures, elevated sensitivity to threat (based on Pavlovian conditioning paradigms), cognitive bias to threat, and specific anxiety neurocircuitry. However, inconsistency in findings across developmental stages, lack of distinction among the individual anxiety disorders, and some overlap in findings with depressive disorders continue to confound attempts to nail down even the nosological validity of anxiety disorders as a distinct group! The DSM-5 revisions attempt to incorporate new research to bolster the diagnostic system and will likely result in incremental steps toward increased diagnostic validity and reliability, but addressing the evidence base honestly requires that we recognize we are still a long way off from a goal of diagnostic entities that have the kind of pathophysiologic validity of many recognized medical disorders.

The reviews commissioned by the Anxiety Work Group clearly indicate that much empirical work is left to be done. A common theme across these reviews was the call for additional research, and in numerous instances, the authors noted that there was simply insufficient empirical evidence for them to draw conclusions regarding central questions they had been asked to review. Whereas the DSM system is not perfect, it has become indispensable as it helps to bridge researchers and clinicians and is used extensively across settings such as insurance funding, treatment, and legal proceedings (Frances and Widiger, 2012). A system based on clinical description, such as we have, cannot match the validity (and even to some degree, the reliability) of a system based on objective medical tests; however, a mental disorder diagnostic system based on objective tests remains a long-term goal rather than a reality (Bernstein, 2011). The DSM was and is still meant to be a living document that serves as a framework for both research and clinical work that can expand and change based on accumulating knowledge. The mind is very complex, and the lofty goal of carving psychiatric nature at its joints requires more clearly elucidating how it functions and how missteps along its very complicated functioning can result in psychiatric illness.

Kendler has criticized commonly held explanatory models for psychiatric illness and puts forth the need to conceptualize the causes of psychiatric illnesses with “empirically based pluralism” (e.g., Kendler, 2008, 2012). He suggests that psychiatry has had the tendency to inaccurately dichotomize the etiology of disorders because of the influence of Descartes and computer functionalism. Descartes’ dualistic approach to psychiatry distinguishes between the mind (thinking) and the brain (physical) as two fundamentally separate entities and, following from this, that disorders are either organic (brain based) or functional (mind based). Similarly, Kendler points out that the advent of the computer era ushered in the functionalist perspective that our functioning runs parallel to that of computers, such that the computer hardware is synonymous with our brain and the software is synonymous with our mind. He suggests that this dichotomous thinking about mind/brain functioning continues to influence our conceptualization of the etiology of psychiatric illness, and beyond it simply being inaccurate,

it has impaired our ability to integrate research from multiple domains into our understanding of psychiatric illness. In one of his articles (Kendler, 2012), he makes the case for the inaccuracy of this dualistic perspective by reviewing the biological, psychological, and higher order (social, political, and cultural) etiological effects on major depression, alcohol dependence, and schizophrenia. The presented research indicates that each of the three disorders is affected by factors from each domain and that these factors are not independent but, rather, mediate and moderate each other both within and across domains. Thus, he concludes that understanding the nature of psychiatric illnesses requires an appreciation for the complex interplay between factors from various domains that do not fit into the neat mind/brain divide. He further suggests that a pluralistic view is driven by research and not a priori theory.

On first glance, this view might seem at variance with the notion that psychiatric disorders could be mapped to definitive genetic etiologies tied to neuronal circuit pathophysiologies. However, recent meta-analyses of neuroimaging studies provide tantalizing clues that PTSD, GAD, and MDD share specific neurocircuitry characteristics (hyperactivity of the dorsal anterior cingulate cortex, which is responsible for monitoring and expression of anxiety, and hypoactivity of the ventral anterior cingulate cortex, responsible for extinguishing fear responses) that are distinct from more classic “fear disorders” like panic, social anxiety, and the phobic disorders (Etkin, 2012). Ironically, this does not accord with the proposed DSM-5 changes, as it does not suggest PTSD is unique from all anxiety and mood disorders, nor that GAD is similar to other anxiety disorders.

Related to Kendler’s call for an understanding of the complex interplay between factors is NIMH’s Research Domain Criteria (RDoC) project (National Institute of Mental Health, 2011). The NIMH has indicated that it will focus its funding priorities on projects that are developed within this framework. It is meant to guide research in a manner that bypasses current diagnostic systems by organizing the focus of research around the following five domains: negative affect (e.g., loss, fear, anxiety), positive affect (e.g., approach motivation, reward learning), cognitive systems (e.g., attention, perception, working memory), systems for social processes (e.g., attachment, imitation), and arousal/regulatory systems. Research into these domains is further structured around specific units of analysis: genes, molecules, cells, circuits, physiology, behavior, self-reports, and paradigms. It is noted that this initial structure is meant to be a starting point that reflects the current state of knowledge and that it will be modified and adjusted as warranted by new research findings (Sanislow et al., 2010). Within this framework, participants would *not* be selected based on current diagnostic categories, but rather, for example, a sample of all patients presenting to an anxiety clinic could be studied to investigate amygdala functioning in response to fearful stimuli (Sanislow et al., 2010). The hope is that by not restricting research to current diagnostic categories research knowledge will develop that is more apt to identify the underlying mechanisms of mental illness. RDoC efforts can be seen as providing a complementary path to that of DSM-5 for the study of mental disorders. It follows that this knowledge would

eventually translate into practitioners being able to supplement clinical evaluation with functional or structural imaging, genomic sequencing, or lab-based evaluations of fear conditioning to more effectively determine prognosis and effective treatment (Insel et al., 2010).

As noted (Insel, 2009), the RDoC project is motivated by lofty long-term goals that may prove to dramatically affect the field. However, it also rests on three assumptions: mental illnesses are brain disorders, neural circuit dysfunction can be identified through tools of neuroscience, and genetic and clinical neuroscience research will provide biosignatures that will augment clinical management (Insel et al., 2010). If these assumptions turn out to be valid, then the RDoC project may lead to a revolution in our understanding of anxiety and other forms of mental illness. Until that day, DSM and its latest iteration (DSM-5) will continue to serve as the clinical guidepost for our field.

DISCLOSURES

Dr. Keough has no conflicts of interest to disclose. She currently receives NIMH funding through a National Research Service Award Institutional Training Grant (T32MH082709-01A2).

Dr. Stein is paid as co-editor-in-chief for *UpToDate in Psychiatry*, and as associate editor for the journal *Depression and Anxiety*. His research is funded by NIMH, the VA, and the Department of Defense.

Dr. Roy-Byrne has grant funding from NIDA and NIMH, receives salary for editor-in-chief duties for *Depression and Anxiety*, *UpToDate in Psychiatry*, and *Journal Watch Psychiatry*, and has received stock options as a consultant and advisor to Valant Medical Solutions, a behavioral health EMR company.

40 | GENETICS OF ANXIETY DISORDERS

JAVIER A. PEREZ, TAKESHI OTOWA, ROXANN ROBERSON-NAY,
AND JOHN M. HETTEMA

INTRODUCTION

This chapter provides a broad overview of the state of research in the genetics of the major anxiety disorders (ADs). We will primarily address findings regarding the categorical clinical syndromes as defined in DSM; however, several other human anxiety-related phenotypes (ARPs) are also discussed in relation to these, as indicated by the research data. We conceptually divide the chapter into three main sections: genetic epidemiology (adult and pediatric), human molecular genetics, and animal genetic models. We refer the reader to detailed reviews of the genetics of ADs (Hovatta and Barlow, 2008; Norrholm and Ressler, 2009; Smoller et al., 2009), including a special issue of the *American Journal of Medical Genetics Part C* devoted to this topic (Smoller and Faraone, 2008).

GENETIC EPIDEMIOLOGY OF ADs

In this section, we review the available data on genetic epidemiology of adult ADs. As reviewed in Chapter 12, the “chain of evidence” for genetic investigations begins with family studies, which compare rates of illness in relatives of those who have the condition (case probands) with rates in relatives of healthy controls. Higher rates in the former group of relatives, as parameterized by a relative risk (RR) or odds ratio (OR) greater than 1.0, suggest familial aggregation. The next step relies on either adoption studies (which are not available for ADs) or twin studies to differentiate genetic from within-family environment as sources of aggregation. Twin studies compare resemblance for a condition between members of a twin pair using the fact that identical (monozygotic, MZ) twins share 100% of their genes while nonidentical (dizygotic, DZ) twins share only 50% of their genes on average. One commonly used measure of twin resemblance is the probandwise concordance, that is, the proportion of cotwins of affected index twins who are also affected. If average concordance for MZ pairs is greater than that for DZ pairs, this is evidence for a genetic component to family resemblance. With larger twin samples, one may also estimate the proportion of individual differences due to the effects of genetic factors (heritability). For conditions with substantial heritability, gene finding (linkage or association) studies are undertaken to identify which specific genes contribute to risk.

A 2001 meta-analysis summarized findings across extant family and twin studies for several individual or categories of

adult ADs (Hettema et al., 2001). Few family studies have been published since then, as it is now well established that all ADs moderately aggregate in families. More twin studies have been conducted, however, with emphasis on the etiology of comorbidity or developmental risk. While the former meta-analysis is over a decade old, it still provides the most systematic integration of data across primary studies of several of the ADs. We will refer to results of that meta-analysis and augment with data from more recent studies, where available.

FINDINGS FROM FAMILY AND TWIN STUDIES OF ADULT ADs

PANIC DISORDER

As reviewed by Schumacher and colleagues, data from 19 controlled family studies overall support the familial aggregation of panic disorder (PD), with relative risk to first-degree relatives (FDRs) ranging 3–17 (Schumacher et al., 2011). Five of these meeting strict inclusion criteria were analyzed in the meta-analysis, the results of which showed a highly significant association between PD in the proband and PD in FDRs. Summary OR across the five studies was 5.0 (95% CI: 3.0–8.2) and the unadjusted aggregate risk based on 1,356 total FDRs of PD probands was 10.0%, compared with 2.1% in 1,187 control relatives. Additionally, one study suggests higher familial risk associated with early-onset PD in the proband.

The two largest sources of adult twin data for most of the ADs, including PD, are the population-based Virginia Adult Twin Study of Psychiatric and Substance Use Disorders (VATSPSUD), and the Vietnam Era Twin (VET) Registry. The former consists of approximately 9,000 twins from male and female same-sex and opposite-sex pairs born in Virginia, while the latter is of comparable size but contains only U.S. male twins who served during the Vietnam War. The size of these samples permits the use of structural equation modeling to assess the relative contributions of genetics, common family (shared) environment, and individual specific (nonshared) environment to the liability of PD. Both samples reported higher MZ than DZ concordance, suggesting a genetic component to PD, consistent with some prior smaller twin studies. Both VATSPSUD and VET studies estimated heritability of PD to lie between 30% and 40%. The remaining source of individual differences derived from individual specific environment not shared between twins. In addition, the VATSPSUD found no evidence that genetic risk factors for PD significantly differ between men and women.

GENERALIZED ANXIETY DISORDER

Two published family studies of generalized anxiety disorder (GAD) were included in the aforementioned meta-analysis. Both studies, derived from clinical probands, supported the familial aggregation of GAD, and together they show a significant association between GAD in the proband and in their FDRs, with a summary OR of 6.08 (95% CI: 2.5–14.9). Both the VATSPSUD and the VET Registry examined broadened GAD syndromes via twin analyses, with an overall heritability of 31.6% (95% CI: 24–39%) when data from both samples were combined via meta-analysis. Other twin studies report heritability estimates for GAD in this range.

PHOBIAS

Fyer and colleagues performed a series of analyses examining specific phobia (SP), social phobia (SOC), and agoraphobia (AG) and their relationship with each other and PD. They reported higher rates of SP in relatives of SP probands compared with control relatives (31% versus 9%), higher rates of SOC in relatives of SOC probands (16% versus 5%), and higher rates of AG in relatives of AG probands (10% versus 3%). Another family study reported higher rates of AG in relatives of probands with AG compared with control relatives (11.6% versus 4.2%, OR = 3.0). Two studies of SOC found that familial aggregation is primarily due to the generalized subtype. Meta-analysis across family studies found a highly significant association between phobias in the proband and in FDR, with a summary OR of 4.07 (95% CI: 2.7–6.1).

Only two large, adult twin samples have comprehensively examined the genetics of phobias in adults. A series of analyses in the VATSPSUD examining phobic fears and disorders found that twin resemblance was due largely to genetic factors across AG, SOC, and SP, estimating that genetic factors explain from one-third to two-thirds of their individual differences. Similar heritability estimates were recently reported from a study of about 1,400 female twins from the Norwegian Institute of Public Health Twin Panel (NIPHTP) (Czajkowski et al., 2011).

OBSESSIVE-COMPULSIVE DISORDER

As reviewed by Nestadt and colleagues, most of the 15 published family studies of obsessive-compulsive disorder (OCD) support its familial aggregation (Nestadt et al., 2010). Five family studies included in the meta-analysis provided a highly significant association between OCD in the proband and FDRs (summary OR = 4.0, 95% CI: 2.2–7.1), with an unadjusted aggregate risk based on 1,209 total FDRs of OCD probands of 8.2% versus 2.0% in 746 control relatives. Secondary analyses in several of these studies suggest that younger age of onset may further increase familial risk for OCD.

Due to the complex assessment requirements and relatively low prevalence rates of diagnostically defined OCD, many twin studies have only examined broadened phenotypes consisting of OC symptoms or features (reviewed in van Grootheest et al., 2005). A study of OC traits and symptoms assessed by the Leyton Obsessional Inventory in 419 complete pairs from a London-based volunteer twin registry reported heritability estimates of 44% for OC traits and 47% for symptoms, with

the remainder of the variance for these measures explained by nonshared environment. Self-report OC symptoms from the Padua Inventory were examined in 527 female twin pairs from the VATSPSUD. Factor analysis identified two major factors accounting for 62% of the variance that appeared to roughly correspond to obsessions and compulsions, with heritabilities of 33% and 26%, respectively.

OCD is a heterogeneous disorder, with several distinct symptom patterns (“dimensions”) that can differ widely across patients (Leckman et al., 2001) (see Chapter 48). Preliminary family and twin studies report that these dimensions are individually heritable and might reflect the influence of distinct but correlated underlying genetic factors. This has potentially important implications for molecular genetic studies of OCD (Miguel et al., 2005).

POSTTRAUMATIC STRESS DISORDER

Several recent reviews of the genetics of posttraumatic stress disorder (PTSD) are available in the literature (Afifi et al., 2010; Koenen, 2007). The study of the genetics of PTSD is complicated by the requirement of a specific environmental exposure in its diagnostic criteria. The classification of a subject as not carrying an increased risk for PTSD (i.e., “healthy”) is predicated on the condition that they are unaffected only after experiencing a significant trauma. Only a handful of published family studies exist, mostly examining general psychopathology in the relatives of PTSD probands to identify correlated familial risk factors. Their overall findings suggest that a family history of either anxiety or depressive disorders or both may increase an individual’s risk for developing PTSD after experiencing a significant trauma.

Two twin samples have studied the etiology of risk for PTSD. Self-report symptoms of PTSD from the reexperiencing, avoidance, and hyperarousal clusters were analyzed in 4,042 male twin pairs from the VET Registry (True et al., 1993). The MZ twin correlations were higher than the DZ correlations, and heritabilities in the range of 30–35% were estimated for most of the individual symptoms after controlling for the effects of trauma exposure; nonshared environment explained the remaining variance in liability to PTSD. A second, smaller twin study extended these findings to female subjects and PTSD resulting from civilian traumas (Stein et al., 2002). For pairs in which both twins were exposed to trauma, MZ pairs were more highly correlated than DZ pairs for all of the PTSD symptom clusters, with heritability estimates in a similar range as those from the VET Registry study.

Twin studies have also attempted to estimate the degree to which the effects of genetic and environmental risk factors interact with each other beyond their independent effects on the phenotype ($G \times E$). In other words, does the effect of adverse environmental exposures vary by degree of genetic liability (“genetic control of sensitivity to the environment”)? Twin studies have established the importance of $G \times E$ effects for ADs (Lau et al., 2007; Silberg et al., 2001a). $G \times E$ effects are of particular relevance for PTSD (Afifi et al., 2010; Koenen et al., 2009), since traumatic environmental exposure is a prerequisite for its development. Another layer of complexity comes from

twin studies that suggest exposure to many “environmental” experiences is due to behaviors partially driven by their own underlying genetic factors (Kendler and Baker, 2007).

PEDIATRIC ADs

Studies of anxiety in pediatric samples have used varying phenotypic definitions via different types of assessment instruments. These range from broad, often continuous scores for “anxiety” (e.g., Child Behavior Checklist [CBCL]) or anxious temperament, to groups of individual anxiety symptoms (e.g., the Screen for Child Anxiety Related Emotional Disorders [SCARED]), to specific diagnostic syndromes. We will briefly summarize the major findings from these in turn.

Studies of broad anxiety scores in child and adolescent twins report significant but moderate heritability (ranges 20–60%) for the Anxiety Problems scale of the CBCL (Spatola et al., 2010), fears (Rose and Ditto, 1983), state anxiety (Legrand et al., 1999), and anxious/depression scores (Boomsma et al., 2005). Unlike in adult samples, many of these studies also report significant influences of shared family environment.

Few family studies exist using childhood AD probands. A family study of children with ADs, in general, found elevated rates of ADs in their FDRs compared with FDRs of children without an AD (Last et al., 1991), supporting the familial aggregation of pediatric onset ADs. The only specific AD that has been systematically examined for familial aggregation using childhood probands is OCD, with two of the three extant studies reporting higher OR than was typical among studies with adult probands. In concordance with risk estimated from family studies, heritability estimates of OCD in children (45–65%) are generally higher than those from adult studies (reviewed in van Grootheest et al., 2005).

The design of some family studies, rather than attempting to interview all FDRs, limit their assessment to rates of illness in children of affected parents, allowing one to prospectively identify a “high-risk” sample. A meta-analysis of high-risk studies using parental probands with ADs found a significant increase in rates of ADs in general (OR = 3.91) as well as each specific type of AD (OR ranges from 2 to 4) in their offspring (Micco et al., 2009). Rates of OCD are particularly high (OR = 8.7). Interestingly, the rates of major depression (MD) in those offspring are also elevated (OR = 2.67) (see section on comorbidity that follows).

Among specific ADs, separation anxiety disorder (SAD) has received significant research attention, likely owing to its earlier age of onset and frequency. The results for twin studies of SAD have been mixed, with some studies supporting genetic as well as both common and unique environmental events as critical to its expression, while other studies do not observe significant shared environmental factors. An extensive meta-analysis of childhood SAD, which pooled together 18 cohorts with over 30,000 twin subjects, indicated that both genetic (43%) and shared environmental (17%) factors significantly accounted for its familial aggregation (Scaini et al., 2012). Unlike most individual studies, this analysis also possessed adequate power to detect differential heritability estimates between females (52%) and males (26%).

PD has a rather late age of onset compared with some other ADs (median 24 years), although a small subset of adolescents develop PD. Childhood SAD is hypothesized to share etiologic roots with PD, and a recent longitudinal twin study determined that the association between earlier SAD and adult-onset panic was largely explained by common genetic influences between them (Roberson-Nay et al., 2012).

SOC is one of the most prevalent ADs in youth, second only to specific phobias. A study in adolescent female twins reported heritability for SOC of 16% with no significant role for shared environment (Nelson et al., 2000). In a study based on child report using the SCARED, only genetic (53%) and nonshared environmental (47%) influences significantly accounted for variance in self-reported SOC symptoms (Ogliari et al., 2006). An even higher heritability (76%) was reported in a study of 4-year-old twins for the temperamental trait of shyness/behavioral inhibition, a risk factor for SOC (Eley et al., 2003).

DEVELOPMENTAL CHANGES IN GENETIC AND ENVIRONMENTAL RISK FOR ADs

As summarized in Chapters 44 and 71, ADs onset differentially across development, with puberty being a particularly salient time for increase in risk for some new or comorbid conditions. Twin studies conducted in children at different ages or longitudinally can examine the changing effects of genetic and environmental risk factors over time. As reviewed by Franic and colleagues, heritability for anxious/depressive symptoms are highest in early age groups and decrease with age, with correspondingly increasing importance for shared family environment into middle childhood (Franic et al., 2010). However, this trend appears to reverse as children develop through adolescence into adulthood for a range of phenotypes including anxiety symptoms (Bergen et al., 2007). As children age through puberty, family environmental influences decline in significance, consistent with the developmental progression for their sphere of influence from family to peers and beyond.

A longitudinal study of Swedish twins that recorded fear measures at four time points between ages 8 and 20 found that the role of genetic factors salient for fears during middle childhood (ages 8 to 9) subsequently declined over time, with new genetic risk factors coming “online” in early adolescence, late adolescence, and early adulthood (Kendler et al., 2008b). These results suggest that genetic effects for the expression of fear are “developmentally dynamic,” from middle childhood through the young adult years. The mechanisms behind changes in genetic influences as a function of age are not well understood, but the findings suggest that certain genes may be differentially activated at different stages of development. While DNA structure is stable across the life span, gene expression and epigenetic processes are dynamic, potentially explaining developmental changes in genetic influences on the manifestation of fear and anxiety.

Longitudinal studies also provide valuable information regarding the genetic basis for developmental unfolding and the fluctuating nature of psychiatric syndromes over time. Some disorders exhibit homotypic continuity, with onsets in childhood and continuing of similar symptom profiles into adulthood (e.g.,

social phobia); for others, heterotypic continuity (the prediction of a disorder by a different disorder) is observed. In a pediatric twin sample, stable genetic factors explained most of homotypic continuity in childhood anxiety scales in the short age range from seven and nine (Trzaskowski et al., 2011). Looking at genetic risk across fear types (SOC and three types of SP) in the Swedish twin sample cited earlier, there was genetic innovation and attenuation differentially across fear domains. Namely, the major common genetic factor underlying overall fearfulness was stable across development, while new common and fear-specific genetic risk factors emerged over time (Kendler et al., 2008a). In a study of young adults from the NIPHTP, stability of anxiety and depressive symptoms across two time points was mainly attributable to genetic factors, whereas change was primarily related to environmental influences (Nes et al., 2007). As described earlier, a recent longitudinal twin study found heterotypic continuity between childhood SAD and adult-onset panic was best explained by a common genetic vulnerability (Roberson-Nay et al., 2012). In contrast, the genetic factor associated with childhood overanxious disorder (OAD) did not contribute significantly to adult panic. These results indicate that childhood SAD and adult panic share a common genetic diathesis that is not observed for childhood OAD, supporting the hypothesis of a specific genetic heterotypic link among them. However, symptoms of OAD experienced early in life are influenced by the same genes that influence later depressive symptoms (Silberg et al., 2001b), supporting the findings from adult twin studies that OAD/GAD and MD share a common underlying genetic liability (see next section).

SHARED SUSCEPTIBILITY BETWEEN ADs AND OTHER ARPs

Most, but not all, family studies of the ADs reported relative specificity in their familial aggregation; however, this is not the case with twin studies. Studies in the VATSPSUD sample have found genetic and environmental factors are, to a greater or lesser extent, shared across most of the ADs and with other commonly comorbid disorders like MD. The twin studies cited earlier used multivariate modeling to test whether there was a common factor of “phobia proneness” that increased liability across classes of phobic fears and whether it was genetic, environmental, or both in origin. The best fitting models contained both common and disorder-specific genetic and nonshared environmental influences on all of the phobia subtypes examined, with the proportion of genetic variance explained by common genes varying somewhat by disorder and gender. Similar findings were reported in the NIPHTP study cited earlier, although they found evidence for two common genetic factors differentially loading across the phobia subtypes (Czajkowski et al., 2011). Analyses from the VATSPSUD and the Swedish Twin Registry suggest that GAD and MD share the majority of their genetic risk in common but only a modest proportion of environmental risk factors (Kendler et al., 2006).

Several studies from the VATSPSUD tested broader models of comorbidity between the ADs, or between the ADs, MD, and related phenotypes. One such analysis examined the relationships across several ADs: PD, GAD, AG, SOC, and animal and

situational SP (Hettema et al., 2005). In the best fitting model, the genetic influences on anxiety susceptibility for both sexes were explained by two additive genetic factors shared across the disorders, with significant disorder-specific genetic risk only for AG. The first factor loaded most strongly on GAD, PD, and AG, while the second loaded primarily on SP. SOC was intermediate, in that it was influenced by both common genetic factors. A similar analysis conducted in NIPHTP identified a single common genetic factor of heritability of 54% that accounted for a large proportion of genetic variance across symptoms of PD, GAD, SP (all types), OCD, and PTSD (Tambs et al., 2009). Only SP and OCD had disorder-specific genetic effects of appreciable magnitude. Analyses from other large twin datasets support the hypothesis of a shared genetic diathesis between the AD phenotypes in adults and children as well as between ADs and MD (reviewed in (Middeldorp et al., 2005)). Similarly, the meta-analysis of high-risk studies cited earlier found no significant differences between risk for anxiety or depression in offspring between parental proband groups with either type of disorder (Micco et al., 2009), suggesting that a nonspecific internalizing diathesis is transmitted to offspring.

Studies have consistently demonstrated associations between high levels of anxiety-related personality traits and increased risk of ADs. Neuroticism and extraversion, two normal traits included in most personality inventories, are generally elevated and lowered, respectively, in subjects with anxiety and depressive disorders; they also likely mediate anxiety-depressive comorbidity (Bienvenu et al., 2001). Twin studies suggest that some of the genetic factors that influence these personality traits overlap those that increase susceptibility for anxiety and depressive disorders. (Bienvenu et al., 2007; Hettema et al., 2006; Kendler et al., 2006).

GENETIC EPIDEMIOLOGY SUMMARY

Overall, genetic epidemiological studies support a moderate level of familial aggregation (OR 4–6) for adult ADs. The source of this familial risk is predominantly genetic in origin, with heritability of about 30–50%. Pediatric ADs are possibly even more highly heritable, with genetic effects dynamically changing throughout development. Twin studies suggest that ADs do not seem to “breed true”; that is, their genetic architecture is not isomorphic with their symptomatic presentations and classifications, sharing risk factors with each other and related phenotypes like depression and anxious personality traits. This helps to explain their patterns of comorbidity as well as their developmental progression.

HUMAN MOLECULAR GENETICS

LINKAGE AND CANDIDATE GENE ASSOCIATION STUDIES

Two main approaches are applied to identify susceptibility genes in human studies: linkage and association studies. Linkage studies are performed in pedigrees with several affected individuals to identify chromosomal loci likely to harbor a gene influencing a biological trait or condition. While effective to identify highly

penetrant genes of large effect seen in classic Mendelian disorder, linkage has, with few exceptions, not been very fruitful for most complex phenotypes encountered in medicine, including anxiety. Several linkage studies have been performed for ARPs, with few consistent findings between studies (reviewed in Hovatta and Barlow, 2008; Smoller and Faraone, 2008). Suggestive linkage has been reported for regions on chromosomes 4q, 9q, 13q, 14q, and 22q in PD (reviewed in Maron et al., 2010), 9p in OCD (Nestadt et al., 2010), and 8p for the anxiety-related personality trait of harm avoidance (HA) (Cloninger et al., 1998). A reanalysis of several PD linkage studies supported linkage on chromosomes 4q and 7p (Logue et al., 2012). The most intensively studied ARP using linkage is neuroticism. A recent meta-analysis of all available genome-wide linkage studies of neuroticism using eight independent samples with over 14,000 subjects supported linkage on chromosomes 9, 11, 12, and 14 (Webb et al., 2012). In the same study, similar analysis using a smaller set of samples found suggestive evidence for linkage on chromosomes 1, 5, 15, and 16 for ADs. The results for ADs and neuroticism were moderately but significantly correlated, supporting the results from twin studies suggesting shared genetic susceptibility.

Association studies allow one to test specific genes or markers within genes for their contribution to a phenotype. They may take the form of case-control comparisons in unrelated individuals or family-based transmission tests. To date, most association studies of ADs have focused on candidate genes, which have to be chosen using a priori knowledge, either from their position under a linkage peak or their biologic function as relevant for the pathophysiology of the disease. The most widely studied candidate genes for ADs are genes involved in neurotransmitter systems or related to stress response. In their review, Maron and colleagues summarized more than 350 candidate gene findings for PD, concluding that most of these results remain inconsistent, negative, or not clearly replicated (Maron et al., 2010). Failure to identify susceptibility loci in PD may be due to differences in phenotypic assessment, heterogeneity at the genetic level, and underpowered studies with small sample sizes (issues in association studies of many phenotypes). Several association findings, such as for the genes *regulator of G-protein signaling 2* (*RGS2*), *adenosine 2A receptor* (*ADORA2A*), and *catechol-O-methyltransferase* (*COMT*), were replicated in other studies, sometimes in other ARPs (Table 40.1). For example, the *COMT* gene polymorphism (Val158Met) has been implicated in susceptibility to PD by several studies in independent samples. *COMT* encodes an enzyme metabolizing the monoamine neurotransmitters. The valine (Val) allele shows a significantly higher *COMT* activity relative to the methionine (Met) allele. A meta-analysis of six case-control studies showed significant association of the *COMT* 158 Val allele with PD in Caucasian samples and, conversely, a trend toward association of the *COMT* 158 Met allele with PD in the Asian samples (Domschke et al., 2007). Given the multiple positive findings, *COMT* seems to be one of the most consistent association findings for ADs.

The other extensively studied gene in genetic studies of ADs, as well as MD, is the serotonin transporter gene (particularly, its promoter length polymorphism, *5HTTLPR*), involved in the action of SSRI drugs. The short allele is associated with lower expression of the serotonin transporter gene (*SLC6A4*)

and, consequently, lower activity of the transporter. Lesch and colleagues initially reported the association of the *5HTTLPR* short allele with anxiety-related personality traits (Lesch et al., 1996). Since then, a large number of studies have attempted to replicate the association, but the results have been inconsistent (similar to reports of association between MDD and this polymorphism). Also, meta-analyses of the association studies between the *SLC6A4* gene and anxiety-related personality traits are inconclusive: modest overall association with neuroticism as measured by the neuroticism-extraversion-openness personality inventory but no association with HA or neuroticism as measured by the Eysenck Personality Questionnaire (Munafò et al., 2009). Furthermore, a meta-analysis of OCD suggested an association with the long allele in the childhood-onset subgroup and Caucasians (Bloch et al., 2008), whereas a meta-analysis of 10 association studies of PD did not show overall association between *5HTTLPR* and PD (Blaya et al., 2007).

Several candidate genes involved in the (hypothalamic-pituitary-adrenal) HPA stress response system have been implicated in PTSD. Binder and colleagues reported significant interactive effects, but no main effects, of polymorphisms in *FKBP5*, a gene that regulates glucocorticoid receptor sensitivity, and severity of child abuse history in a sample of around 900 primarily African-American adults (Binder et al., 2008). A female-specific association with PTSD and fear discrimination was reported in the same sample for a marker in an estrogen response element of *ADCYAP1R1*, the gene encoding the receptor for pituitary adenylate cyclase-activating polypeptide (PACAP) (Ressler et al., 2011). Also, PACAP blood levels correlated with PTSD symptoms and startle responses of females in a fear-conditioning paradigm. Other interesting AD-candidate gene associations, some of which were replicated in other studies (Table 40.1), include: (1) overall AD phenotypes with *glutamic acid decarboxylase 1* (*GAD1*) and (2) OCD with both the *glutamate transporter* (*SLC1A1*) and *brain-derived neurotrophic factor* (*BDNF*) genes.

GENOME-WIDE ASSOCIATION STUDIES

Table 40.2 lists extant Genome-Wide Association Studies (GWAS) of anxiety-related personality traits and ADs. Unlike candidate gene studies, which require a priori knowledge for gene selection, GWAS provides an unbiased survey of common genetic variation across the entire genome (see Chapter 12). The first reported GWAS for an anxiety phenotype was published in 2008 (Shifman et al., 2008) using DNA pooling methods in about 2,000 individuals selected on extremes of neuroticism scores from a cohort of 88,000 people. Among 450,000 SNPs investigated, only one SNP within the *phosphodiesterase 4D* (*PDE4D*) gene was replicated in one of three independent samples tested. They concluded that no loci explained more than 1% of variance of the trait and that many loci with small effects account for its heritability. The second neuroticism GWAS was conducted in 1,200 U.S. Caucasian participants, in which the most promising markers were subsequently tested for replication in 1,900 German subjects (van den Oord et al., 2008), demonstrating nearly genome-wide association for

TABLE 40.1. Candidate gene of anxiety disorders and anxiety-related phenotypes showing association in other studies

GENE		LOCATION	PHENOTYPE	FUNCTION
<i>RGS2</i>	<i>Regulator of G-protein signaling 2</i>	1q31.2	PD, PTSD, extraversion	Regulator of G protein signaling
<i>GAD1</i>	<i>Glutamic acid decarboxylase 1</i>	2q31.1	GAD, PD, agoraphobia, social phobia	GABA synthesis
<i>SLC1A1</i>	<i>Glutamate transporter</i>	9p24.2	OCD	Glutamate transmission
<i>BDNF</i>	<i>Brain-derived neurotrophic factor</i>	11p14.1	OCD, harm avoidance	Neurotrophic factor
<i>CCKBR</i>	<i>Cholecystokinin B receptor</i>	11p15.4	PD	Neuropeptide transmission
<i>DRD4</i>	<i>Dopamine receptor D4</i>	11p15.5	OCD, PD, neuroticism	Dopamine neurotransmission
<i>HTR2A</i>	<i>5-hydroxytryptamine receptor 2A</i>	13q14.2	OCD, PD	Serotonin neurotransmission
<i>5HTTLPR</i>	<i>Serotonin transporter</i>	17q11.2	OCD, PTSD, neuroticism	Regulator of serotonin reuptake
<i>COMT</i>	<i>Catechol-O-methyltransferase</i>	22q11.2	PD, anxiety-related personality, phobic anxiety	Catecholamine degradation
<i>ADORA2A</i>	<i>Adenosine A2 receptor</i>	22q11.2	PD	Adenosine regulation

PD, panic disorder; OCD, obsessive-compulsive disorder; PTSD, posttraumatic stress disorder; GAD, generalized anxiety disorder

TABLE 40.2. Genome-wide association studies of anxiety disorders and related personality traits

REFERENCE	PHENOTYPE	SAMPLE	GENOTYPING ARRAY(S)	MOST SIGNIFICANT FINDING
Shifman et al. (2008)	Neuroticism (EPQ)	2,054 individuals with extremely high scores on neuroticism	Affymetrix 100 K and 500 K	<i>PDE4D</i> (5q12)
van den Oord et al. (2008)	Neuroticism (EPQ)	1,227 U.S. participants for GWAS; 1,880 German subjects for replication	Affymetrix 500 K	<i>MAMDC1</i> (15q21)
Otowa et al. (2009, 2010)	Panic disorder	200 cases and 200 controls for GWAS; 558 cases and 566 controls for replication	Affymetrix 500 K	<i>TMEM16B</i> (12p13)
Calboli et al. (2010)	Neuroticism (EPQ)	2,235 individuals from population-based sample	Affymetrix 500 K	<i>NKAIN2</i> (6q22)
Terracciano et al. (2010)	Neuroticism (NEO-PI)	3,972 individuals from a population within Sardinia	Affymetrix 10 K and 500 K	<i>SNAP25</i> (20p12)
Erhardt et al. (2011)	Panic disorder	216 cases and 222 controls for GWAS; 693 cases and 693 controls for replication	Illumina 300 K	<i>TMEM132D</i> (12q24)
de Moor et al. (2012)	Neuroticism, extraversion (NEO-PI)	17,375 individuals from 10 samples for discovery (partially overlapped with sample in Terracciano et al., 2010); 3,294 individuals from five samples for replication	Affymetrix 10 K, 250 and 500 K; Illumina 6 K, 317 K, 370 K, 550 K, 610 K, 1 M; Perlegen 600 K	<i>MTR</i> (1q43) for neuroticism; <i>PSAT1</i> (9q21) for extraversion

EPQ, Eysenck Personality Questionnaire; GWAS, genome-wide association studies; NEO-PI, neuroticism-extraversion-openness personality inventory.

SNPs in *MAMDC1* when combining the two samples. A recent meta-analysis of GWAS for personality traits, combining data from 17,000 subjects, reported genome-wide significant association for traits of openness (near *RASA1* gene on 5q14.3) and conscientiousness (in *KATNAL2* gene on 18q21.1). However,

there were no genome-wide significant findings for neuroticism or extraversion (de Moor et al., 2012).

The first AD GWAS was conducted in 200 PD cases and 200 controls in the Japanese population, reporting several potential novel loci for susceptibility to PD (Otowa et al., 2009). However,

a follow-up study in a larger sample failed to show any significant association of these genes with PD. The second GWAS of PD, conducted in three German samples, reported two associated SNPs located in *TMEM132D* on 12q24.3 (Erhardt et al., 2011). Risk genotypes for PD were associated with higher *TMEM132D* mRNA expression levels in the frontal cortex. They also demonstrated that *TMEM132D* was associated with anxiety-related behavior using a mouse model of extremes in trait anxiety. Of note, none of these analyses found overlap with previously reported candidate genes, so these results require replication in independent, adequately powered samples.

Several international research collaborations have formed to investigate the genetics of ADs, similar to efforts by the Psychiatric Genetics Consortium for other psychiatric disorders. For example, the Panic International Consortium (PanIC) aims to replicate earlier association findings and to identify new markers using the largest combined sample of PD subjects. The Obsessive-Compulsive Foundation International Genetic Consortium (OCF-ICG) is performing a GWAS of OCD using a sample size of over 3,000 cases and controls. Several groups are also currently conducting large GWAS of PTSD in trauma-exposed subjects. Our group is leading a GWAS meta-analysis, using data from six independent samples from the United States, Europe, and Australia of over 20,000 subjects, to discover novel genes that are responsible for common genetic risk shared across ADs using quantitative anxiety factor scores that, in principle, increase the statistical power to detect genes of small effect.

HUMAN MOLECULAR GENETICS SUMMARY

Linkage studies of ADs have produced inconclusive results, and GWAS have not reached genome-wide significance, to date. This is similar to the experience for a similar psychiatric phenotype, MD (see Chapter 30). This implies that a large number of genes with small effects, rather than a small number of genes of moderate-to-large effects, account for the heritability of these phenotypes. Thus, very large, well-characterized samples and even larger meta-analyses are needed before unambiguous findings will be available. On the other hand, several candidate AD genes have been replicated and confirmed in other ADs, suggesting their pleiotropic effects across these phenotypes. Therefore, we emphasize that very large GWAS using common genetic factors across ADs provide a powerful strategy to identify their susceptibility genes.

ANIMAL MODELS FOR STUDYING THE GENETICS OF ADs

The genetic basis of ADs has been supported by well-established animal models (Jacobson and Cryan, 2010). The human and mouse genome share many common features whereby almost all genes have a respective counterpart. Humans and rodents also share similar autonomic responses and related defensive behaviors to threatening stimuli. Many of these behaviors are modeled and measured in rodents with the use of pharmacologically validated behavioral tasks testing anxiety-like behavior (ALB). Moreover, functional brain mechanisms governing ALB involving regions

such as the amygdala and prefrontal cortex (PFC) are phylogenetically well preserved in rodents (see Chapter 41). Thus, while recognizing their obvious limitations, as no animal model can mimic the full spectrum of anxiety in humans, rodents are considered a vital tool for advancing our basic understanding of the genetic and neurobiological basis of AD.

In the last decade, there has been an increase in “translational studies,” where human genetic findings are being functionally validated by subsequent work in rodents and vice versa (Sartori et al., 2011). Inbred strains have supported the development of transgenic and knockout (KO) models, while recombinant inbred strains have contributed to the discovery of quantitative trait loci (QTL) associated with ALB. These approaches have been extended with the use of molecular techniques to functionally characterize AD candidate genes. In the following section, we will (1) summarize the most current advances in the genetics of AD as supported by research methods in rodent models and (2) provide examples on cross-species approaches that have supported and validated genetic research on AD.

GENE IDENTIFICATION THROUGH ANIMAL MODELS OF ANXIETY

To model ARB in rodents, researchers have relied on various paradigms and behavioral tests to assess defensive responses to naturally occurring (e.g., vulnerability to predators) and laboratory-provoked (e.g., tail shock) threats (reviewed in Chapter 41). These can be further subdivided into conditioned (learned) and unconditioned tests (ethologically based). Unconditioned tests including open field tests (OFTs), elevated plus maze (EPM), and light-dark box (LDB) measure spontaneous or natural responses to innate aversive and threatening stimuli. Conditioning paradigms such as fear conditioning (FC) and fear-potentiated startle (FPS) rely on the learned pairing of a neutral stimulus (i.e., conditioned stimulus; CS) with an aversive stimulus (unconditioned stimulus; US) and subsequent conditioned fear responses (i.e., freezing and startle) are measured during the presence of the CS and absence of the US. Such conditioned responses are hypothesized to model phobias and PTSD.

Inbred mice are a classic tool for investigating the genetic basis of many medical syndromes. Mice from the same strain are almost 100% identical between their respective genomes. Thus, interstrain genetic differences have helped investigate heritable and stable behavioral phenotypes related to anxiety. In Table 40.3, we provide a summary of the various strain differences in ALB measured in different tests. Inbred mice display individual differences in ALB in both conditioned and unconditioned tests. BALB/c, A/J, AKR/J, and S129/SvImJ are known as typically highly anxious strains. Interestingly, the S129/SvImJ strain displays a unique profile for high anxiety in the OFT, LDB, and FC, including an innate inability to extinguish fear. Deficits in fear extinction (FE) of S129/SvImJ are well described (Hefner et al., 2008), in which genetic differences associated with extinction are also correlated with deficiencies in cortico-limbic activation of fear circuitry (see Chapter 41). Thus, it has been hypothesized that genetic

TABLE 40.3. Profile of common inbred mouse strains on anxiety-like behavior

TEST	HIGH ANXIETY	AVERAGE ANXIETY	LOW ANXIETY
Open field	S129/SvImJ, A/J AKR/J, BALB/c, BALB/CbyJ, DBA/2J		C57BL/6J, FVB/NJ
Elevated zero maze	A/J, AKR/J, BALB/c		
Elevated plus maze	A/J, AKR/J, BALB/c	C57BL/6J, A/J	FVB/NJ
Light-dark box	A/J, BALB/CbyJ, BALB/c, S129/SvImJ	C57BL/6J, C3H/HeJ	FBV/NJ
Social interaction	A/J, BALB/cByJ, 129S1/SvImJ	AKR/J, C57BL/6J, C3H/HeJ	FBV/NJ
Conditioned fear and fear extinction (freezing)	S129/SvImJ, A/J	BALB/CbyJ	C57BL/6J, FVB/NJ

differences accounting for deficits in FE in this strain could account for deficits in the activation of the relevant components of the fear circuit.

The use of inbred strains for investigating genes that may account for polygenic traits of ALB has been extended with the advent of QTL studies. QTL analyses seek to identify an association between a specific phenotype and a marker locus for a set of two or more genes. QTL analysis is commonly carried out by crossing two or more strains followed by subsequent rigorous inbreeding across multiple generations to derive new independent lines. After careful breeding, successive generations of new inbred strains will contain fixed recombination of genes derived from the original gene pool. Profiling of differences in ALB in the recombinant lines such as BXD or AXB/BXA are subsequently used to identify the chromosomal locations related to the phenotype.

QTL strategies of ALB have yielded loci on many mouse chromosomes (1, 4, 5, 7, 8, 9, 10, 11, 13, 14, 18, 19) (reviewed by Flint, 2003). Linkage on chromosome 1, 4, and 15 were consistently found across the three more common ALBs (OFT, EPM, and LDB), where each QTL primarily influenced different phenotypic components: chromosome 1 (exploration), chromosome 4 (activity), and chromosome 15 QTL (avoidance). These three QTLs accounted for almost 21% of the total genetic variance, while genes accounted for 26% of the total phenotypic variance in the analyzed rodent population. Interestingly, the syntenic region on human chromosome 1 coincides with linkage peaks reported for several human ARPs (reviewed in Fullerton, 2006). Further dissection of the chromosome 1 region provided support for three separate murine QTLs (Yalcin et al., 2004), including effects attributable to the *RGS2* gene. *RGS2* has since been reportedly associated with several ADs and ARPs in humans.

It should be noted that QTLs help localize genetic effects to particular chromosomal regions but do not identify specific susceptibility genes; this typically requires further dissection using complementary methods such as gene expression profiling with microarrays. The combination of these approaches, known as expression-QTL (eQTL), is emerging as a promising tool for precise identification of genes underlying many medical phenotypes in rodents. Recent studies have applied these together to mice bred to establish high and low freezing lines presenting differences in FC. After validating gene expression

differences between the selective lines with quantitative polymerase chain reaction (qPCR), a number of genes have been confirmed to be in close proximity to, or within the boundaries of, the behavioral QTLs, including tyrosinase (Tyr) suppressor of Ty 16 homologue (*Supt16h*), endonucleoside triphosphate diphosphohydrolase4 (*Entpd4*; aka *Lysal1*), and diacylglycerol kinase, gamma (*Dgkg*) (Ponder et al., 2008).

Expression QTL analyses will require further development using recombinant inbred lines. However, inbred strains have been used with high-throughput molecular approaches to determine differences in gene expression associated with ALB. After surveying six inbred mouse strains on the LDB and OFT, Hovatta and colleagues performed gene expression profiling using microarrays to assess global gene expression in several brain regions linked to anxiety (Hovatta et al., 2005). They analyzed gene expression differences across several relevant brain regions between anxious and nonanxious mice across six inbred strains. They identified two novel candidate genes, glyoxalase 1 (*Glo1*) and glutathione reductase 1 (*Gsr*), which code for enzymes involved in metabolic pathways regulating oxidative stress. Further validation was demonstrated by viral-mediated gene overexpression and RNA interference (RNAi) knock-down in the target tissues, resulting in increasing or decreasing ALB, respectively.

The study of ALB in rodents has also profited from selective breeding of outbred animals. This strategy enriches for specific traits and enhances their specificity and homogeneity. Subsequent lines obtained after selectively breeding start from the same genetic outbred background, providing an etiologic association between differences in their genome and observed trait differences. Among the most notable selectively bred rodent models of ALB are the high (HAB), normal (NAB), and low (LAB) ALB mouse lines derived from CD-1 outbred mice based on behavioral differences in the EPM. HAB mice also display high anxiety in other unconditioned tests such as LDB and OFT and conditioned tests such as cued and contextual FC. Several candidate genes have been identified in relation to differential ALB between HAB and LAB mice. For example, the C(+40)T SNP in the first exon of the arginine/vasopressin (*AVP*) peptide precursor gene in LAB mice has been reported to cause an amino acid substitution from alanine to valine at the third position in the signal peptide. This SNP substitution is associated with ALB in an F2 panel of HAB and LAB mice. Sequencing performed within regions 2.5 Kb up- and downstream of the *AVP* gene locus

identified several polymorphic loci that differ between the HAB and LAB lines (Bunck et al., 2009). Allele-specific transcription analysis revealed a LAB-specific 75% decrease in transcription rate compared with the HAB-specific allele. AVP expression in the paraventricular nucleus of the hypothalamus was found to correlate with anxiety-like and depression-like behaviors. Moreover, a genotype/phenotype association was shown in an F2 panel, supporting a causal contribution of the AVP promoter deletion to ALB.

In the rat, the selectively bred High Responder (bHR) and bred Low Responder (bLR) models are similarly characterized by significant differences in ALB in the OPF, LDB, and EPM. Interestingly, these rats also present significant differences in depression-like behavior, consistent with human studies showing that depression and anxiety share common genetic factors. *Fibroblast Growth Factor-2 (FGF-2)*, a novel gene candidate previously noted to be downregulated in postmortem brains of severely depressed individuals, was shown to regulate, in part, individual differences between bHR and bLR (Perez et al., 2009). The bLRs exhibit significantly low levels of FGF-2 in the hippocampus, but when animals are treated with FGF-2, their ALB resembles that of a bHR. The role of FGF-2 on anxiety has been further supported by a recent report showing that FGF-2 RNAi knockdown in the hippocampus increased ALB. FGF-2 has also been implicated in FE, whereby treatment with FGF-2 has consistently been shown to increase extinction of conditioned fear in both young and adult rats (Graham and Richardson, 2011).

GENE-TARGETING APPROACHES

Genetics of ALB have also been investigated via the development of KO and transgenic mouse models. Similar to human candidate gene studies, many targeted genes were initially selected based on their relevance as pharmacological targets (i.e., monoamine and GABA-ergic genes). More novel gene targets were later developed based on neurobiological findings relevant to ALB. More recently, gene-targeting approaches have served to validate human genetic findings. Thus, throughout the last 15 years, there has been an increase in abundance of KO and transgenic overexpressing mouse models that have demonstrated significantly increasing or decreasing effects on ALB (summarized in Table 40.4). Moreover, the Cre-lox recombination system has enabled conditional and controllable deletions or insertions of genes in specific brain regions, cell types, and at specific time points (for details on the cre-loxP system see Chapter 8: “Transgenic Tools and Animal Models of Mental Illness”).

Tissue- and developmentally specific KO methods have been applied in studying serotonin 1A receptor (5HT1A) function in ALB (reviewed by Gordon and Hen, 2004). Serotonin is involved in mood regulation, and drugs acting on the serotonin system are effective in treating anxiety and depressive disorders. Three separate mouse strains with deleted 5-HT1A receptors have consistently exhibited increased anxiety. However, the 5-HT1A receptor is expressed in two separate neuronal populations in the brain: acting as an autoreceptor on serotonin-containing neurons of the raphe nuclei and as a heteroreceptor on neurons in the forebrain. Tissue-specific conditional rescue demonstrated that expression of the 5-HT1A

receptor in the hippocampus and cortex, but not the raphe nuclei, was sufficient to reinstate the anxiety-like phenotype of KO mice. Moreover, using conditional KO techniques, researchers showed that early developmental, but not adulthood, expression of the 5-HT1A receptor is essential for this

behavioral rescue. Together, these results suggest that signaling by serotonin via forebrain 5-HT1A receptor during development is required for normal ALB in adulthood.

The specificity of benzodiazepines (BZDs) on their interaction with the α-subunits of the GABA-A receptor was investigated with the use of genetic knockin methods. The efficacy of BZDs derives from binding and modulating the activity of GABA-A receptors. BZDs bind the α-subunit of the GABA-A receptors, enhancing the efficacy of GABA. There are six isoforms of the α-subunit, two of which are insensitive to BZDs as they lack a conserved histidine residue found in each of the four BZD-sensitive isoforms. By substituting histidine for arginines through targeted mutations on the α1, α2, and α3 subunits, it was demonstrated that α2 was responsible for the anxiolytic effects of diazepam, a BZD, on the LDB and EPM in mice.

We note that transgenic animals have limited utility in characterizing gene function at the molecular level for specific phenotypes like ALB. This is because (1) disruption in the expression of a single gene typically has pleiotropic effects on a wide variety of phenotypes, and (2) the relationship between any individual gene and a polygenetic phenotype is not isomorphic, by definition. Thus, more integrative cross-species approaches are required to capture the complexity of ALB.

TRANSLATIONAL NEUROGENETICS OF ANXIETY: FROM RODENT TO HUMAN AND BACK

Recent translational studies have attempted to use cross-species approaches to couple neurogenetic findings in humans with rodent models of ALB (Sartori et al., 2011). Besides the efforts of Hovatta and colleagues and the studies on *RGS2* reviewed earlier in this section, other examples exist of research that integrates data across human and rodent studies of anxiety phenotypes to identify novel AD candidate genes. The PD GWAS described in the previous section further validated the genetic association of *TMEM132D* via studies in mice: SNP rs13478518, located in exon 9, was significantly associated with the level of ALB, and upregulation of *TMEM132D* mRNA was observed in the cingulate cortex of HAB mice (Erhardt et al., 2011). A functional polymorphism (Val66Met) of the *BDNF* gene has recently been implicated in fear extinction. Mice expressing the *BDNF* Met allele, which is uncommon in humans, exhibited increased ALB and impaired FE relative to mice expressing the Val allele. Interestingly, similar impairment in FE has also been observed in humans with the Met allele. Using fMRI, impairment in extinction resulting from the Met allele was shown to be accompanied by deficient activity in the ventromedial prefrontal cortex and increased amygdala activation in both human and mice (Soliman et al., 2010). Several other studies have reported genetic effects in human anxiety phenotypes for genes identified from rodent studies (Donner et al., 2008; Hettema et al., 2011; Smoller et al., 2001).

FUTURE DIRECTIONS—EPIGENETICS

Epigenetic mechanisms potentially contribute, at least in part, to some of the observed genetic basis for ADs. As discussed in

Chapter 7, epigenetic modifications involve long-lasting alterations in gene expression that (1) are transmissible, (2) are affected by environmental factors, and (3) do not involve changes to the genome sequence. These are caused by posttranslational alterations including methylation, phosphorylation, and acetylation at specific residues including arginine, histidine, lysine, serine, and threonine. While the mechanisms underlying such effects on anxiety are yet to be determined, the fact that environmental events can alter risk for ADs suggests that epigenetics can play a role. For example, recent rodent studies support the hypothesis that early-life adversity increases risk for the development of psychopathology via negative impact on brain mechanisms underlying emotionality. Altered maternal care of rat pups increases methylation within the promoter region of the glucocorticoid receptor (GR) gene (Weaver et al., 2004). GR methylation decreases GR expression during adulthood and is thought to mediate the effects of early-life stress on increased anxiety and HPA axis alterations. Moreover, early life maltreatment leads to methylation of BDNF promoters in the rat, resulting in decreased BDNF expression in the prefrontal cortex into adulthood. Interestingly, early-life adversity in rats leads them to mistreat their own offspring, resulting in significant DNA methylation in the offspring. This underscores the transgenerational impact of such mechanisms on the phenotype and further supports potential non-DNA-mediated inheritance (reviewed in Sartori et al., 2011).

ANIMAL MOLECULAR GENETICS SUMMARY

There exist several well-validated animal models of ALB applicable to the identification of genetic loci underlying AD phenotypes and their biological effects. They provide complementary approaches using selected breeding and manipulations of both genetic and environmental factors not available in humans. The hope is that, like for other complex genetic medical syndromes, bidirectional translational studies between animal models and humans will provide critical insight into the pathophysiological basis of ADs and, ultimately, new targets for intervention.

SUMMARY

The major ADs exhibit moderate familial aggregation and heritability due to genetic risk factors that are common between them as well as those that are disorder specific. Similar findings apply when one expands the phenotypes to include anxiety-related personality traits and some aspects of unipolar depression. Similar to other psychiatric disorders, many candidate gene association studies have been published, with a small set of genes that have been consistently validated for their role in one or more anxiety phenotypes. GWAS of ADs are in their infancy, with only a few published studies so far and more to come in the next few years being conducted by large consortia. Animal studies provide a particularly promising complementary approach to human studies, since animal models for anxiety phenotypes are among the best validated across psychiatry. Several examples already exist of complementary and concurring genetic evidence across species supporting the involvement of particular biological systems in anxiety-related behaviors.

41 | NEUROBIOLOGY OF FEAR AND ANXIETY: CONTRIBUTIONS OF ANIMAL MODELS TO CURRENT UNDERSTANDING

CHRISTOPHER K. CAIN, GREGORY M. SULLIVAN, AND JOSEPH E. LeDOUX

INTRODUCTION

Animal models are *experimental preparations developed in one species for the purpose of studying phenomena occurring in another species* (McKinney 2001). Since human studies are often impractical or unethical, researchers depend on animal models to study the neurobiological mechanisms of fear and anxiety and to evaluate new treatments, especially drugs. There are approximately 100 animal models of fear and anxiety in the literature. We will focus on the models that have contributed most to our current understanding of the neurobiological mechanisms underlying fear and anxiety, and those with the greatest potential to expand our knowledge of pathological anxiety.

Although we will not attempt to summarize the contribution of animal models to the discovery and development of new anxiolytic drugs, it will become apparent that researchers in industry and academia have largely focused on different animal models. We will argue that this strategy, although useful for a time, is now unnecessary and may be impeding progress for both groups. The path forward, in our opinion, is to focus on animal models amenable to studies of the brain circuits and neural processes that mediate threat processing and defensive responding. This may be essential for advancing our understanding of neurobiological processes relevant to anxiety, identifying the causes of pathological anxiety and predicting how drugs may influence these relevant circuits and dysfunctional processes.

LANGUAGE AND CONCEPTUAL FRAMEWORK

A challenge for research on animal models of human psychiatric disorders is developing an appropriate and useful language to relate preclinical and clinical findings. On the one hand, animal models are only useful to the extent that they resemble a human problem, and similar language can improve communication between clinicians and preclinical researchers. On the other hand, these models are limited by differences in the brains of humans and other animals, and imprecision in nomenclature can complicate interpretation and application of preclinical findings. It is particularly important to be clear about which aspects of human anxiety can be studied using animal models. It will also be helpful to define a general

conceptual framework for discussing the relationship between fear, anxiety, and animal models of human disorders.

DEFENSIVE RESPONDING, THREAT PROCESSING, AND FEELINGS

Criteria for diagnosing anxiety disorders often use terms that refer to emotional symptoms, such as *afraid, worried, stressed, anxious, distressed, or concerned* (DSM-IV-TR 2000). Human anxiety disorders are defined by such emotional symptoms, along with behavioral and physiological symptoms. Because emotional symptoms involve feelings, subjective internal states of consciousness, that are not observable and can only be communicated through language, they are difficult to approach scientifically. Animals with less complex brains are unlikely to experience feelings in the way humans do, and do not possess language to relay feelings. It is therefore extremely important that we resist the temptation to anthropomorphize and view animal models as a tool to reveal mechanisms of feelings; they cannot. Among the perils of such, this can lead to overinterpretation of preclinical results and/or false rejection of animal models that fail to predict human feelings.

A more productive route is to focus on evolutionarily conserved brain systems that detect and respond to threats or actual harm. These systems control the physiological and behavioral defensive responses (DRs) that contribute to anxiety disorder symptoms when dysfunctional. For instance, humans and rats exhibit many of the same behavioral (e.g., freezing, fight, escape), autonomic (e.g., cardiovascular or respiratory), and endocrine (e.g., hormone release) responses when in danger. Core components of the underlying neurocircuitry also show a striking degree of overlap. For example, in both species, the amygdala plays a crucial role in detecting and responding to threats, the hippocampus provides critical contextual information, and the ventromedial prefrontal cortex (vmPFC) can suppress threat responses. The accompanying cellular, hormonal, and molecular processes involved are also remarkably similar. Thus, it is appropriate to model human anxiety-related DRs in other mammals because they are similar, controlled by conserved networks that function unconsciously, and are objectively observable (LeDoux, 2012). Further, human feelings of fear and anxiety depend on DRs. This will be the focus of the chapter. When we have occasion to refer to conscious feelings,

these will be labeled as fearful feeling, conscious feeling, and so on. In order to make a subtle but important distinction, we will use the term *threat* when referring to responses to cues that predict harm, whereas the broader term *defensive* will refer to responses triggered by threats or actual harm.

TOPOGRAPHY OF DEFENSIVE RESPONDING

Fear and *anxiety* are used in many ways, sometimes interchangeably but sometimes to label distinct reactions to aversive stimulation. *Fear* is usually used to denote a state elicited by clearly defined environmental threats, either innately aversive or learned. This fear state functions to cope with immediate threats and is more intense than anxiety, but also shorter lived. For example, rodents will often freeze when threatened, but freezing subsides quickly when the threat is removed. *Anxiety* often describes threat responding elicited by more diffuse cues. Anxiety states can last longer than fear and function to cope with more distant, or poorly defined, threats. For example, rodents hug the walls in an unfamiliar or brightly lit environment (thigmotaxis), a behavior that likely evolved to thwart detection by predators. Since they often operate on very different time scales, fear responses can be more reflexive, whereas anxiety can include more complex cognitive processes exemplified in humans by anticipation and worry.

Although fear and anxiety often refer to different aspects of threat responding, sometimes mediated by different brain regions, they are not always clearly dissociable in natural situations or laboratory experiments. The distinction is clouded further when one considers drug classifications or diagnostic criteria for human disorders. Therapeutic agents are routinely categorized as *anxiolytic/antianxiety* with no category for *anti-fear* drugs. Further, although most consider anxiety states to be weaker than fear, many human anxiety disorders are defined by the intensity and form of fear responses. Thus, in addition to anthropomorphic perils, the terms *fear* and *anxiety* fail to clearly define alternate mental states with distinct response profiles. Functional behavior system (FBS) approaches may provide a better framework for considering threat-related defensive responding. Rather than attempt to divide fear and anxiety into separate phenomena, FBS approaches assume that both result from activation of *defense* or *survival circuits* that evolved to protect organisms from harm, especially predators (Blanchard et al., 1989; LeDoux, 2012). For instance, predatory imminence theory (PIT) suggests that DRs are arranged hierarchically along a continuum, and the particular responses elicited depend on the proximity of the threat (Timberlake and Fanselow, 1994). In PIT, threats activate DRs and divert animals from their *preferred activity pattern*. DRs at the low end of the spectrum, like thigmotaxis, are elicited when danger is possible but not imminent. DRs at the high end of the spectrum, like fighting or escape, are elicited by imminent threats, like an attacking predator. DRs function to protect the animal from threats or actual harm, and return the animal to its preferred activity pattern.

FBS approaches are useful because they remove ambiguity in other anxiety/fear distinctions but still capture much of the nuance implicit in other definitions. They nicely explain the

progression of defensive responding as threats escalate. Threats that are unlikely, poorly defined, or distant serve to weakly activate survival circuits, resulting in relatively minor deviations from the preferred activity pattern. As threats become more likely, better defined, and closer, survival circuit activation increases, and animals deviate further from their preferred activity pattern. Ultimately, the strongest DR, defensive fighting, is elicited when all earlier responses fail to prevent threat escalation. It should be apparent that weaker DRs can occur over a much greater time frame whereas stronger DRs are often reflexive reactions to immediate threats (Fig. 41.1).

Before proceeding, a brief discussion of triggering stimuli and DR forms is warranted. Some triggering stimuli are innate; however, plasticity in survival circuits allows novel stimuli to gain control of DRs through experience. DRs also reflect an interaction between survival circuit activation and environmental options. For example, animals cannot flee in small laboratory testing chambers with no exits. Lastly, although mammalian DRs are remarkably similar in function and form (Blanchard et al., 1989), the exact behaviors are usually species specific (so-called species-specific defense responses or SSDRs; Timberlake and Fanselow, 1994). This simply means that a mouse will exhibit caution, freeze, flee, or fight differently than a monkey or human. Thus, although survival circuits are highly conserved neural systems for detecting and responding to danger, exact responses are usually unlearned, hard-wired reactions determined by evolution within a particular niche.

ANXIETY MODELS AMENABLE TO NEUROCIRCUIT ANALYSIS

Not all models are amenable to circuit analysis. Animal models can only contribute to our understanding of precise neurobiological mechanisms of defensive responding if a neural circuit mediating specific DRs can be identified and exploited. In line with the FBS approach outlined in the previous section, models amenable to neurocircuit analysis take advantage of discrete, well-defined triggering stimuli and innate, stereotyped DRs. This anchors the behavior to a neural system at the entry to, and exit from, the central nervous system. Models in which the stimulus conditions are diffuse or the responses lack stereotyped expression provide less guidance for studies that seek to identify key structures between the sensory and motor systems that underlie DRs.

Circuits are identified using a number of techniques. For instance, various lesions can demonstrate the necessity of specific brain regions. Disconnection lesions are particularly useful for showing that two different brain regions operate in series within a circuit to mediate a specific behavior. Extracellular recording of single neuronal units in awake, behaving animals is also extremely valuable for identifying information flow in neurocircuits. Other techniques, such as local infusion of drugs, brain stimulation, intracellular recording, or imaging of activity-dependent gene expression and/or energy metabolism, can provide converging evidence for the existence of a defined behavioral neurocircuit. Here it becomes evident why discrete triggering stimuli and

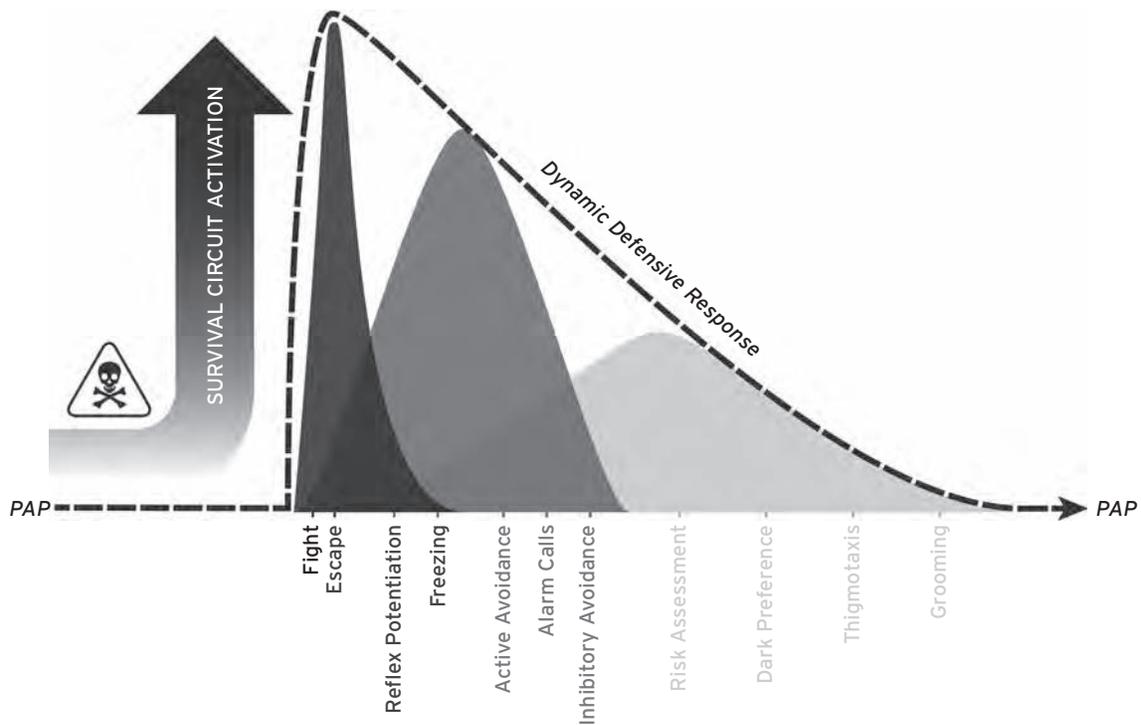

Figure 41.1 Threats trigger survival circuit activation and initiate defensive responding. Defensive responses function to prevent harm, minimize exposure to threats, and return the organism to its preferred activity pattern (PAP). DRs are organized hierarchically, and more imminent threats lead to greater survival circuit activation; more intense, reflexive DRs; and more total time away from the PAP.

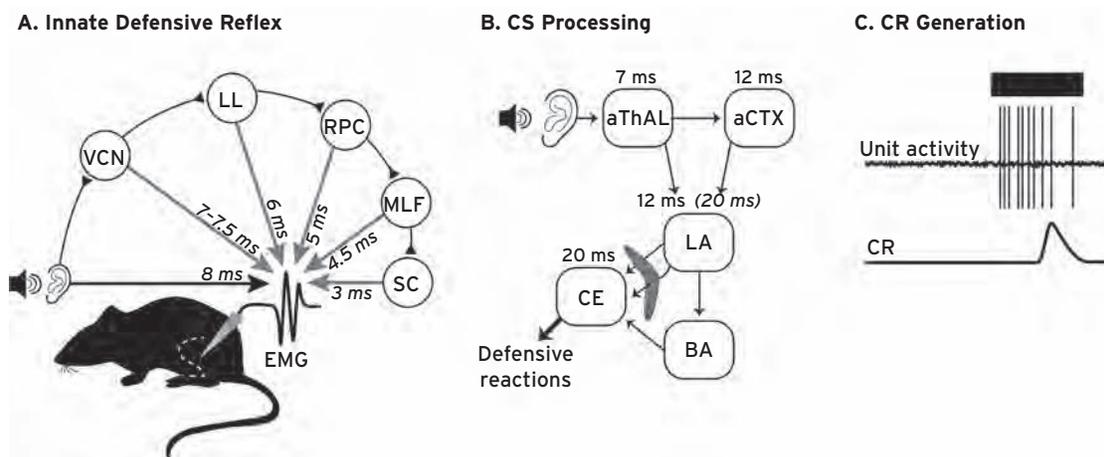

Figure 41.2 Examples of animal models amenable to neurocircuit analysis. (A) Acoustic startle is an innate, and extremely fast, defensive reflex (8 ms from sound onset to initiation of muscular response). Once lesion studies identified components of the underlying circuit, neural stimulation studies helped establish the order of these nuclei within the circuit, by measuring the latency of startle responding following stimulation (Davis et al., 1982). VCN: ventral cochlear nucleus; LL: lateral lemniscus; RPC: nucleus reticularis pontis caudalis; MLF: medial longitudinal fasciculus; SC: spinal cord. (B) Pavlovian threat processing involves rapid sensory processing and amygdala activation. Recording of CS-evoked neural activity helped identify this core component of the mammalian survival circuit. Again, latency measures helped establish the order of nuclei within the circuit. aThal: auditory thalamus; aCtx: auditory cortex; LA: lateral amygdala; BA: basal amygdala; CE: central amygdala. (C) A very precise neural circuit has been identified for Pavlovian eyeblink conditioning in the cerebellum, and postconditioning, CS-evoked activity in the interpositus nucleus initiates eyeblink CRs (Medina et al., 2002).

stereotyped responses are so important. By relating the timing of neural responses to the occurrence of stimuli and DRs, one can track information flow through a circuit beginning with stimuli that activate the circuit and ending with neural activity causing precise behavioral responses (Fig. 41.2). Once

a circuit is identified, the role of specific brain areas, cells, synapses, molecules, and genes can be elucidated. This strategy, pioneered in studies of invertebrates (e.g., Bailey et al., 2000), has been successfully applied to studies of mammals (Davis et al., 1982; Medina et al., 2002).

NORMAL VERSUS PATHOLOGICAL FEAR AND ANXIETY

Fear and anxiety are normal, adaptive responses to threatening environmental challenges. When threats activate survival circuits, behavior is restricted to responses compatible with SSDRs, and autonomic and endocrine processes divert bodily resources away from nonessential processes (e.g., digestion) and toward systems needed to execute defense (e.g., musculature and brain). Ideally, the degree of activation is proportional to the threat, and an adaptive, or normal, response will subside soon after the threat is gone. This can be illustrated by the contribution of corticosteroids to defensive responding. Aversive stimuli can trigger an endocrine *stress response*. This includes the rapid release of corticosteroids into the peripheral circulation, which has a wide variety of effects on bodily processes, including (1) increasing blood glucose and blood pressure, (2) enhancing perception and memory, and (3) suppressing nonessential immune and reproductive functions. Corticosteroids, through a hypothalamic-pituitary-adrenal (HPA) axis feedback loop, also play a crucial role in limiting the duration of the stress response. The system is rapidly activated to deal with danger and then turned off when the threat is gone. Thus, when functioning properly, threat processing circuits promote survival and maximize time in the preferred activity pattern.

Pathological fear and anxiety can refer to either impaired or facilitated threat responding. For instance, patients with amygdala damage have deficits detecting and responding to threats. Some, like patient S. M., who has no amygdala function due to Urbach-Weithe disease, reportedly also fail to experience fearful feelings (Feinstein et al., 2011). Impaired amygdala function has real-life consequences; S. M. has a history of being victimized and abused, likely a result of her inability to recognize dangerous situations and respond appropriately.

Although rare disorders can produce defensive systems that are pathologically *hypo*responsive, the vast majority of anxiety disorders involve systems that are *hyper*responsive (Rosen and Schulkin, 1998). Thus, pathological fear and anxiety usually refer to threat responding that is exaggerated, inappropriate, or prolonged (Fig. 41.3). *Exaggerated* refers to DRs that are stronger than the situation requires. This could mean responding with full-blown stress responses in unfamiliar environments when only vigilance is warranted. Or perhaps

responding to an unlikely threat as if it were 100% guaranteed to happen. *Inappropriate* DRs are triggered by stimuli that are not actually dangerous. *Prolonged* refers to DRs, including HPA axis activation, which persist well after the threat is diminished. Together, these factors describe states of fear and anxiety that are more intense, more frequent, and more often present in daily life.

ANIMAL MODELS OF FEAR AND ANXIETY

Since human anxiety disorders are varied and complex, animal models do not typically attempt to mimic full DSM syndromes (McKinney, 2001). Rather, they are adapted to specify and study key components of clinical syndromes. Researchers have approached this problem in many different ways, with varying degrees of success. While much has been learned about threat processing, defensive behavior, and learning in studies of invertebrates and other mammals (Bailey et al., 2000; Kalin, 2004), research on rodents has arguably contributed the most systematic and detailed information and will be the focus here. Ultimately, animal models are judged based on how well they reveal neurobiological mechanisms contributing to human anxiety and how well they predict the efficacy of treatments.

VALIDITY OF ANIMAL MODELS

Validity refers to the degree that a given model is useful for some purpose (McKinney, 2001; Willner, 1991). *Face validity* refers to phenomenological similarities between the model and the human psychiatric condition. Animal models have a high degree of face validity when etiological factors, symptoms, underlying physiology, and treatment effects are similar to the human disorder. *Construct validity* refers to the theoretical rationale for linking a process in a model to a process hypothesized to be important in a human disorder. Due to shared aspects of their phylogenetic histories, humans and other animals are often homologous at molecular, cellular, synaptic, and circuitry levels of analysis. Finally, a model is considered to have good *predictive validity* when it can anticipate similar effects in humans. In the realm of drug development,

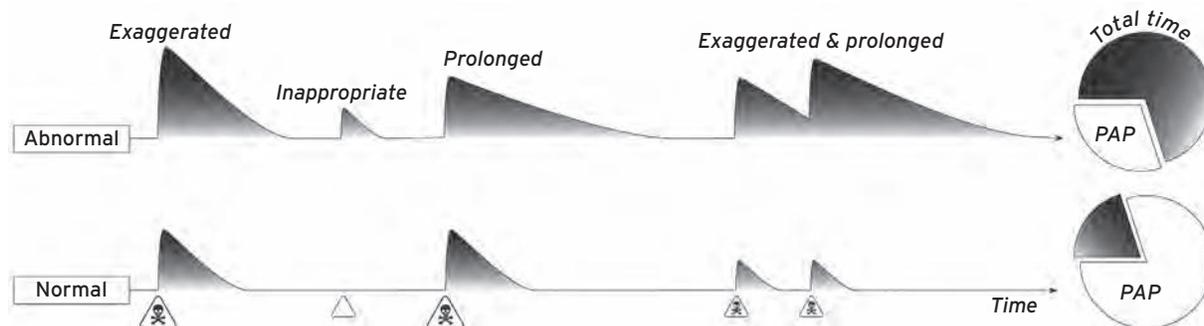

Figure 41.3 Schematic representation of pathological defensive response profiles. Note that abnormalities reduce the amount of time spent in the preferred activity pattern (PAP).

predictive validity is the ability to identify and rank drugs for therapeutic efficacy in humans.

Validity arguments are fundamentally epistemological and should not be used as the sole basis for evaluating the usefulness of an animal model. This is summed up nicely here:

Animal models are tools for our use: They are not developed as part of a beauty contest, with a prize for the most convincing. If a model cannot readily be used, it is of little value, however elegant. Thus, the successful construction of a valid model should not be seen as an end in itself, but as a useful step in the investigation of a scientific problem. As such, validity can be assessed only in relation to the broader objectives of the research program.

WILLNER (1991)

This last point is important. Different models may be useful for different purposes, depending on scientific and practical considerations. For instance, a model for rapid screening of drugs may have great predictive validity but little obvious construct validity. However, this could still be useful for developing new treatments, even if it may not be useful for unraveling neurobiological mechanisms of human anxiety. Thus, validity assessments are judgments made with appropriate context and based on available data, not exact measurements.

STATE VERSUS TRAIT ANXIETY

State anxiety is a temporary condition that is elicited by a stimulus or situation. *Trait anxiety* is an enduring condition that occurs across multiple situations or tests but is not necessarily pathological. Usually, tasks that assess trait anxiety are more valuable, as human disorders, and the rodent equivalents, are thought to be fairly stable. Unfortunately, many unconditioned animal models assess state anxiety, as is suggested by the relatively poor reliability in individual performance within or between tasks (Andreatini and Bacellar, 2000).

NORMAL VERSUS ABNORMAL RESPONDING

Most animal models evaluate “normal” fear and anxiety processes, where subjects are grouped and effects are reported as variation around a mean. Preexisting variability, genetic or otherwise, is averaged out. Evaluation of normal behavior is important; however, these studies may not adequately model the processes that cause human anxiety disorders. Anxiety disorders affect only a portion of the population, and for specific disorders like PTSD, only a subset of traumatized individuals develop pathological anxiety (Yehuda, 2007). Thus, animal models that examine abnormal responding, or outliers, may be of particular value. Researchers approach this problem using two basic strategies: (1) by performing standard assays but focusing on individuals with abnormal responses that mirror human pathology or (2) by introducing manipulations that skew group averages toward an abnormal response profile. Examples of these strategies will be discussed later.

ANIMAL MODELS OF NORMAL FEAR VERSUS ANXIETY

Animal models can be roughly divided into those that have an explicit learning component, and those that do not. Here we will distinguish between *unconditioned* and *conditioned* anxiety models. Note, however, that this terminology is not perfect; some unconditioned assays are referred to as *spontaneous*, *unlearned*, or *innate* anxiety in the literature (Takahashi et al., 2008), and some models involve nonassociative sensitization learning, which is not commonly considered “conditioning.” Where relevant, these distinctions will be pointed out.

UNCONDITIONED MODELS

Unconditioned models examine DRs elicited by a novel test situation, not cues associated with prior aversive experience (Blanchard et al., 1989; Takahashi et al., 2008). These assays utilize ethologically relevant behavioral end points that are thought to be sensitive indices of an animal’s natural anxiety/fear. Although there are many different unconditioned models of fear and anxiety, in the next section we discuss more commonly used rodent assays.

Innate Aversion to Light or Open Spaces

Rodents are nocturnally active small prey animals, and several popular unconditioned assays capitalize on their natural tendency to avoid brightly lit, open spaces. These assays elicit DRs akin to the *preencounter* behaviors of PIT, which likely evolved to protect animals in uncertain or weakly threatening situations. It has been argued that these weaker DRs reflect a degree of survival circuit activation that, in humans, corresponds to worry or mild anxiety (Craske, 1999; Rau and Fanselow, 2007). Examples are the elevated plus maze (EPM), light/dark, and defensive withdrawal tests. These assays are popular because they are easy to run, are cost-effective, require no learning phase, and reliably predict anxiolytic activity of *some* drugs (e.g., benzodiazepines) in humans. However, the imprecise nature of triggering stimuli (brightness/openness with no clear onset/termination) and resultant DRs (e.g., percentage of time spent in bright/open area, usually over many minutes) make it very difficult to define the underlying neural circuit. Further, these assays are sensitive to subtle variations and often produce inconsistent findings (Hogg 1996). Perhaps most problematic, they often fail to detect activity of nonbenzodiazepine anxiolytics (Kehne and Cain, 2010).

Light-enhanced startle is a related assay, but it has an advantage over those to the preceding because it is amenable to circuit analysis (Davis et al., 1982). In brief, this assay examines how an innate aversion to bright light can potentiate defensive reflexes by influencing neural processing in the well-characterized acoustic startle circuit (see Fig. 41.2). Light-enhanced startle has helped implicate specific brain regions (e.g., bed nucleus of the stria terminalis, or BNST), and molecules (e.g., corticotropin-releasing factor type 1, or CRF1, receptor), in the mediation of anxiety (Walker et al., 2009).

Social Behaviors

The unconditioned social interaction test measures the tendency of one animal to investigate and interact with a novel

conspecific when the two are placed in a closed, brightly lit arena (File and Seth, 2003). The separation-induced ultrasonic vocalization model in rat pups is another example. In both tests the eliciting stimulus and resultant response are social in nature. Social anxiety assays have been successfully used to rapidly screen and characterize anxiolytic agents with diverse mechanisms of action, showing some superiority over alternative unconditioned anxiety models. The social interaction test has also been reliable enough to implicate some general brain areas in anxiety, such as the amygdala, hippocampus, and brain stem neuromodulatory centers. However, no precise neural circuit has emerged that would allow for detailed analyses of cellular, synaptic, and molecular mechanisms for these effects. Subtle procedural variations can also cause inconsistent results between laboratories.

Antipredator Models

Given that DRs evolved primarily to protect against predation, stimuli associated with predatory animals are also useful for modeling fear and anxiety (Blanchard et al., 1989; Takahashi et al., 2008). In these assays, predator stimuli are presented to rodents, and DRs ranging from defensive fighting down to weaker responses like risk assessment are measured. Pharmacological studies of antipredator responses have been conducted; however, these assays are primarily used to map the neural circuits underlying innate fear/anxiety, often for comparison with the circuitry mediating conditioned threat responses. Gene expression and lesion studies suggest that unconditioned responses to predator cues depend on slightly different brain regions (e.g., medial amygdala, BNST) from conditioned responses. These assays may be particularly useful for modeling ethologically relevant human phobias (Rosen, 2004).

Summary of Unconditioned Models

Unconditioned fear/anxiety assays are popular for evaluating drugs with anxiolytic potential. However, they may not be ideal models of human psychopathology because most assess state, rather than trait, anxiety, and they can be sensitive to very minor procedural variations (e.g., time of day, lighting conditions). Perhaps more problematic, they are not amenable to circuit analysis and neurobiological studies. The light-enhanced startle and antipredator assays are exceptions. These are unique because response triggers and DRs can be discrete and precisely defined, thus allowing for examination of underlying circuits and neural mechanisms. For instance, light-enhanced startle takes advantage of the known acoustic startle circuit and evaluates how anxiogenic manipulations interact to facilitate defensive reflexes. Antipredator studies have been similarly successful in defining differences between the brain regions mediating learned versus unlearned fear/anxiety. Together unconditioned assays have implicated the extended amygdala, septohippocampal system, PFC, and various brainstem neuromodulator centers (e.g., locus coeruleus or raphe nuclei) in anxiety-like responding (Gray and McNaughton, 2000; Karpova et al., 2011; Knapska et al., 2007), though precise neurobiological mechanisms are still largely unknown.

ASSOCIATIVE CONDITIONING MODELS

Brain systems that detect and respond to threats are not simply innately wired stimulus–response mechanisms; they are also plastic, allowing organisms to learn new predictors of danger. Learning can involve nonassociative and/or associative plasticity. Nonassociative learning occurs when repeated exposure to a single stimulus leads to stronger (sensitization) or weaker (habituation) responding. Both sensitization and habituation have been studied in relation to anxiety, however, usually as modulators of associative responses. We therefore emphasize associative learning processes here.

Associative learning is critical for establishing DRs to novel/innocuous stimuli, and for learning to cope with, or suppress, these responses. Two classes of associative learning with particular relevance to fear and anxiety are *Pavlovian threat conditioning (PTC)* and *aversive instrumental conditioning*. We refer to *conditioned threats* instead of the traditional *conditioned fears* for reasons outlined earlier in the Defensive Responding, Threat Processing, and Feelings section and elsewhere (LeDoux, 2012). PTC is particularly important for many reasons; the conditions for learning are simple, learning is rapid and long-lasting, a basic neurocircuit has been identified, and a great deal is known about the underlying synaptic, cellular, and molecular processes. PTC may also be a prerequisite for other critical forms of anxiety-related learning such as avoidance. Finally, PTC is a powerful tool for investigating how established pathological memories, and/or responses, may be regulated or suppressed through new learning.

Pavlovian Threat Conditioning

Behavioral Aspects of PTC When neutral conditioned stimuli (CSs) are temporally paired with naturally aversive unconditioned stimuli (USs) PTC occurs (Fig. 41.5). Any sensory stimulus can serve as a CS, including social and complex configural cues like contexts, and USs can be any unpleasant or painful stimulus. Auditory CSs and footshock USs are commonly employed in laboratory experiments partly because researchers can precisely control the delivery of these stimuli. Prior to conditioning, subjects respond weakly to the CS. After conditioning, CS-alone presentations elicit a cassette of DRs including freezing, autonomic reactions, neuroendocrine responses, as well as potentiation of somatic reflexes like startle and eyeblink, collectively referred to as conditioned fear/threat responses (CRs; Fig. 41.4). CRs indicate that associative learning took place, provided that similar responses fail to occur when the CS and US are not paired (unpaired) during conditioning. Although CRs can sometimes resemble unconditioned responses to the US (e.g., startle), CRs nearly always take a different form. CRs can be generated with as little as one CS–US pairing and can last a lifetime. PTC also establishes the CS as secondary incentive that can support instrumental avoidance and higher order Pavlovian conditioning (discussed later).

PTC Neurocircuitry The amygdala is a core component of the mammalian threat-processing circuitry and is essential for learning, storing, and expressing PTC memories (Cain and LeDoux, 2008) (Fig. 41.5). It is composed of a dozen or

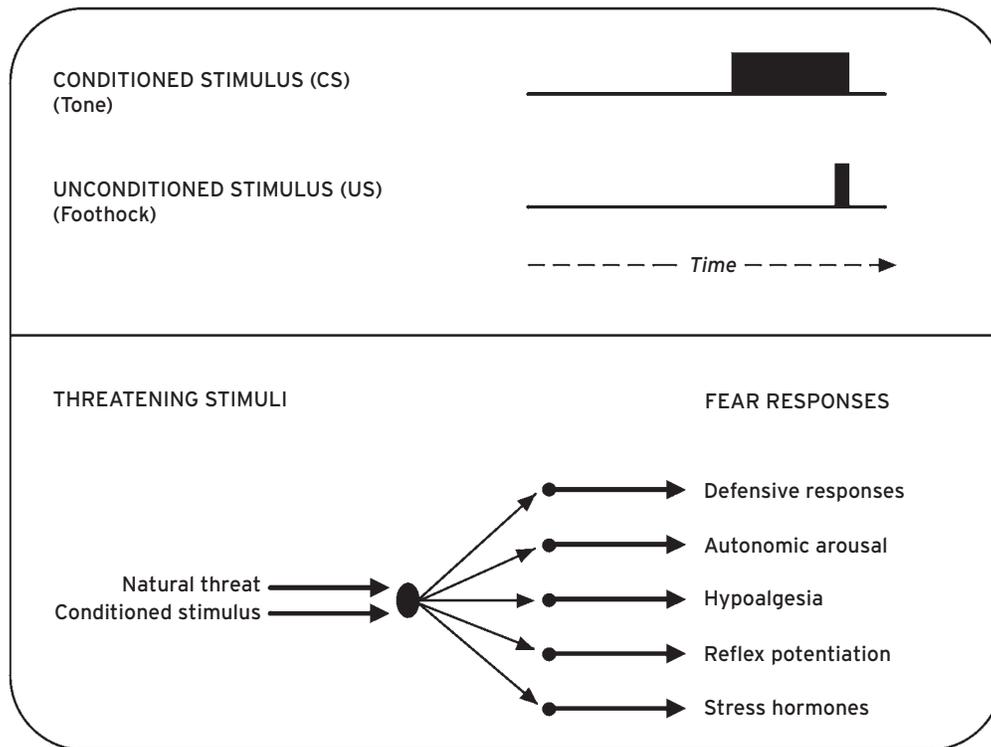

Figure 41.4 Protocol for inducing Pavlovian threat conditioning and common defensive (fear) responses.

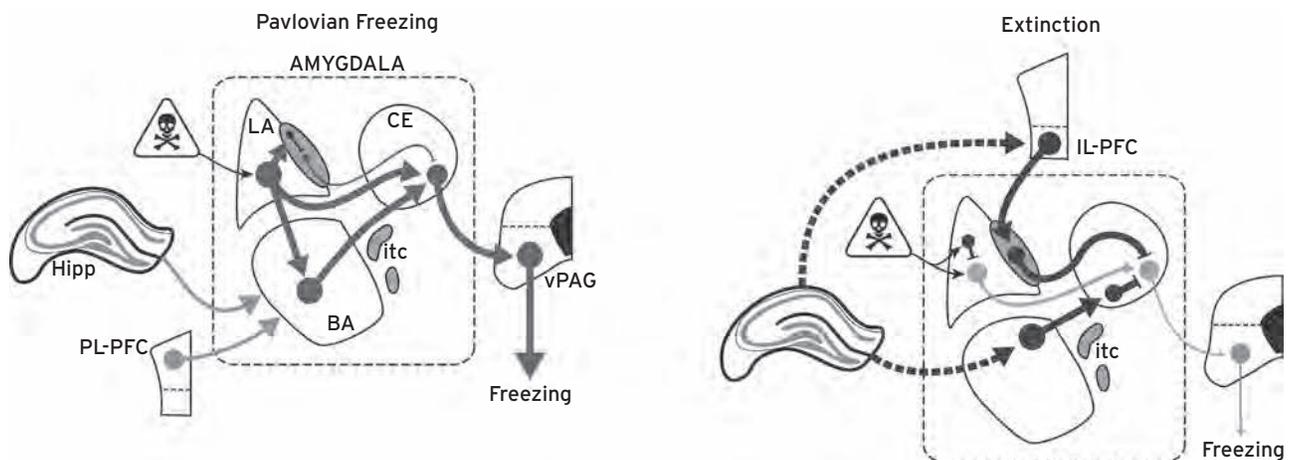

Figure 41.5 Core neural circuit mediating Pavlovian threat conditioning and extinction. Pavlovian freezing is used as an example for simplicity. (Left) The amygdala plays a critical role in detecting and responding to conditioned threats. Postconditioning, threats activate LA neurons, which in turn activate CE both directly and indirectly (via projections to BA, or to the intercalated cell masses which causes disinhibition of CE). CE outputs project to downstream effector regions (e.g., ventral PAG) that mediate specific DRs (e.g., freezing). Hippocampal inputs to BA provide contextual information, and prelimbic-PFC neurons help sustain conditioned responding over longer intervals. (Right) Extinction learning counteracts threat responding in at least three ways: (1) by strengthening feedforward inhibition in LA, (2) through infralimbic-PFC activation of intercalated cells, and (3) through a subset of BA cells that project to CE interneurons and inhibit CE output. Hippocampus plays a critical role in gating extinction according to context and via connections to il-PFC and BA extinction neurons.

so bilateral nuclei that reside in the temporal lobes. Of these, three have been the focus of much of the research on PTC: the lateral (LA), central (CE), and basal (BA) nuclei. LA neurons receive converging auditory (CS) and somatosensory (US) information from thalamic and cortical processing regions as early as 12 ms following stimulus onset. LA neurons in turn communicate with CE both directly and indirectly via projections to BA and intercalated cells. Although CE contributes

to learning and memory (Gozzi et al., 2010; Haubensak et al., 2010; Wilensky et al., 2006), CE is best known for its role in controlling expression of Pavlovian CRs (Ciocchi et al., 2010; Johansen et al., 2011; Knobloch et al., 2012). BA appears to have a complex role in the expression of CRs that is only beginning to be understood (Amano et al., 2011; Herry et al., 2010). Because the role of LA is best understood, it will be the focus of the discussion here.

LA is essential for learning, consolidation, expression, reconsolidation, extinction, and many other aspects of PTC (Cain and LeDoux, 2008; Johansen et al., 2011). Several recent findings provide especially strong support for the central role of LA in PTC. For instance, using optogenetics we recently demonstrated that artificial PTC memories could be created in rats by pairing standard auditory CSs with depolarization of LA neurons (Johansen et al., 2010). CS presentations after training elicited freezing, even though rats never received any footshocks. Although freezing was weaker than observed after real conditioning with footshock USs, that the rats froze at all was a testament to the importance of LA for PTC learning. Further, lesions of LA conducted 16 months after PTC, nearly the entire adult lifetime of the rat, severely disrupt conditioned freezing (Gale et al., 2004). Finally, using a clever combination of molecular tools, researchers recently demonstrated how a subset of LA neurons (~20%) outcompete their neighbors to store PTC plasticity, and were able to identify and erase PTC memories by ablating only those neurons (Josselyn, 2010). Together these findings firmly implicate LA in the learning, storage, and expression of PTC memories.

Extra-amygdala regions also make important contributions to PTC learning and expression. The hippocampus plays an important role in conditioning to more complex contextual cues, most likely through CS-related projections to BA (Maren and Fanselow, 1995). However, hippocampus plays a time-limited role in expression of contextual CRs; systems-level consolidation processes transfer this memory to more cortical brain regions like the anterior cingulate (Teixeria et al., 2006). Prelimbic PFC also appears to help maintain expression of CRs like freezing even after short-latency neural responses in amygdala adapt during CS presentations (Burgos-Robles et al., 2009).

Synaptic Plasticity in LA Associative pairing of the tone and shock induces synaptic plasticity between CS afferents and LA neurons (for review, see Johansen et al., 2011). PTC also results in synaptic plasticity in structures afferent to the LA (e.g., thalamus, cortex; Quirk et al., 1997; Weinberger, 1995). However, these are unlikely to be essential for threat conditioning at the level of behavior for three reasons: (1) inactivation of the LA prevents learning and memory, indicating that these structures alone cannot support PTC, (2) plasticity in these afferent structures appears to depend on LA function, and (3) conditioning-related plasticity in LA emerges before changes in afferent regions. Together these findings suggest that PTC changes the way a CS is processed in an emotional circuit involving LA, and this plasticity allows the CS to control expression of DRs after the aversive experience (Cain and LeDoux, 2008; Fig. 41.6).

Molecular Mechanisms of PTC in LA With mounting anatomical, physiological, and behavioral evidence implicating the LA in PTC, many researchers have focused their efforts on deciphering the molecular signaling cascades important for learning/memory in this region. The majority of studies employ genetic and pharmacological manipulations coupled with PTC to determine the function of specific molecules. Manipulations carefully timed with respect to training and

testing allow researchers to distinguish between involvement in learning, short-term memory (STM), and long-term memory (LTM) processes. Related studies have also probed the molecular mechanisms of LTP, usually using *in vitro* brain slice preparations while stimulating sensory afferents and recording in the LA. However, we will omit coverage of *in vitro* LTP as this topic has been covered in detail elsewhere and the results are generally in agreement with *in vivo* manipulations. A detailed review of the large body of molecular work related to PTC is beyond the scope of this chapter (for review, see Johansen et al., 2011); however, we will highlight the contributions of a few key molecular players to illustrate how long-lasting plasticity between sensory afferents and LA neurons is achieved.

There appear to be several important molecular stages to PTC-related plasticity in LA. First, receptors and ion channels at the synapse translate presynaptic activity into postsynaptic activation of signaling cascades by elevating intracellular calcium concentrations. NMDA (*N*-methyl-D-aspartate) receptors, L-type calcium channels, and metabotropic glutamate receptors are crucial for this process. α CaMKII (calcium/calmodulin-dependent protein kinase two) is particularly important for short-term memory/plasticity and may covalently modify existing synaptic proteins, like the alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptor, to facilitate glutamatergic transmission. PKA (protein kinase A) and MAPK (mitogen-activated protein kinase) are important for long-term memory/plasticity. When activated, they translocate to the nucleus to stimulate CREB (cAMP-responsive element binding protein)-mediated transcription. Long-term changes in synaptic transmission are ultimately achieved by transcription of the appropriate genes, translation of new proteins, and incorporation of these new proteins at the synapse. For instance, the production and synaptic insertion of new AMPA receptors are critical for PTC (Rumpel et al., 2005). Transcription and translation may also help form new synapses between sensory afferents and LA neurons (Ostroff et al., 2010). Together, molecular work in the PTC pathway demonstrates that synaptic receptors/channels, intracellular kinases, and nuclear machinery respond to CS-US pairings in a coordinated fashion to change CS processing in the LA and allow new stimuli to control defensive responding.

Exciting new work illustrates how molecular alterations in amygdala networks can alter threat processing and possibly contribute to human psychopathology. For instance, the discovery of an acid-sensing ion channel in LA that detects CO₂-related changes in pH and elicits DRs has exciting implications for understanding neuropathology in panic disorder, since CO₂-enriched air can precipitate panic attacks (Ziemann et al., 2009). And other studies demonstrate that allelic variants in genes affecting catecholamine catabolism (COMT) and serotonin reuptake (5-HTT) strongly predict hyperresponsiveness of defense-related neurons and behavior, including those responsible for threat conditioning, consistent with the notion of stable trait anxiety (Domschke and Dannlowski, 2010).

Variations of the PTC Procedure The simple PTC procedure described in the preceding is the most common tool for studying fear and anxiety reactions. It is simple because it usually involves discrete, unimodal CSs and USs with few pairings

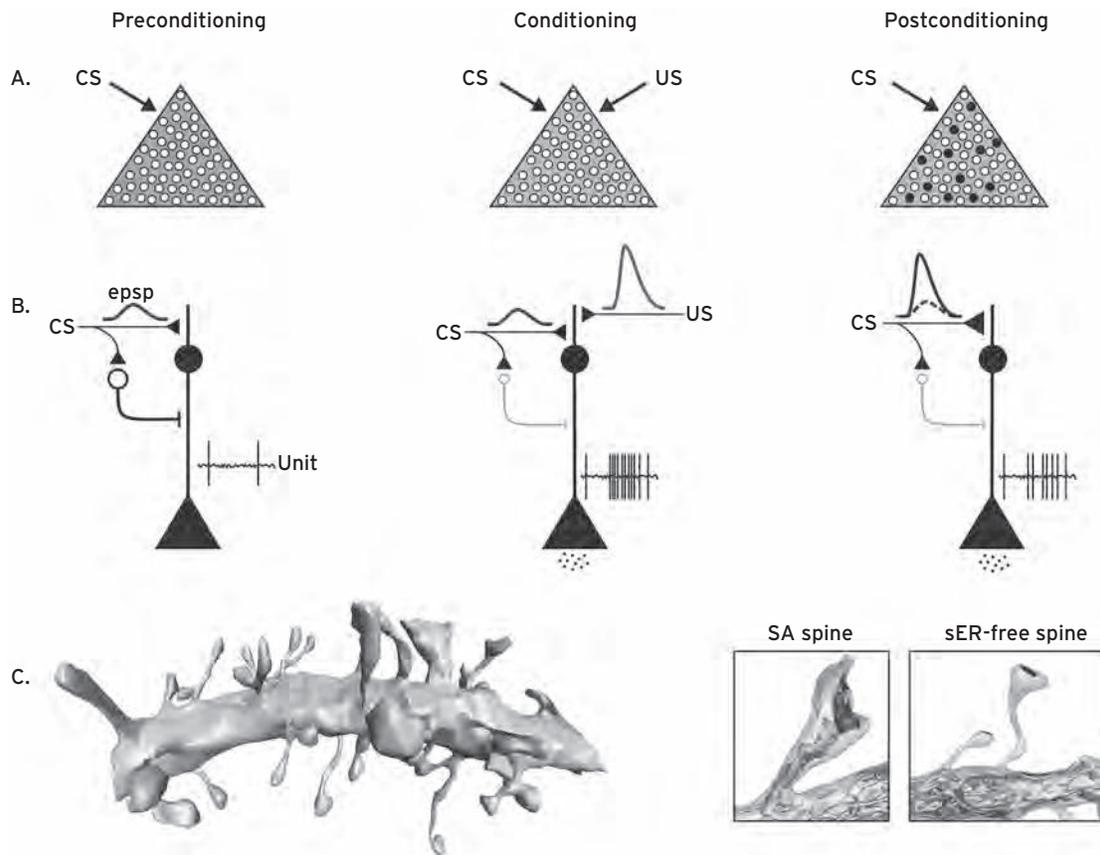

Figure 41.6 The identification of a neurocircuit has greatly facilitated studies of cellular processes important for defensive learning. For instance, approximately 20% of LA neurons outcompete their neighbors during conditioning, via a CREB-dependent mechanism, to learn and store PCT plasticity (A). Prior to conditioning, CS presentations result in weak depolarization of LA neurons and little to no activation of downstream brain areas mediating DRs. However, with CS-US pairings, neurons are strongly depolarized, resulting in initiation of an LTP-like process that strengthens the synapses between CS afferents and LA neurons. Following conditioning, CS presentations strongly depolarize LA neurons, trigger action potentials, and release neurotransmitters to activate downstream brain areas mediating expression of DRs. Recent work suggests the importance neuromodulators like dopamine and norepinephrine to the induction PTC plasticity in LA, both by direct action on excitatory cells and by suppression of feedforward GABAergic inhibition (Ehrlich et al. 2009) (B). Identification of this critical component of the neurocircuit has also allowed for detailed anatomical analyses of LA dendrites (C). For instance, studies using serial electron microscopy to reconstruct segments of LA dendrites after conditioning suggest that larger and more stable spines (SA spines) increase in frequency following conditioning and smaller (smooth ER-free) spines increase postsynaptic density area.

(<10) given with 100% contingency (all CS and US presentations are paired). There are countless variations on the PTC procedure that could help elucidate specific aspects of fear and anxiety. Here we will mention just a few.

The standard PTC procedure produces robust freezing in rodents, suggesting that CSs can strongly activate survival circuits and produce relatively high-level DRs, similar to those associated with human fear. Recent studies have attempted to model the uncertainty of anxiety more effectively by reducing CS/US contingency, increasing the CS-US delay, or by introducing an interval between the end of the CS and the US. Other variations use complex cues to signal the US, such as contextual stimuli. Much less is known about the neurobiology of these phenomena, but they are promising approaches for unraveling the neural mechanisms of anxiety and structures such as the BNST, hippocampus, and ACC, which have been implicated (Waddell et al., 2006; Walker et al., 2009).

Still another PTC variation assesses how aversive CSs suppress other nondefensive responses such as bar pressing for food. The most common of these assays is called conditioned

suppression or the conditioned emotional response (CER) test. These assays are more complicated, require much more training, and have the added layer of food/water deprivation that can muddle interpretation of results. The neural mechanisms of CER and simple PTC are similar, but there are subtle differences. Recently it has been suggested that conditioned suppression is a unique form of Pavlovian-instrument transfer (Balleine and Killcross, 2006) and thus may not be an ideal way to assess PTC directly.

Studies of retrieval-induced learning may also explain the development of some key anxiety disorder symptoms and suggest novel strategies for treatment. As in PTC, cues associated with trauma can reactivate traumatic memories. Such reminders can be severely disruptive, triggering intrusive images and thoughts that accompany a progressive worsening of anxiety symptoms, especially for memory-based disorders like PTSD (Southwick et al., 1999). Preclinical studies indicate that retrieval renders fear memories labile, probably to allow for the incorporation of new information, which is followed by a new consolidation process (reconsolidation). There is

ample evidence in the literature that retrieved memories can be reconsolidated in a stronger (fear incubation) or weaker state (Cain et al., 2012). Models that exploit these processes to examine new treatment options will be discussed later.

Summary of Pavlovian Threat Conditioning PTC has arguably enjoyed the most success as an animal model of fear and anxiety. The PTC model has good face, construct, and predictive validity, at least in terms of normal human fear and anxiety. The ability to identify and dissect a basic neural circuit has undoubtedly contributed to this model's success. Procedural variations may even allow for studies of weaker, anxiety-like DRs that were previously thought to require unconditioned anxiety models like the EPM. This system, along with variations in the procedure and/or additional learning phases that depend on PTC, may hold the most potential for modeling key aspects of human pathological anxiety as well.

Instrumental Avoidance Conditioning

Unlike PTC, where subjects learn about relationships between environmental stimuli and react accordingly, instrumental paradigms allow the subjects to *control* exposure to aversive stimuli. There are many variations on the instrumental theme, but here we will focus on two common assay types: passive or inhibitory avoidance (IA) and active avoidance (AA). Avoidance is a hallmark of many human anxiety disorders; however, like fear and anxiety, avoidance mechanisms evolved because they were adaptive and helped protect organisms from threats. But excessive avoidance may interfere with normal functioning and become maladaptive. Here we will discuss normal avoidance and summarize what is known about the underlying neurobiology. Later sections will examine how avoidance can become maladaptive.

Inhibitory Avoidance IA learning involves withholding a response that was previously punished, typically by shock. Although PTC undoubtedly occurs in these situations, the animal has control over exposure to the shock and shock-paired cues; thus, IA is instrumental in nature. There are many obvious parallels between IA and human psychopathology in the realm of anxiety. For example, agoraphobics inhibit actions that expose them to places in which escape would be difficult or embarrassing. Acrophobics inhibit actions that expose them to heights. Some unconditioned assays discussed earlier (e.g., EPM) may also be considered inhibitory avoidance of innately aversive stimuli. Conflict paradigms, like the Vogel test, also fall into this category. In these assays, rats are punished for appetitive actions (e.g., licking a water spout) with US presentations (e.g., shock). Conflict tests are billed as anxiety models, with the “anxiety” response reflected in the ratio between pre- and postpunishment responding (Gray and McNaughton, 2000). IA paradigms are widely used and influential animal models of anxiety and fear. IA tests are commonly used to screen and compare drugs with potential to combat anxiety in humans, primarily because they are very sensitive to benzodiazepine anxiolytics (especially conflict paradigms).

The greatest successes of IA may be its contributions to our understanding of the role neuromodulatory systems play in consolidation of explicit memories and expression of punishment-based memories. Countless drugs have been administered after IA training that either facilitate or impair subsequent memory. Drugs that facilitate IA are seen as cognitive enhancers; those that impair IA may have anxiolytic potential (or be amnesic). The most common finding is that postconditioning amygdala processes modulate the consolidation of explicit memories stored elsewhere in the brain—probably by stimulating neuromodulatory centers (McGaugh, 2004). This is usually demonstrated by infusing drugs directly into the amygdala after IA training and showing LTM effects. Although the neurocircuitry of IA remains somewhat elusive, it is clear that it differs from that of simple Pavlovian PTC; IA depends on extra-amygdala brain regions that are not required for simple PTC (e.g., septohippocampal system), and post-training amygdala manipulations that impair IA have no effect on LTM for PTC (Gray and McNaughton, 2000; Wilensky et al., 2006). As IA may be the most common form of avoidance cited as pathological in human anxiety disorders, more work is clearly needed to precisely define the neural circuits, and synaptic, cellular, and molecular processes mediating this form of instrumental learning.

Active Avoidance For many decades following Pavlov's work, conditional fear and its neural basis were commonly studied with active avoidance protocols (Cain and LeDoux, 2008). In a typical experiment, rats were presented with tone–shock pairings on one side of a two-compartment chamber. Movement to the opposite side (shuttling) terminated the tone and prevented a shock presentation. These avoidance responses (ARs) served as the dependent measure of fear learning, and animals exhibited responses more frequently and with shorter latencies as training progressed.

Avoidance proved to be a difficult paradigm for the analysis and explanation of learning mechanisms. This was partly because AA learning trials were those that successfully avoided the shock, and it was difficult to explain how absence of the US could reinforce the response. Debates still rage about the mechanisms of AA learning; however, one prominent early theory remains, called two-factor, two-process, or sometimes fear theory (Rescorla and Solomon, 1967). In brief, these theories assume that PTC occurs on early training trials, before an AR is acquired. Then, on subsequent trials, fear is aroused by the CS. When an AR is performed, the CS terminates, fear diminishes, and no US is encountered. These theories suggest that fear reduction associated with CS termination somehow reinforces the response. Although still controversial, there are reports that rodents can learn to escape an aversive CS even when no shock is present during training (escape from fear paradigms; e.g., Cain and LeDoux, 2007). These theories are popular with some partly because they provide an entry into the AA neurocircuit through the known Pavlovian threat conditioning circuitry.

Instrumental AA, like PTC and IA, is a normal, adaptive behavior that gives subjects control over threats in dangerous environments. Indeed, AA mechanisms may even contribute

to beneficial active coping strategies that prevent unnecessary fear (discussed later). However, like PTC and IA, AA can become maladaptive and contribute to human pathology.

Early studies found that impairing amygdala function disrupts the acquisition and recall of AA, although null effects or even facilitated AA were also reported. More recent investigations, focusing on subregions of the amygdala and other brain structures, paint a clearer picture (Fig. 41.7). Whereas LA and BA are critical for AA learning in several preparations, CE processes appear to constrain or oppose AA learning, possibly because CE mediates competing threat reactions like freezing (Lazaro-Munoz et al., 2010). Interestingly, several labs have shown that the amygdala dependence of AA is transient; when animals are trained beyond asymptotic performance, amygdala lesions no longer impair AA responding (Gabriel et al., 2003). This suggests that with overtraining AA may become habitual and depend on other, extra-amygdala regions. Dorsal striatum and motor cortex have been suggested as sites with possible significance; however, this remains unconfirmed. Recent unpublished findings from our lab also implicate the vmPFC in AA. This makes sense since Pavlovian reactions like freezing must be suppressed to allow for AA learning, and vmPFC is perfectly situated to suppress CE-mediated responses and allow performance of instrumental actions (Amano et al., 2010).

Two bodies of work, one older and one more recent, provide several key insights into how AA learning may be achieved in relation to the PTC circuitry. Michael Gabriel's

laboratory implicated amygdala processes in AA very early on, in addition to other brain regions such as the ACC, thalamus, and sensory cortex (Gabriel et al., 2003). Interestingly, measuring training-induced neural activity changes (TIA) during AA training in rabbits, this group showed that LA plasticity precedes plasticity in other regions, and TIA effects in other regions depend on LA plasticity. This emphasizes the importance of LA to AA learning, which is consistent with AA evolving from prior PTC. New studies from multiple laboratories suggest that a distinct population of inhibitory cells in the lateral CE may also play a key role in gating fear (and possibly enabling AA). These interneurons express PKC δ and oxytocin receptors, and function to inhibit the output cells of the medial CE and allow for more active DRs (Ciocchi et al., 2010; Haubensak et al., 2010).

Summary of Instrumental Aversive Conditioning Avoidance has a clear relationship to human anxiety disorders as many are partly defined by excessively avoidant behaviors and thoughts. IA has been widely used to investigate drugs that may have utility in treating human anxiety and has enjoyed reasonable predictive validity. Although IA suffers as a model for studying precise neurobiological mechanisms because it lacks a clearly identified neural circuit, this paradigm has greatly contributed to our understanding of the role that neuromodulators play in consolidation of explicit memories and expression of punishment memories. AA research also has clinical implications, both as a problem (e.g., obsessive-compulsive disorder) and as a potential

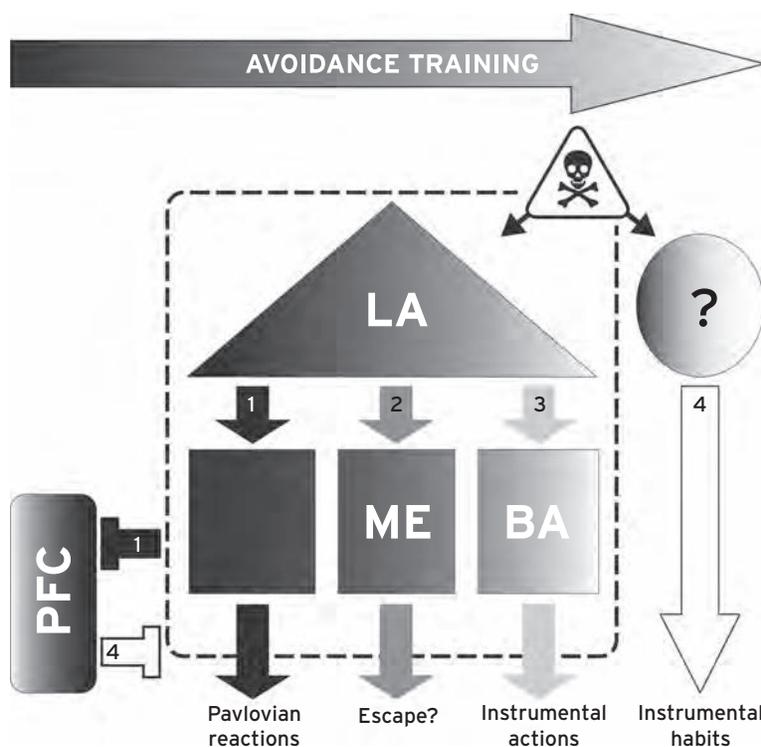

Figure 41.7 Working model of active avoidance. Early in AA training, failure to avoid leads to PCT trials and Pavlovian reactions mediated by LA and CE (1). CE also suppresses PFC activity. As training progresses, animals may first learn to escape via processes that depend on LA and medial amygdala (ME) (2). Eventually, il-PFC activity suppresses CE outputs and allows for AA learning, which depends on LA and BA processes (3–4). Overtraining of AA responses leads to amygdala-independent, and possibly habitual, AA (4). It is not yet known which brain region(s) mediate overtrained AA behavior; however, striatal and motor systems are likely candidates (Cain and LeDoux., 2008).

positive coping mechanism (discussed later). However, until recently AA research has stagnated. A resurgence of AA research, conducted using the successful blueprint of PTC, is already providing a much better understanding of the behavior, brain circuits, and neural mechanisms involved. Clearly more research is needed on both forms of avoidance given their role in human pathological anxiety.

Inhibition of Anxiety and Fear

Animal models can also focus on forms of learning that reduce or suppress DRs. The preceding sections described situations where survival circuits are activated and defensive responding is elicited. But as in most systems, what goes up must come down, and the mammalian brain has multiple ways to constrain and/or reverse the activation of defense responses. This is true of both behavioral and physiological responding. Here we will discuss a few key examples.

Negative Feedback in the HPA Axis The hypothalamic-adrenal-pituitary (HPA) axis is a major component of the acute stress response, a highly activated physiological state that prepares the organism by diverting energy and resources from nonessential processes (e.g., digestion) and mobilizing them to prime sensorimotor processes necessary for defensive responding. A properly functioning HPA axis turns itself off once the threat is gone, partly via glucocorticoid-mediated inhibition of hypothalamic and pituitary processes. In some human disorders, dysregulation of the HPA axis is implicated, and stress responding can be prolonged, leading to a number of adverse effects on bodily processes, health, and defensive responding (McEwen, 2004). HPA axis dysregulation can be assessed with tests like the dexamethasone suppression test. These models demonstrate that pathology can result from a failure of inhibition, not just excessive excitation, of DRs (Kehne and Cain, 2010).

Latent Inhibition and Extinction Minor modifications of the basic Pavlovian PTC procedure can profoundly influence the degree of survival circuit activation and the form of defensive responding. PTC occurs because the CS reliably predicts the US, and subsequent CS presentations allow the animal to anticipate unpleasant outcomes. But what if the CS does not always predict the US? In latent inhibition (LI), subjects are first exposed to a series of stimuli with no bad outcome. Then, standard PTC occurs using the same stimuli. DRs to the CS are nearly always weaker than the control condition, where no pre-exposure to the stimuli occurs. Extinction is a similar procedure but in reverse. Following PTC, subjects are repeatedly exposed to the CS without the anticipated US. This training contradicts the predictive validity of the CS and creates a new inhibitory CS–NoUS association (Bouton et al., 2006). Then, on subsequent trials conditioned responding is greatly diminished, or absent, depending on the amount of training. It is believed that extinction doesn't erase the original CS–US association but, rather, that behavior postextinction is the net result of competition between excitatory and inhibitory CS memories. Thus, one could imagine a scenario where one or both of these processes are impaired, leading to abnormally strong or persistent CRs even if basic PTC processes are normal.

Although some neurobiological studies have been conducted on LI in preclinical models, most of these relate to disorders like schizophrenia, where this learning process is disrupted. However, in the past 15 years there has been an explosion of fear extinction research, and we now know a great deal about its neural mechanisms (Milad and Quirk, 2012) (Fig. 41.5). For instance, vmPFC is essential for rapidly expressing extinction memories. Neural activity in vmPFC increases with extinction training, and electrical or growth factor (BDNF [brain-derived neurotrophic factor]) stimulation of vmPFC can induce extinction. vmPFC projects to inhibitory intercalated cells in the amygdala that can suppress CE-mediated threat reactions. LA and BA also play key roles in extinction learning. Several studies indicate that NMDA receptors, BDNF, calcineurin, MAP kinase, cannabinoid receptors, and GABA (gamma-aminobutyric acid) receptors in these regions participate in fear extinction learning (Myers and Davis, 2007). And BA neurons also appear to select between high- and low-fear states postextinction (Herry et al., 2010). Opioid-mediated input from the periaqueductal gray (PAG) may provide the error signal driving extinction plasticity (McNally et al., 2004). Finally, the hippocampus plays a critical role in the context-dependent expression of fear extinction; extinction is strongest in the place where CS-alone presentations occurred, and the hippocampus provides this critical signal (Bouton et al., 2006). Thus, animal models of extinction are seen by many as critical to understanding human pathological anxiety and barriers to its treatment (Cain et al., 2012; Jovanovic and Ressler, 2010). Indeed, a recent study of fear extinction revealed deficits in fear extinction recall and vmPFC activity when PTSD patients were challenged with an extinguished CS, consistent with preclinical findings (Milad and Quirk, 2012).

Conditioned Inhibition (CI) The CI procedure shares many features with extinction, but unlike extinction, where the CS comes to have ambiguous meaning, CI training produces a stimulus that has purely inhibitory properties. CI training produces a “safety signal” whose presence indicates that no harm will come.

CI learning is complicated and a bit difficult to study, but a few recent publications in rodents suggest that plasticity in the amygdala and striatum play a role. For instance, mice show weakened responses in LA to a conditioned inhibitor, but strengthened responses in the overlying striatum (Rogan et al., 2005). Rats trained similarly show reductions in synapse size in the LA (Ostroff et al., 2010). Thus, like extinction, conditioned inhibitors have the potential to identify safe circumstances and suppress DRs, and dysfunctional CI mechanisms may present as excessive fear/anxiety, even if those processes are operating normally. Impaired CI learning has recently been observed in patients with PTSD (Jovanovic et al., 2012), supporting the notion that dysfunctional inhibitory learning can lead to inappropriate responding (generalization) in anxious people.

ANIMAL MODELS OF PATHOLOGICAL FEAR AND ANXIETY

As discussed, the bulk of animal model research focuses on normal, group-averaged responses in naïve animals. This

research is important for gaining a solid understanding of the basic neurobiological processes that operate in human fear and anxiety. However, there is growing appreciation that these models cannot say much about the pathologies causing human disorders, especially if they fail to probe trait anxiety.

Researchers have recognized these problems for years and have taken many different approaches toward improving animal models of human anxiety disorders. Unfortunately, nearly every group uses its own method to coax rats into responding abnormally, which makes comparisons between models extremely difficult. Nevertheless, some important insights have been gained from these efforts, and we will attempt to summarize some major methods for modeling pathological fear and anxiety in animals. The list is not meant to be exhaustive or to suggest that one model is superior to another—it is merely meant to illustrate how researchers have used multimodal or hybrid approaches to examine pathological, rather than normal, defensive responding.

PHYSIOLOGICAL MANIPULATIONS

Physiological models have been used to examine how alterations in survival circuit neurons affect defensive responding. This is usually achieved by delivering chemicals or sensitizing electrical stimulation (i.e., kindling) to induce hyperexcitability in specific brain regions (e.g., amygdala, hypothalamus; Rosen and Schulkin, 1998). For example, models considered relevant to panic disorder (PD) combine treatments with panicogenic drugs with tests of unconditioned or conditioned DRs in rats (Shekhar et al., 2003; Sullivan et al., 2003). In one such model, the respiratory stimulant doxapram is administered prior to threat conditioning. Doxapram induces hyperventilation and panic attacks in most PD patients, by activating carotid body chemoreceptors to produce a (false) visceral signal to the brain of poor air. Doxapram treatment leads to facilitation of PTC, which has been linked to amygdala hyperexcitability and enhanced CRF release in CE. Because the circuitry of PTC is well characterized, it is possible to test the hypothesis that this visceral signal induces panic-like symptoms by altering threat processing in specific amygdala microcircuits.

DEVELOPMENTAL MANIPULATIONS

Developmental models have assessed the effects of early life stress on fearful and anxious behaviors manifested later in life. In rodents, for example, early maternal deprivation permanently alters central CRF systems as well as related behavioral and hormonal responses to stressors throughout life (Sullivan, 2003). Ecologically informed studies of maternal availability have likewise identified similar outcomes in non-human primates. Bonnet macaque monkeys raised in variable foraging demand conditions respond to novel situations with increased anxiety compared with age-matched monkeys raised as low-foraging demand controls. As adults, these monkeys exhibit significant differences in cerebrospinal fluid levels of monoamines, somatostatin, and CRF. These findings agree with evidence from humans that early exposure to severe stress is a risk factor for the development of mood and anxiety disorders (Heim and Nemeroff, 2002). Far less researched, but of equal importance, are indications that mild early-life stressors

can also foster resilience (stress inoculation), perhaps by facilitating vmPFC-mediated inhibition of amygdala and emotional regulation processes (Lyons et al., 2010).

STRESS-ENHANCED FEAR LEARNING IN ADULTS

Behavioral manipulations in adulthood that affect structure and function of survival circuits often involve exposure to acute or chronic stressors that alter defensive responding, especially PTC. These models are sometimes referred to by the abbreviation: stress-enhanced fear learning (SEFL; e.g., Rau and Fanselow, 2007). Stress is achieved in many ways, including restraint, immobilization, cold exposure, electric shock, predator exposure, and underwater submersion. Exposure to these stressors in adulthood increases aggression, alters context-elicited DRs, affects performance on the EPM, and attenuates spatial memory. Restraint stress also facilitates PTC, results in dendritic atrophy in hippocampus and PFC, suppresses neurogenesis in the dentate gyrus, and induces dendritic hypertrophy and sprouting of new synapses in the amygdala (McEwen, 2004). These stress-induced aspects of neural plasticity suggest a putative link between remodeling of defensive circuits and the development of anxiety as modeled in adult rodents. Chronic stress and underwater submersion have also been used in rodent research to mimic the requisite stressful events of traumatic anxiety disorders such as PTSD. Generally speaking, SEFL effects are interpreted as interactions between nonassociative sensitization processes and associative PTC processes. Thus, stressful manipulations may produce hyperexcitability in neural circuits that lower the threshold for defensive responding, and/or enhance PTC learning/consolidation. Such interpretations model key aspects of psychopathology theories in humans, such as Roger Pitman's "overconsolidation" theory of PTSD (for discussion, see Cain et al., 2012).

GENETIC MANIPULATION

Genetic manipulations before assessment of behavioral DRs in rodent models have generally been achieved in two ways. One is selective breeding of rat strains with the goal of enhancing or attenuating particular measures of fear and anxiety. For instance, the Wistar-Kyoto (WKY) rat strain has an extreme AA phenotype that may model aspects of human anxiety disorders. WKY rats show abnormally rapid acquisition in a difficult AA task and also fail to show the normal "warm-up" effect characteristic of other strains (Servatius et al., 2008). The other strategy is creation of transgenic animals that have altered expression of particular genes that code for proteins in brain circuits of interest, and evaluating performance on fear and anxiety assays. An example comes from studies of PTC in the serotonin (5-HT) 1A-receptor knockout mouse. When previously context-conditioned 5-HT1A-null mice are tested in the same context but with novel cues added, they do not exhibit the normal CR decrement seen in wild-type mice (Klemenhagen et al., 2006). This difference in sensitivity to novel stimuli has been likened to a memory bias for threatening cues in an otherwise neutral environment, as may occur in human patients with PD or PTSD. Given the well-described role of hippocampus in providing a representation of context to amygdala, focused

investigation of hippocampus–amygdala interactions involving the 5-HT1A receptor is suggested.

Naturally occurring genetic polymorphisms related to anxiety have also been studied, and again, the 5-HT system is implicated. In particular, an insertion/deletion event in the 5-HT transporter linked polymorphic region (5-HTTLPR) is known to produce long (l) and short (s) alleles in humans and rhesus monkeys. *In vitro*, the short allele decreases transcriptional efficiency, which may alter expression of the 5-HT transporter and disrupts control of extracellular concentrations of 5-HT in neural circuits. Humans homozygous for the short allele (s/s) show more anxiety, muscle tension, shyness, and avoidance compared with humans who are homozygous (l/l) or heterozygous (l/s) for the long allele, and greater activation of survival circuits when challenged with threats (Domschke and Dannlowski, 2010).

INDIVIDUAL DIFFERENCES

It has been proposed that consideration be given to individual differences in susceptibility and resilience in animal models of anxiety disorders (Yehuda and LeDoux, 2007). This is particularly important in models for PTSD, as it is well documented that similar exposures to a horrific trauma results in development of PTSD for a relatively small proportion of those exposed. Of note, phenotypic variability in most animal models of fear and anxiety is obscured by the usual practice of reporting the variation around the mean. Recent work shows that “fear reactivity” in conditioned animals is normally distributed in unselected Sprague-Dawley (SD) rats (Yehuda and LeDoux, 2007; Fig. 41.8). When high-fear reactivity rats are extinguished, two additional groups emerge: a fast-extinguishing group and a slow-extinguishing group. The slow-extinguishing group is proposed to have relevance for PTSD, which involves a failure to recover from trauma and is associated with impaired fear extinction recall and reductions in vmPFC activity (Milad and Quirk, 2012).

Related work has recently been conducted with AA in unselected SD rats (Lazaro-Munoz et al., 2010). In many AA studies, a subset of rats show extremely poor AA acquisition and are usually excluded from further analyses. However, these studies demonstrated that poor avoidance was associated with

abnormally high expression of competing Pavlovian reactions like freezing. CE lesions that eliminated freezing rescued AA performance without further training. This phenotype may also model a deficit in certain human anxiety disorders, as excessive Pavlovian reactions prevented the poor avoiders from performing a response that could prevent them from harm, even though they had apparently learned that they could avoid harm. Similar to microarray analyses of gene expression in selectively bred rats, these trait-selected rats offer opportunities to correlate gene expression with fearful and anxious phenotypic expression. Thus, models that consider individual phenotypic differences in fearful and anxious responding will likely be among the more effective for modeling anxiety disorders and identifying brain circuits and neuronal processes mediating abnormal anxiety.

MODELS FOCUSED ON TREATMENT AND COPING PROCESSES

Although several of the previous sections allude to implications for treatment of human anxiety disorders, some animal models explicitly attempt to model processes important for learning to suppress, or cope with, fear. The best accepted animal model of treatment learning is extinction. Exciting newer ideas involve disrupting reconsolidation and AA to understand active coping mechanisms for gaining control over threatening circumstances.

Fear Extinction

Extinction processes can be relevant to human treatment in many ways. Generally speaking, extinction training contradicts previously held beliefs or expectations. This creates a new inhibitory memory that competes with a conditioned threat memory for control of behavior. The result is a reduction, or elimination, of conditioned responding. Extinction can be used to reverse expression of both Pavlovian and instrumental CRs, although therapists typically focus on extinction of Pavlovian fear. Consider, for instance, a subject who exhibits pathological avoidance of some fear-eliciting stimulus. The therapist may seek to extinguish fear of this stimulus; however, this can be difficult since avoidance is typically strong, and one cannot extinguish CS

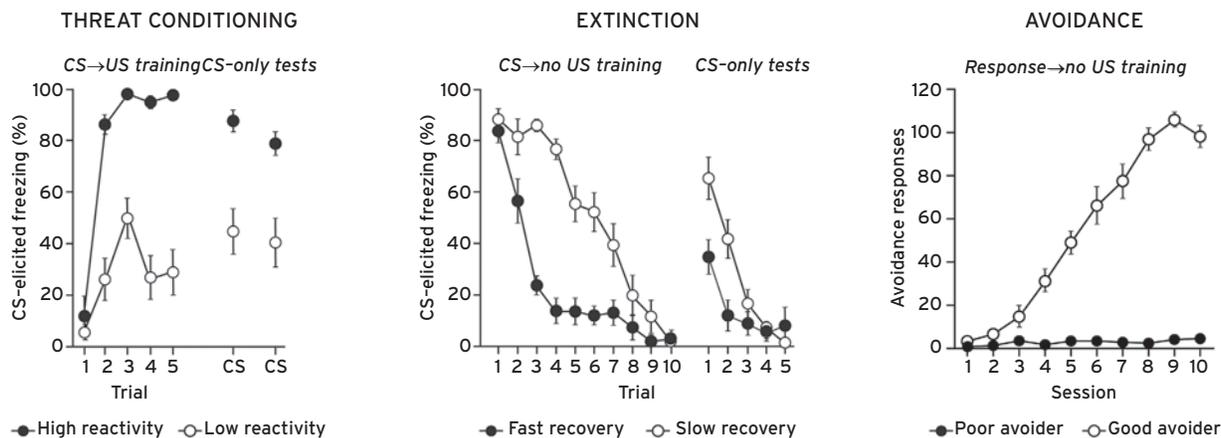

Figure 41.8 Exploiting natural response variation in key defensive learning tasks may facilitate studies modeling pathological fear/anxiety processes. In each task, the top and bottom 20% are shown.

fear if the subject avoids the CS altogether. In this case, a therapist may employ response prevention techniques followed by fear extinction. Response prevention means blocking ARs and essentially forcing exposure to the fear-arousing stimulus. Then, exposure, sometimes prolonged exposure (Foa, 2011), is used to extinguish CS fear. If successful, CS fear will diminish along with the motivation to avoid. Extinction is a component of most successful cognitive-behavioral therapies (CBTs) for fear and anxiety disorders, and there is good evidence that extinction-based treatments provide measurable relief to patients with wide-ranging anxiety disorders (Craske, 1999).

Unfortunately, fear extinction has some notable drawbacks. First, some anxiety disorders are accompanied by impairments in fear extinction (Milad and Quirk, 2012). Second, it has been known since Pavlov that extinction memories are “fragile,” and more recent preclinical studies reliably show that expression of extinction is transient. The phenomena of renewal, reinstatement, and spontaneous recovery all show how extinction treatments are temporary—CRs return when the context changes, new stressors are experienced, or time passes (Bouton et al., 2006). Thus, it is not surprising that preclinical and clinical researchers have been intensely researching ways to facilitate extinction learning and make it more durable.

Although this topic alone could fill a book, we will highlight several important lines of animal model research that could directly affect the efficacy and permanence of extinction-based therapies. First, many laboratories are investigating how the timing of exposures can enhance extinction. It appears that some degree of temporal massing of CS exposures (sometimes called *flooding*) can enhance initial extinction learning, and once extinction learning begins, sessions spaced out in time facilitate consolidation/LTM (Cain et al., 2003; Li and Westbrook, 2008). Specific variations on this theme have even been reported to produce erasure of PCT memories, presumably by blocking the reconsolidation of reactivated memories with extinction training (Quirk et al., 2010).

Many other studies are evaluating the effects of biological proteins and psychoactive drugs on fear extinction, especially drugs commonly used to treat anxiety (Milad and Quirk, 2012). Several findings are worth highlighting here. First, a number of agents have been found to enhance extinction learning/memory when given before or after CS exposures. These include D-cycloserine, yohimbine, fluoxetine, venlafaxine, valproic acid, cannabidiol, estradiol, corticosterone, and BDNF. Several others have been found to impair fear extinction, most notably benzodiazepines (e.g., valium), blockers of $\alpha 1$ adrenergic (e.g., prazosin) and μ -opioid (e.g., naloxone) receptors (Bernardi and Lattal, 2010; Bouton et al., 2006; McNally et al., 2004). Particularly exciting are findings that extinction therapy can lead to fear memory erasure if combined with appropriate drugs, like SSRIs (Karpova et al., 2011). Such effects suggest that it may be possible to return the defensive circuitry to a developmental state where extinction routinely produces erasure of aversive memories (Quirk et al., 2010). Finally, very recent preclinical studies suggest that deep brain stimulation of specific regions, like vmPFC or ventral striatum, can enhance extinction recall (Rodriguez-Romaguera et al., 2012).

Fear Reconsolidation and Incubation

Interest is gaining in a newer line of preclinical research on the neural mechanisms of reconsolidation and incubation. In brief, memories for conditioned threats become labile when reactivated, perhaps to update the memory trace before it is reconsolidated. This raises the exciting possibility that clinicians can modify or even block the storage of reactivated fear memories. Reconsolidation blockade is typically achieved with drugs that interfere with protein synthesis (Nader et al., 2000); however, these are not suitable for use in humans. Studies are underway to evaluate other ways to blunt reconsolidation. These include drugs that affect protein synthesis and memory such as β -adrenergic receptor blockers (e.g., propranolol; Debiec and LeDoux, 2006), and behavioral interference or extinction procedures (Quirk et al., 2010). In a related phenomenon, fear incubation, recurring activations can enhance reconsolidation processes and produce progressively stronger fear memories—reminiscent of anxiety disorders like PTSD where intrusive memories become progressively more disruptive (Pickens et al., 2009). Although little is known about the neural mechanisms of fear incubation, norepinephrine makes the clearest contribution (Debiec et al., 2011). Reconsolidation can be a double-edged sword when it comes to treatment, however, as cognitive enhancers can cause decreases or increases in threat responding, depending on the amount of CS exposure and the relative recruitment of extinction versus reconsolidation/incubation processes (Lee et al., 2006).

Avoidance, Escape, and Active Coping

A new twist on an old animal model of fear and anxiety suggests that aspects of human active coping can be modeled in laboratory rodents. Although instrumental escape and avoidance are normal and adaptive learning processes, they have a very negative connotation today, partly because they are listed as defining features of many human anxiety disorders. However, escape/avoidance contributions to human pathology reflect the adoption of responses that disrupt life activities, most likely inhibitory avoidance responses that cause one to disengage from the world. Although escape and active avoidance (E-AA) mechanisms can also contribute to pathology, they may represent an ideal way to cope with environmental threats. In E-AA, subjects learn a specific response or action that escapes environmental threats and prevents harm. Thus, E-AA gives subjects control over environmental threats, allowing them to operate in dangerous environments yet stay safe. Lack of control is also a defining feature of many mood and anxiety disorders (DSM-IV 2000). In this sense, adaptive E-AA responses resemble active coping strategies that contribute to resilience and facilitate recovery following trauma (Stewart and Yuen, 2011). Adaptive E-AA responses have some other added benefits, too: they prevent the expression of Pavlovian reactions indicative of human fear and anxiety, and, unlike extinction, this suppression appears to persist, as long as the AA response is available (Cain and LeDoux, 2007; Helmreich et al., 2012; Solomon and Wynne, 1954). AA mechanisms and individual differences were discussed previously, but more research on instrumental E-AA and active coping mechanisms may support another evidence-based treatment method in humans,

which may be especially useful for those who respond poorly to other forms of therapy (van der Kolk, 2006).

BEHAVIORAL INHIBITION THEORY OF ANXIETY

In 1982, Jeffrey Gray put forth a theory of anxiety based largely on the notion that classic anxiolytics, like alcohol, barbiturates, and (especially) benzodiazepines, could be useful tools for identifying good animal models of anxiety (Gray and McNaughton, 2000). Since only some DRs were sensitive to these drugs, Gray viewed fear and anxiety as separate response classes, and his definition of anxiety was distinct from that discussed earlier. According to Gray, anxiety reflected a *conflict* between motivations to approach certain stimuli and avoid others. Thus, anxiety was not simply weaker defensive responding to less certain or imminent threats, but a state triggered when one must choose to move toward threats in order to approach other, usually appetitive, goals. For instance, a rat may suppress foraging when presented with a predator odor but still engage in other active behaviors. Gray viewed this *behavioral inhibition (BI)* as distinct from fear-elicited DRs like freezing, which suppress all actions.

BI theory was very influential and affected the development and usage of animal models of anxiety. For instance, benzodiazepines suppressed DRs measured with conflict tests (e.g., Vogel test), IA, and several of the now-popular unconditioned assays (e.g., EPM) but often failed to suppress Pavlovian CRs and AA. Thus, conflict tests, IA, and unconditioned assays were deemed superior animal models of anxiety.

Gray also reasoned that “seat of anxiety” could be identified using brain lesions that produced a behavioral profile similar to the classic anxiolytics. This led to the septohippocampal (SH) theory of BI and anxiety, since lesions of this system impaired punishment effects, IA, and other anxiety-like behaviors in the unconditioned assays. This logic also led Gray to initially reject the notion that the amygdala played a central role in anxiety, since amygdala lesions impaired PCT and AA (unlike the anxiolytic drugs) and sometimes failed to affect the BI assays. In later years, Gray reformulated his theory to include a relatively minor role for the amygdala, mainly because fear-potentiated startle was shown to depend on the amygdala and was also sensitive to anxiolytics from diverse mechanistic classes (Davis, 1990).

Although influential, especially in the realm of drug development, the septohippocampal BI theory has steadily lost ground as new findings accumulate (LeDoux, 2002). First, SH injections of classic anxiolytics often failed to affect BI. Second, the classic anxiolytics all modulated GABAergic neurotransmission, and new anxiolytics were discovered that were effective in treating human anxiety but ineffective in prominent BI models (e.g., β -blockers, 5HT_{1A} agonists, SSRIs). Third, an enormous body of research suggested that the core function of the hippocampus related to declarative, spatial/contextual, and working memory, not conflict resolution as proposed by Gray’s BI theory. Thus, SH lesion effects could be explained better by theories hypothesizing that this system provided contextual information to the amygdala threat–response system. Fourth, an equally large body of preclinical and clinical work

implicated the amygdala, extended amygdala, and prefrontal cortex in defensive responding and human anxiety. Finally, the septohippocampal physiological mechanism for BI proposed by Gray, theta rhythms, does not appear to play a central role in primate, including human, anxiety. To the contrary, detailed mechanisms of neural processing and plasticity have been discovered in the amygdala, PFC, and hippocampus that can explain the role of neurotransmitter systems, and the action of anxiolytic drugs targeting these systems, in anxiety (see preceding section). These brain regions are now routinely implicated in human anxiety with imaging and neural recordings.

Although BI theory has run into some difficulties, we are not suggesting that the animal models used to support this theory are unrelated to fear and anxiety. Assays that involve punishment, IA, and innately aversive stimuli surely activate survival circuits and DRs relevant to human fear and anxiety. However, recent work strongly suggests that models based on PTC are capable of activating survival circuits to a similar degree, and these models are much better tools for studying the underlying neurobiological mechanisms mediating defensive responding—at both ends of the behavioral spectrum. The notion that approach–avoidance conflicts make a unique contribution to anxiety may still have merit, however, this conflict is probably inherent in all defensive deflections from the preferred activity pattern.

CONCLUSIONS

Current treatments for human pathological anxiety are inadequate; although some individuals respond favorably to psychotherapy and/or pharmacotherapy, both treatment approaches have unacceptably low long-term success rates (Cukor et al., 2010). Meanwhile, the needs of anxiety patients continue to grow, as does the already staggering cost to society (Smith, 2011). Given this unmet need and potential for massive profits, why then are pharmaceutical companies dropping drug development programs for anxiety at an alarming rate? The short answer: it’s too risky. When the drug discovery/development process takes 10–20 years, with an average cost of \$1.3 billion, these companies are understandably risk averse (Paul et al., 2010). Although there are many contributing factors, the inability of standard animal models to accurately predict efficacy in human anxious populations plays a major role (Smith, 2011).

Generally speaking, preclinical drug discovery leans heavily on pharmacology-based animal models like those used to support BI theory. These benzodiazepine-sensitive assays primarily test conflict behaviors, IA, and unconditioned responses to innately aversive stimuli. Although these assays probe a wide range of anxiety-related behavior, all represent difficult models for studying underlying neural circuits and precise neurobiological mechanisms. Thus, they select for “pharmacologic isomorphism” but often cannot assess the mode of action for new agents, predict enhanced efficacy over current standards, or explain failures in the clinic that could guide future decisions and refine anxiety models (Geyer and Markou, 2002).

In contrast to the recent troubles in drug discovery, studies of the neurobiology of fear and anxiety have had great success over the past few decades (Johansen et al., 2011). This branch of

research relies much more heavily on models amenable to neurocircuit analysis. For instance, Pavlovian threat conditioning uses discrete, controllable stimuli to induce learning, activate survival circuits, and elicit defensive responding. DRs typically studied include reflexive or stereotyped behaviors with clear, measurable onset and termination (Davis, 1990; Medina et al., 2002). These features greatly facilitate circuit analysis by allowing researchers to relate neural responses to triggering stimuli and behavior. Circuit-based models like PTC have vastly improved our understanding of the detailed cellular, synaptic, molecular, and genetic contributions to defensive responding and learning.

Although it was once believed that PTC could not elicit the anxiety-like responses that form the basis of many human disorders, recent work suggests otherwise. For instance, conditioning with reduced contingency, long duration CSs, complex CSs, or conditioned reinforcers can all produce less imminent/certain threats that elicit anxiety-like responses. Additional training phases can also model inhibitory (e.g., CI or extinction) or instrumental (e.g., AA) learning processes that likely make direct contributions to recovery and coping processes. Perhaps most important, circuit-based models like PTC allow one to hypothesize how a new treatment may achieve a positive effect in the context of known neurobiological and psychological processes.

Circuit-based models of anxiety are also consistent with recent efforts to reclassify human mental disorders. There is a growing realization that diagnostic criteria for anxiety disorders based on therapist interviews and personal reports of emotional symptoms may not accurately reflect underlying pathology in core anxiety processes. Thus, efforts such as the NIMH Research Domain Criteria Project (RDoC) aim to study basic dimensions of observable behavior and neurobiological measures related to pathological anxiety. The ultimate goal is to provide a knowledge base about core anxiety processes that will inform new diagnoses and treatment approaches. Increasing efforts to apply the preclinical circuit-based approach to new studies in experimental animals and people is likely to facilitate this process and remove much of the uncertainty associated with subjective emotional measures and models relying too heavily on validation by existing drugs.

DISCLOSURES

Dr. Cain has no conflicts of interest to disclose.

Dr. Sullivan serves as a member of the Scientific Advisory Board of Tonix Pharmaceuticals, Inc. and has served as a consultant to Ono Pharma USA, Inc.

Dr. LeDoux has no conflicts of interest to disclose.

42 | DIFFERENTIAL ROLES OF GABA RECEPTORS IN ANXIETY

HANNS MÖHLER

INTRODUCTION

GABA AS SET POINT FOR ANXIETY STATES: GABAERGIC DEFICIT IS CAUSAL FOR ANXIETY

In response to a threat, actual or psychological, evolutionary conserved brain systems orchestrate a physiological and behavioral defensive response. When these brain systems are dysfunctional, feelings of fear and anxiety can reach the pathological level of anxiety disorders. Core features of the underlying neurocircuitry include a hyperreactivity of the amygdala as a threat detection system and a hypoactivity of the ventromedial prefrontal cortex as a top-down control for the suppression of a threat response. (Cain, Sullivan, and LeDoux, this volume, Chapter 41). Among the neurotransmitters involved, GABA, the major inhibitory neurotransmitter in the brain, is a critical set point in the fear and anxiety circuits. An acute reduction of GABA transmission causes anxiety. For instance, healthy volunteers experienced panic anxiety when GABA_A receptor function was reduced by the administration of a nonselective benzodiazepine site partial inverse agonist (FG 7142) (Horowski and Dorow, 2002). Pathophysiologically, a defective GABA system is a predisposition to continuing to experience anxiety or fear. Panic anxiety patients show a GABA_A receptor deficit with strongest decrease in cortical areas, in particular in orbitofrontal cortex, insula, and in dorsolateral prefrontal cortex, with the severity of anxiety symptoms correlating with the deficit in GABA_A receptors as shown by [11C] flumazenil PET (Hasler et al., 2008). Furthermore, in combat veterans with PTSD, a dramatic GABA_A receptor deficit (–41%) was apparent in the dorsolateral prefrontal cortex (for review, see Möhler, 2012). Similarly, mutant animals with a targeted constitutive partial reduction of GABA_A receptor, function which mainly affected the hippocampus and cerebral cortex and somewhat the amygdala, displayed a behavior indicative of trait anxiety, reminiscent of generalized anxiety disorder in humans. The animals showed enhanced attention to threat cues, a negative bias to ambiguous cues and a concomitant harm avoidance behavior (Crestani et al., 1999; Earnheart et al., 2007). Conversely, drug-induced enhancement of GABA transmission (benzodiazepines, tiagabine, neurosteroids) exerts anxiolytic activity in the treatment of anxiety disorders (Iosifescu, Murrough, Charney this volume, Chapter 47). The behavioral anxiolytic action of a benzodiazepine such as alprazolam is accompanied by the dampening of the heightened activity of particular anxiety-related brain areas as shown by fMRI in volunteers undergoing an anxiety challenge (cholecystokinin-tetrapeptide i.v.). (Leicht et al., 2013). Thus, anxiety is induced

by a reduction of GABA transmission while an enhancement of GABA transmission alleviates anxiety.

BENZODIAZEPINES, A SERVO MECHANISM FOR GABA_A RECEPTOR FUNCTION

Benzodiazepines such as alprazolam are anxiolytic agents with a fast onset of action. They act as positive allosteric modulators of GABA_A receptors. It has long been a mystery how classical benzodiazepines are able to exert anxiolytic activity via a neurotransmitter system as ubiquitous as the GABA system, in particular as these drugs can also act as sedative-hypnotics, muscle relaxants and anticonvulsants. The distinctive pharmacology is largely due to the dose-dependent degree of receptor occupancy in the brain. Generally, anxiolytic activity is achieved at low receptor occupancy (about 20%; Facklam et al., 1992) while sedation and anticonvulsant activity requires higher receptor occupancy levels and correspondingly higher drug doses. The exclusive docking site of these drugs, which was originally termed *benzodiazepine receptor* (Möhler and Okada, 1977), is an allosteric binding site present in all benzodiazepine-sensitive GABA_A receptors (about 80% of all GABA_A receptors), which provides three important features: (1) Synapse selectivity: The benzodiazepines do not act unless the GABA-A receptor is activated by GABA drug action and is restricted to operational synapses. (2) Ceiling effect: When all GABA_A receptors are fully activated in a synapse, benzodiazepines are unable to increase the peak amplitude of the current response beyond the physiological maximum, a feature that is thought to contribute to the clinical safety of benzodiazepines. (3) Bidirectional modulation: Depending on the type of ligand, positive or negative allosteric efficacy in receptor modulation can be achieved. Thus, the pharmacology of ligands of the benzodiazepine site ranges from anxiolytic to anticonvulsant effects for classical benzodiazepine-type ligands (agonists, also termed *positive allosteric modulators*, PAMs) to anxiogenic and convulsant effects of beta-carboline-type ligands (inverse agonists, also termed negative allosteric modulators, NAMs).

Synaptic GABA_A receptors are activated by a brief, nonequilibrium exposure to millimolar GABA (Fig. 42.1). In the presence of a therapeutically active benzodiazepine, the affinity for GABA is increased, which corresponds to a shift of the GABA dose/response curve to the left (i.e., for the same quantum of GABA, more receptors are activated and the amplitude of the GABA response is increased). In keeping with an increase in

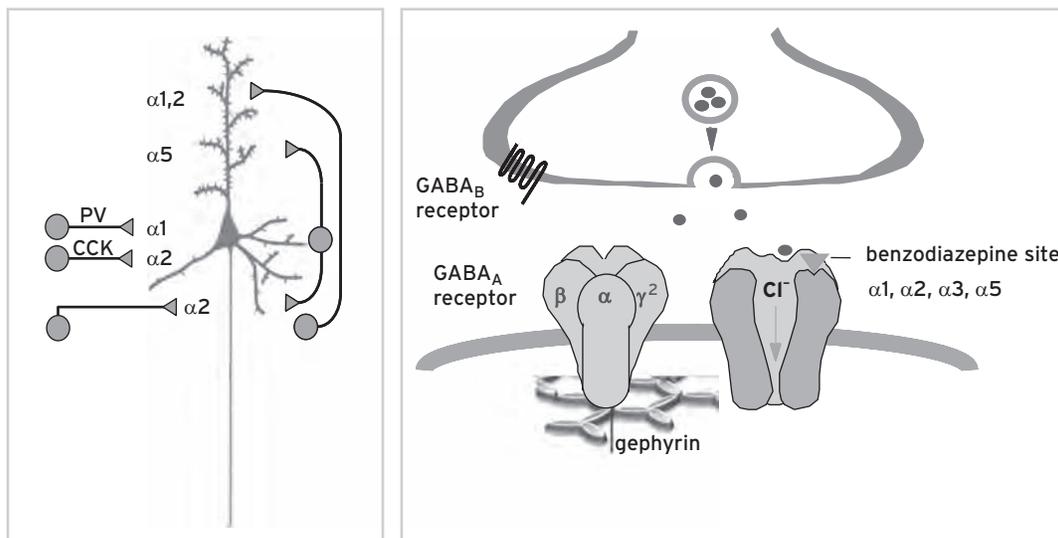

Figure 42.1 Left: Scheme of the domain-specific innervation of a principal cell by diverse interneurons. Distinct distributions of GABA receptor subtypes are schematically indicated by the type of α -subunit. Right: Scheme of a GABAergic synapse. The heteropentameric GABA_A receptor forms a membrane-spanning chloride ion channel by which GABA (dots) gates fast postsynaptic inhibition. Receptors containing an α_1 , α_2 , α_3 , or α_5 subunit in conjunction with a β -subunit (β_2 , β_3) and the γ_2 subunit are benzodiazepine sensitive and represent the majority (about 80%) of all GABA_A receptors. Depending on the type of ligand acting at the allosteric modulatory benzodiazepine site, GABA_A receptor function can either be enhanced e.g., by classical benzodiazepines such as diazepam (positive allosteric modulators also termed agonists) or reduced (negative allosteric modulators or inverse agonists, Table 42.2). Besides interacting with the major clustering protein gephyrin, GABA_A receptors undergo regulated trafficking in a dynamic adaptation of their cell surface expression (Lüscher et al., 2011). Slow GABAergic inhibition is mediated by G-protein coupled metabotropic GABA_B receptors that cause slow postsynaptic inhibition by opening inwardly rectifying K⁺ (GiRK) channels (not shown). GABA_B receptors are present presynaptically on some glutamatergic nerve endings (see Fig. 42.3) and, as auto receptors, on some GABAergic interneuron nerve terminal, where they cause inhibition of transmitter release by limiting Ca²⁺ entry.

affinity, the decay of the spontaneous miniature inhibitory postsynaptic current (mIPSC) is prolonged. However, in various GABA synapses the amplitude of the mIPSCs remained unaltered in the presence of a benzodiazepine agonist, which has been interpreted to indicate that a single quantum of GABA can saturate all GABA_A receptors in the respective synapse and the maximum peak response is not further enhanced by the drug. Nevertheless, even at maximal GABA_A receptor activation, the drug-induced prolongation of individual mIPSCs still remained and resulted in a slightly increased peak amplitude of the compound inhibitory response which is caused by the summation of several mIPSCs. Thus, the action of a benzodiazepine drug appears to be cell- and synapse specific, reflecting local differences in the number of receptors in the cleft or in the GABA concentration released into the cleft. The drug effects will therefore vary with the operational configuration of the GABAergic synapse. Nevertheless, the most pronounced drug effects are expected in synapses operating at suboptimal level, which bodes well for the treatment of pathophysiologies characterized by a reduced GABAergic drive. The action of benzodiazepines on the GABA_A receptor can be compared to the servo mechanism of the brake system in a car. The servo mechanism kicks in only when the brake is activated but does not increase the maximum braking power (for review, see Hajos et al., 2000; Möhler, 2011).

GABA SYSTEMS OPERATE BY DOMAIN-SPECIFIC TARGET INNERVATION

Complex brains have developed highly targeted GABA systems. A wide variety of interneurons dynamically orchestrate

the spatiotemporal pattern of network activity. This is largely achieved by the domain-specific innervation of the principal cells to permit an independent regulation of various afferent inputs and the timing of the output (Fig. 42.1). For instance, in the CA1 region of the hippocampus, 21 different classes of GABA interneurons were identified based on their distinct location, morphology, cotransmitter (CCK, SOM), or other marker proteins (parvalbumin [PV], calbindin, calretinin) and activity pattern (Klausberger and Somogyi, 2008). Excitation of PV-positive basket cells can generate neural oscillations over high-frequency ranges, pace them, synchronize participating neurons, and maintain their coherence. Crucial for this property is that basket cells act jointly and have a wide outreach. They are electrically coupled via gap junctions and the axonal arbor of each inhibitory interneuron may contact more than a thousand pyramidal cells. Fast-spiking PV basket cells operate with synapses containing GABA_A receptors, which are geared to high-frequency responses (α_1 GABA_A receptors). In contrast, the CCK-containing basket cells, which also target the perisomatic compartment, are not fast spiking and operate with structurally different receptors (α_2 and α_3 GABA_A receptors). Chandelier neurons, which target the axon initial segment of the principal cells in cortex and hippocampus, act as an off-switch by editing the generation and timing of the action potential output and operate with α_2 GABA_A receptors. Interneurons that preferentially target dendritic sites of pyramidal cells, such as Martinotti cells, influence the synaptic input, by affecting input integration, synaptic plasticity, and the generation of calcium spikes. Sir John Eccles famously wrote, “I always think that inhibition is a sculpturing process. The

inhibition, as it were, chisels away at the (...) mass of excitatory action and gives a more specific form to the neuronal performance at every stage of synaptic relay” (Eccles, 1977).

DIVERSITY OF GABA_A RECEPTOR SUBTYPES

The diversity of interneurons is paralleled by a striking diversity of structurally distinct GABA_A receptors. The combinatorial assembly from different subunit classes provides distinct kinetics and pharmacological properties with important consequences for synaptic function and therapeutic drug actions. There is a family of 19 subunits (α_{1-6} , β_{1-3} , γ_{1-3} , δ , ϵ , θ , π , ρ_{1-3}) available for the formation of heteropentameric receptors with a central chloride ion channel pore to be gated by GABA (for review, see Olsen and Sieghart, 2009; Rudolph and Knoflach, 2011). To accommodate the input of diverse interneurons, a principal cell is able to assemble several types of GABA_A receptors and target them to the specific cellular domains and synapses.

The most frequent GABA_A receptor subtype is the α_1 receptor subtype, assembled from two α_1 , two β_2 , and one γ_2 subunit (Fig. 42.1). It is highly enriched in synapses and meets the kinetic requirements for high-frequency neurotransmission with a rapid rise and decay time of conductance changes. Correspondingly, fast-spiking PV basket cells drive pyramidal cells via α_1 GABA_A receptors. Other synaptic receptors contain α_2 or α_3 subunits in combination with β_2 or β_3 subunits and the γ_2 subunit. Thus, the predominant receptor subtypes that mediate phasic synaptic inhibition are α_1 , α_2 , or α_3 GABA_A receptors. Each of these receptors is, however, also found in extrasynaptic plasma membranes, and no receptor subtype has yet been found to have an exclusive synaptic location. This is thought to be largely due to reversible posttranslational modifications that determine the degree of synaptic anchoring of the receptors. However, some GABA_A receptors are excluded from synapses and mediate tonic inhibition by sensing ambient GABA concentrations. They comprise α_5 GABA_A receptors (α_5 , β_3 , γ_2) and the receptors characterized by a δ subunit, mostly associated with an α_4 or α_6 subunit (Table 42.1) (Mann and Mody, 2010).

Pharmacologically, receptor subtypes are best differentiated by their ability to respond to benzodiazepine drugs. Benzodiazepine-sensitive receptors are those containing an α_1 , α_2 , α_3 , or α_5 subunit in combination with a β_2 or β_3 subunit and a γ_2 subunit with the benzodiazepine binding site being located at the interface between the α and the γ_2 subunit (Fig. 42.1; Table 42.1). Thus, the α_1 , α_2 , α_3 , or α_5 GABA_A receptor subtypes, which represent about 80% of all GABA_A receptors in the brain, mediate the entire repertoire of benzodiazepine actions (anxiolytic action, muscle relaxant, sedative, and anticonvulsant activity). In contrast, GABA_A receptors that contain an α_4 or α_6 subunit are benzodiazepine insensitive, irrespective of the subunits they are associated with (Olsen and Sieghart, 2009; Rudolph and Knoflach, 2011) (Table 42.1).

RESOLVING THE PHARMACOLOGY OF GABA_A RECEPTOR SUBTYPES

Classical benzodiazepines such as diazepam don't differentiate among the four types of benzodiazepine-sensitive GABA_A

receptors. It was therefore unknown which part of the spectrum of benzodiazepine actions was mediated by which of the α_1 , α_2 , α_3 , or α_5 receptors *in vivo*. Mouse genetics brought the breakthrough (Rudolph et al., 1999). It was known from recombinant GABA_A receptors that the replacement of a conserved histidine (H) residue in the drug binding pocket by an arginine (R) residue rendered the benzodiazepine-sensitive receptors into benzodiazepine-insensitive receptors. Exploiting this molecular switch, four lines of point-mutated mice were generated, which carried diazepam-insensitive α_1 , α_2 , α_3 , or α_5 subunits, respectively. In these animals, a specific part of the spectrum of benzodiazepine actions was expected to be absent and was therefore attributed to the respective wild-type GABA_A receptor subtype. Importantly, with the exception of the α_5 subunit, the point mutation did not affect the expression or distribution of the receptors nor their response to GABA. It was only when a benzodiazepine drug was administered that the presence of the point mutation manifested itself behaviorally. Thus, GABA_A receptor subtypes became functional markers for the neuronal circuits which mediate selective benzodiazepine actions (Table 42.1) (Möhler, 2011; Rudolph and Knoflach, 2011).

α_1 GABA_A RECEPTORS MEDIATE SEDATION

In mice containing benzodiazepine-insensitive α_1 GABA_A receptors (α_1 [H101R]), the sedative action of diazepam (measured by locomotor activity) and its anticonvulsant activity (antipentylenetetrazole) was absent, while its anxiolytic effect (measured in the elevated plus maze and the light/dark choice test) and its myorelaxant action (measured by rotarod and horizontal wire test) were fully retained (Rudolph et al., 1999). These results were confirmed in a separate α_1 point mutated mouse line when comparable test conditions were applied (Crestani et al., 2000; McKernan et al., 2000).

Thus, α_1 subunit-containing receptors mediated the sedative but not the anxiolytic action of benzodiazepines. This result provided a rationale for considering the α_1 receptor subtype as a selective target for the development of ligands with sedative-hypnotic activity (Table 42.2). Conversely, GABA_A receptor subtypes other than α_1 were expected to provide a target for developing tranquilizing agents that would lack sedative side effects and largely dependence liability. A new pharmacology was born (see next section).

α_1 GABA_A RECEPTORS LARGELY MEDIATE DEPENDENCE LIABILITY

The dependence liability of classical benzodiazepines is a side effect of medical concern. When wild-type mice were given the choice to consume a drinking solution with or without the benzodiazepine midazolam, a preference for midazolam developed over the course of several days. In mice containing benzodiazepine-insensitive α_1 receptors [$(\alpha_1$ H101R)], no preference for midazolam developed, pointing to α_1 receptors as the main contributor to dependence liability (Tan et al., 2010). On the cellular level, the preference behavior was attributed to a disinhibition of the reward system represented by dopamine neurons in the ventral tegmental area, activating the reward system. While dopamine neurons

TABLE 42.1. Cellular and subcellular localization of GABA_A receptor subtypes

MAIN SUBUNIT	PROPOSED SUBUNIT REPERTOIRE	BENZODIAZEPINE SITE PHARMACOLOGY	MAJOR SITES OF EXPRESSION	IDENTIFIED NEURONS	SUBCELLULAR LOCALIZATION
α1	α1β2γ2	Major subtype (60% of all GABA _A receptors). Mediates the sedative, amnestic and—to a large extent—the anticonvulsant action and dependence liability of benzodiazepine site agonists.	Cerebral cortex (layers I–VI), hippocampus, amygdala, olfactory bulb, thalamus, basal forebrain, globus pallidus, substantia nigra pars reticulata, inferior colliculus, cerebellum, brainstem	Mitral cells and short-axon cells (olfactory bulb), principal cells and selected interneurons in cerebral cortex and hippocampus, GABAergic neurons in pallidum and substantia nigra, thalamic relay neurons, Purkinje cells and granule cells	Synaptic (soma and dendrites) and extrasynaptic in all neurons with high expression
α2	α2β3γ2	Minor subtype (15–20%). Mediates anxiolytic action of benzodiazepine site agonists	Cerebral cortex (layers I–IV), hippocampal formation, amygdala, striatum, olfactory bulb, hypothalamus, superior colliculus, inferior olive, motor nuclei, spinal cord dorsal horn	Principal cells in hippocampal formation and amygdala, spiny stellate striatal neurons, olfactory bulb granule cells, motoneurons, dorsal root ganglion cells and intrinsic dorsal horn neurons	Mainly synaptic; perisomatic location and enriched in axon initial segment of cortical and hippocampal pyramidal cells
α3	α3β2,3γ2	Minor subtype (10–15%). Mediates anxiolytic action of benzodiazepine site agonist although only at high receptor occupancy.	Cerebral cortex (layers V–VI), amygdala, olfactory bulb, thalamic reticular and intralaminar nuclei, superior colliculus, brainstem, spinal cord, locus coeruleus, raphe, medial septum	Tufted cells (olfactory bulb), reticular thalamic neurons, cerebellar Golgi type II cells, serotonergic and catecholaminergic neurons, basal forebrain cholinergic neurons, principal cells in lateral and basolateral amygdala	Mainly synaptic, including some axon initial segments; extrasynaptic in principal cells of the amygdala and in inferior olivary neurons
α4	α4β2,3δ	Less than 5% of all receptors. Insensitive to classical benzodiazepines.	Dentate gyrus, thalamus	Dentate gyrus granule cells	Extrasynaptic
α5	α5β3γ2	Less than 5% of all receptors. Mediates the memory-enhancing effects of benzodiazepine site partial inverse agonists.	Highest in hippocampus, considerably lower in deep cortical layers, amygdala, olfactory bulb, hypothalamus, superior colliculus, superior olivary nucleus, spinal trigeminal nucleus, spinal cord	Pyramidal cells (hippocampus, cerebral cortex), granule cells and periglomerular cells (olfactory bulb), superior olivary neurons, spinal trigeminal neurons	Extrasynaptic in hippocampus, cerebral cortex, and olfactory bulb; synaptic and extrasynaptic in spinal trigeminal nucleus and superior olivary nucleus
α6	α6β2,3γ2; α6β2,3δ	Less than 5% of all receptors. Insensitive to classical benzodiazepines.	Cerebellum, dorsal cochlear nucleus	Granule cells (cerebellum)	Synaptic (cerebellar glomeruli) and extrasynaptic on granule cell dendrites and soma

(Adapted from Fritschy and Brünig, 2003, and Möhler et al., 2002.)

express α₃ GABA_A receptors, impinging interneurons themselves express α₁ receptors. It is their enhancement by midazolam that apparently provided the overriding input. The ensuing disinhibition of the dopamine neurons is associated with synaptic plasticity processes, which were proposed to underlie drug reinforcement (Tan et al., 2010). The view of α₁ receptors being the prime mediator of dependence liability is in line with pharmacological evidence. Ligands that spare α₁

receptors but act as partial agonists at α₂ and α₃ receptors, such as L-838417 or TPA023 (Table 42.2; see following), showed low or no dependence liability in tests of self-administration or place preference in rodents and nonhuman primates (Ator, 2005, 2010; Licata and Rowlett, 2008). Although the partial extent of efficacy of these agents may have contributed to these results, ligands sparing α₁ receptors can be expected to have a much reduced dependence liability compared with

TABLE 42.2. Pharmacology of benzodiazepine-sensitive GABA_A receptor subtypes*

DRUG	MAIN ACTIVITY	INTERACTION WITH RECOMBINANT GABA _A RECEPTORS
α₁GABA_A RECEPTORS MEDIATE SEDATION		
Zolpidem	Hypnotic	Preferential affinity for α ₁ subtype ¹
Zaleplone	Hypnotic	Preferential affinity for α ₁ subtype ¹
Zopiclone	Hypnotic	Preferential affinity for α ₁ subtype ¹
α₂,α₃GABA_A RECEPTORS MEDIATE ANXIOLYSIS		
L-838417	Anxiolytic and Antinociceptive	Comparable affinity at α ₁ , α ₂ , α ₃ , α ₅ subtype ² Partial agonist at α ₂ , α ₃ , α ₅ (not α ₁) subtype
TPA023 (MK0777)	Anxiolytic	Comparable affinity at α ₁ , α ₂ , α ₃ , α ₅ ; partial agonist at α ₂ , α ₃ subtypes; no efficacy at α ₁ , α ₅ subtypes ³
NS11394	Anxiolytic and Antinociceptive	Comparable affinity at α ₁ , α ₂ , α ₃ , α ₅ ; partial agonist at α ₂ , α ₃ subtypes; nearly full agonist at α ₅ subtype ⁴
TP003	Anxiolytic	Comparable affinity at α ₁ , α ₂ , α ₃ , α ₅ ; full agonist at α ₃ subtype; acts at high receptor occupancy ⁵
α₅GABA_A RECEPTORS: PARTIAL INVERSE AGONISTS ENHANCE MEMORY		
L-655 708	Memory enhancer	Partial inverse agonist with preferential affinity for α ₅ subtype ⁶
α ₅ IA	Memory enhancer	Partial inverse agonist with preferential efficacy at α ₅ subtype ⁷
RO493851	Memory enhancer	Partial inverse agonist with selective affinity and efficacy at α ₅ receptor subtype ⁸

classical benzodiazepines which fail to differentiate between GABA_A receptor subtypes.

α₂ GABA_A RECEPTORS MEDIATE ANXIOLYSIS

In mice containing benzodiazepine-insensitive α₂ GABA_A receptors (α₂H101R), diazepam failed to induce anxiolytic activity (measured in the elevated plus maze test and the light/dark choice test) while its sedative and anticonvulsant activity was fully retained (measured by locomotor activity, rotarod, antipentylenerazole) (Löw et al., 2000). The lack of anxiolytic activity of diazepam in (α₂H101R) mice was confirmed in a conditioned emotional response paradigm (CER) (Morris et al., 2006), in which a conditioning foot shock induces a higher level of stress than in the nonconditioned ethological tests used in the earlier study (Löw et al., 2000).

Thus, the anxiolytic-like action of diazepam is based on the enhancement of α₂GABA_A receptor function. Since this receptor population represents only about 15–20% of all GABA_A receptors, it appears to be strategically positioned in anxiety circuits. In cerebral cortex and hippocampus, the α₂ GABA_A receptors are largely expressed on pyramidal cells. In the perisomatic domain, these receptors mediate mainly the synaptic inhibitory input arising from CCK-containing basket cells. At the axon initial segment, they mediate the GABAergic input from Chandelier neurons, which exert an output control of the firing pattern of principal cells by being able to suppress action potential propagation (Fig. 42.1).

In the amygdala, α₂ GABA_A receptors are prominent throughout. Most conspicuously, the central nucleus (CEA), the output station of the amygdala, contains largely, if not exclusively, α₂ GABA_A receptors (Figs. 42.2 and 42.3) (Marowsky et al., 2004). Thus, α₂ receptors are in a strategic position to attenuate the output from the CEA to the brain areas, which execute the physiological and hormonal fear and anxiety responses. In addition, α₂ GABA_A receptors mediate inhibitory signals in the lateral and basolateral amygdala, areas involved in fear acquisition. The basolateral division also contains α₁ receptors. α₃ GABA_A receptors are a minor subtype throughout. In humans, the pattern of α₁, α₂, and α₃ receptor subtype expression in the amygdala closely corresponded to that in the mouse (Fig. 42.3). The functional significance of the receptor subtypes for the amygdala microcircuits is described later.

Besides their location in different brain areas, α₂ and α₃ GABA_A receptors are also found in spinal cord, being located on primary spinal cord afferents and intrinsic spinal neurons. Using the point-mutated mice described earlier, the ability of diazepam to suppress pathological pain was attributed to these receptor subtypes (Knabl et al., 2008). Indeed, using the compound, L-838417, which acts as partial agonist at α₂ and α₃ receptors (Table 42.2), pain behavior was suppressed in rodent models of inflammatory and neuropathic pain with an efficacy comparable to that of morphine. Furthermore, in contrast to morphine, L-838417, given subchronically, they failed to develop tolerance (Knabl et al., 2008). Thus, new anxiolytic agents acting on α_{2,3} receptor subtypes may, at least partly, have an added antinociceptive potential (Zeilhofer et al., 2009) (Table 42.2).

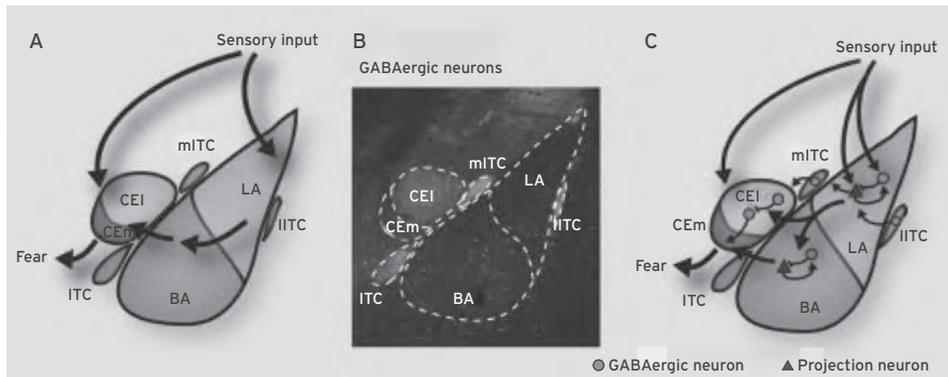

Figure 42.2 General organization of amygdala circuitry and GABAergic neurons. (A) Scheme of the basic organization and overall flow of information within the amygdaloid complex. LA, lateral amygdala; BA, basal amygdala; CEI, lateral subdivision of the central amygdala; CEm, medial subdivision of the central amygdala (CEA); mITC, medial intercalated cell cluster; IITC, lateral intercalated cell cluster. (B) Coronal brain slice stained for the 67 kD isoform of the GABA synthesizing enzyme glutamic acid decarboxylase (GAD67) illustrating the distribution of GABAergic neurons across the amygdaloid complex. (C) Simplified scheme of the organization and function of inhibitory interneurons in amygdaloid nuclei. In the LA and BA, local interneurons are part of feedforward and feedback circuits and control projection neuron output. The IITCs and mITCs relay feedforward inhibition, which may also participate in controlling CEI output. (Images from Ehrlich et al., 2009 used with permission from Elsevier.)

α_3 GABA-A RECEPTORS: A BACKUP SYSTEM FOR ANXIOLYSIS

In keeping with the view that the anxiolytic activity of diazepam is mediated via α_2 GABA_A receptors, the anxiolytic response of diazepam remained unaltered when the α_3 receptor was silenced in mice by a point mutation (α_3 H126R) (measured in elevated plus maze and light/dark choice test), suggesting that alpha3 receptors do not mediate anxiolytic activity. As expected, the sedative, motor-impairing, and anticonvulsant properties of diazepam were likewise unaltered in this α_3 mutant (L \ddot{o} w et al., 2000). Nevertheless, there is significant

evidence that the α_3 GABA_A receptor subtype contributes to anxiolytic activity. In mice with a benzodiazepine-insensitive α_2 receptor [α_2 (H101R) mice], L-838417, a partial agonist acting at the benzodiazepine site of α_2 , α_3 and α_5 receptors, showed anxiolytic activity at a somewhat elevated receptor occupancy (tested in elevated plus maze, fear potentiated startle and conditioned emotional response) (McKernan et al., 2000; Morris et al., 2006). These findings pointed to a contribution of receptors other than α_2 receptors to anxiolysis. Indeed, TP003, a full agonist with selective efficacy at α_3 GABA_A receptors displayed anxiolytic activity as measured in an ethological test (elevated

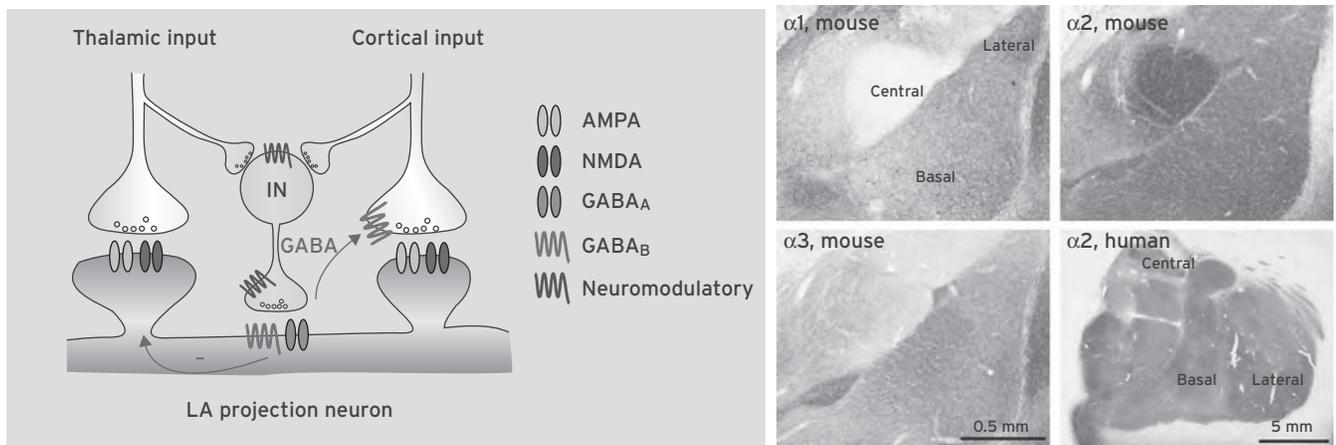

Figure 42.3 Inhibitory gating of long-term potentiation (LTP) in the lateral amygdala in fear acquisition. Left: Pyramidal projection neurons in the lateral amygdala (LA, gray) receive converging thalamic and cortical sensory afferents. LTP at thalamic and cortical sensory synapses, induced by fear conditioning, is tightly controlled by GABA released from feedforward interneurons (medium gray). At thalamic afferents, this control is predominantly postsynaptic via GABA_A receptors. At cortical afferents, this control is presynaptic via GABA_B receptors. The GABA interneurons are targets of neuromodulators that modify their output activity and thereby gate the induction of LTP by transiently altering the level of pre- and postsynaptic inhibitory drive. By depressing GABA feedforward inhibition, dopamine and noradrenaline enhance LTP, while 5HT reduces LTP (figure from Ehrlich et al., 2009). Right: Immunohistochemical distribution of GABA_A receptor subtypes in the amygdala. In the mouse, the α_2 -subunit staining is prominent throughout, in particular in the central nucleus where no α_1 subunit immunoreactivity is detectable. Both subunits produce a diffuse labeling of neuropil in the lateral and basolateral nucleus. The α_3 -subunit is detected in the basolateral nucleus and, to a lesser extent, in the lateral and central nuclei (Marowsky et al., 2004, 2012). Similarly, in human amygdala, α_2 -subunit staining is prominent throughout and most prevalent in the central and basal nucleus. α_1 -subunit staining was prominent only in the lateral nucleus. Minimal staining for α_3 -subunits was apparent throughout the amygdala. [Left: Figure from Ehrlich et al., 2009. Right: Data and image of human amygdala courtesy of J. Sung and H. Waldvogel, Centre of Brain Research, University of Auckland, NZ.]

plus maze in rats) and in a conditioned test paradigm (conditioned emotional response in squirrel monkeys) pointing to α_3 GABA_A receptors as a second target for anxiolysis besides α_2 receptors (Dias et al., 2005).

The two anxiolytic drug targets differ, however, in their systems response sensitivity. Classical benzodiazepines (e.g., diazepam or chlordiazepoxide) show anxiolytic activity, mediated via α_2 receptors, at a low dose when an overall receptor occupancy of 20–25% is reached (Dias et al., 2005; Facklam et al., 1992). In contrast, the level of receptor occupancy required for the minimal effective dose of TP003 (elevated plus maze test) acting at α_3 receptors was 75%, suggesting that three quarters of all α_3 receptors have to be enhanced to reach an anxiolytic response (Dias et al., 2005). The alpha3 receptors are therefore considered to act as a backup system for anxiolytic activity at high receptor occupancy. Presently, most newly developed anxiolytic compounds such as L-838417, TPA023, or NS 11394 interact with both α_2 and α_3 receptors (see next section and Table 42.2). Their primary anxiolytic effect is therefore mediated by α_2 GABA_A receptors while α_3 receptors are recruited in addition when a high receptor occupancy is reached.

α_3 GABA_A receptors are a minor receptor subtype in the brain and are mainly found on catecholaminergic neurons of the brainstem (dopamine, noradrenaline) and basal forebrain cholinergic neurons, which are involved in communicating emotion and vigilance. In the amygdala, α_3 receptors are of minor abundance and, being located extrasynaptically, mediate tonic inhibition of principal cells in the lateral and basolateral domain (Fig. 42.3; Table 42.1) (Marowsky et al., 2012).

α_5 GABA_A RECEPTORS REGULATE HIPPOCAMPUS-DEPENDENT (FEAR) MEMORY

The α_5 GABA_A receptor subtype ($\alpha_5\beta_3\gamma_2$) shows a very restricted expression in the brain with highest density in hippocampus and considerably lower in layer 5 cerebral cortex (Fig. 42.4; Table 42.1). In both regions the receptors are exclusively located extrasynaptically on pyramidal cell dendrites mediating tonic inhibition (Brickley and Mody, 2012). Apparently, the presence of the α_5 subunit seems to override the ability of the γ_2 subunit to promote synaptic localization. Morphologically, being

located at the base of the dendritic spines and the adjacent dendritic shaft of hippocampal pyramidal cells, these receptors represent the first inhibitory counterbalance to the incoming excitatory input transmitted through N-methyl-D-aspartate (NMDA) receptors at the dendritic spine synapses (Fig. 42.4).

Synaptic plasticity and learning are often enhanced by a reduction of GABAergic inhibition. Indeed, transgenic mice with a partial knockdown of α_5 receptors showed enhanced performance in the hippocampus-dependent tasks of trace fear conditioning and appetitive conditioning (Crestani et al., 2002; Yee et al., 2004). Mice with a complete deficit of α_5 receptors (α_5 knockout) likewise showed an improved cognitive performance as evident in spatial learning (water maze) concomitant with an enhancement of neural oscillatory synchrony in hippocampal slices (Collinson et al., 2002; Glykys and Mody, 2007). In both α_5 mutant mouse lines, the enhanced behavioral performance was highly selective in that hippocampus-independent learning (delay conditioning, two-way avoidance) remained unaltered compared with wild type. Thus, the α_5 GABA_A receptors in hippocampal pyramidal cells are control elements of the temporal and spatial associative memory. This is the more noteworthy as it is the tonic inhibition that has taken on a critical role in controlling learning and memory performance (Brickley and Mody, 2012). In contrast, the phasic inhibition of hippocampal pyramidal cells is largely mediated via α_2 and α_3 GABA_A receptors. Correspondingly, classical benzodiazepine responses such as sedation or anxiolytic activity are not linked to the α_5 receptor function (for review, see Möhler, 2007). The role of α_5 GABA_A receptors in cognition prompted the development of drugs that selectively target α_5 GABA_A (see later section).

AMYGDALA MICROCIRCUITS FOR ANXIOLYSIS AND THE VOCABULARY OF GABA_A RECEPTOR SUBTYPES

Among the overall circuitry of anxiety and fear, several microcircuits have been identified in which GABA neurons play a key part in the acquisition, storage, and extinction of fear, in particular in the amygdala and cerebral cortex (Fig. 42.2). They provide the first blueprint for the neuronal circuits through

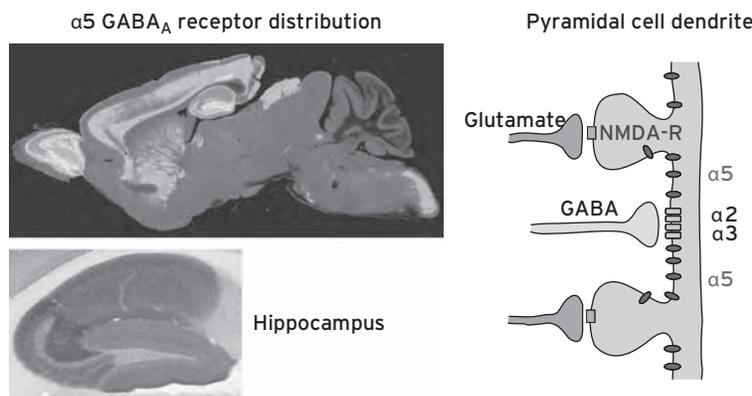

Figure 42.4 Left: Immunohistochemical distribution of the α_5 -subunit GABA_A receptor in parasagittal sections of adult mice with the enlargement of the hippocampal formation showing its prominent dendritic localization (Crestani et al., 2002). Right: Schematic distribution of GABA_A receptor subtypes at pyramidal cell dendrites. In balancing the excitatory input, phasic inhibition is mediated via α_2 and α_3 GABA_A receptors, while α_5 GABA_A receptors, located at the base of dendritic spines and the adjacent dendritic shaft, mediate tonic inhibition. (See color insert.)

which α_2 and α_3 GABA_A receptors mediate anxiolytic drug actions.

LATERAL AMYGDALA: LOCAL GABAERGIC CONTROL OF EXPERIENCE-DEPENDENT PLASTICITY

The amygdala is the site for formation and storage of fear memories, frequently investigated in paradigms of fear conditioning, a form of associative learning acquired by temporal coincidence of a neutral conditioned stimulus (CS, e.g., tone) with an unconditioned aversive stimulus (US, foot shock). The lateral amygdala (LA) is responsible for the linking of the conditioned and unconditioned stimulus and thus for the formation of memory of this experience by which the CS gains access to an emotional response circuit. The combination of CS and US requires the formation of long-term potentiation (LTP) of sensory thalamic input onto the neurons in the lateral amygdala (LA), thereby increasing the activity of the LA projection neurons. The LA neurons drive the fear response by projecting to the basolateral (BLA) and central amygdala (CEA) (Fig. 42.2). The LTP process in the LA is under strong GABAergic feedforward control (Fig. 42.3). For instance, infusion of a GABA_A receptor agonist (muscimol) can block fear acquisition. Similarly, intra-amygdala application of a benzodiazepine, restricted largely to the LA and basolateral amygdala (BLA), is sufficient to induce anxiolysis.

Electrophysiologically, monosynaptic IPSCs recorded from pyramidal-shaped principal cells in the lateral and basolateral amygdala (LA/BLA) of the mouse were carried by α_2 subunit-containing GABA_A receptors and to a smaller amount by α_1 subunit-containing receptors (Marowsky et al., 2004), suggesting that the synaptic feedforward inhibition may be largely mediated by α_2 GABA_A receptor and provide a major target site for anxiolytic drug action. The α_3 GABA_A receptors are expressed throughout LA and BLA, preferentially at extrasynaptic sites mediating tonic inhibition of principal cells (Marowsky et al., 2012). Thus, the LA/BLA is a prominent target for drug-induced anxiolysis based on the enhancement of α_2 and α_3 GABA_A receptor function. Thus, by reducing the excitability of LA projection neurons, benzodiazepine-type drugs are able to limit the fear-inducing impact of CS (Fig. 42.3) (for review, see Ehrlich et al., 2009).

The induction of LTP in the lateral amygdala is constrained not only by activation of GABA_A receptors, but also metabotropic GABA_B receptors (Fig. 42.3). The presynaptic GABA_B receptors, which are presumably activated via synaptic GABA spillover, attenuate the release of excitatory neurotransmitter from cortical and thalamic afferents by limiting the entry of Ca²⁺. In the presence of a GABA_B receptor antagonist, the induction of LTP was facilitated at both cortical and thalamic afferent synapses (Ehrlich et al., 2009). Conversely, anxiolytic activity has been described for GABA_B receptor agonists, although clinical evidence is still lacking.

Presynaptic modulation of GABA neurons by catecholamines in fear acquisition

Under stress and in emotionally charged conditions, dopamine, released from the ventral tegmental area pathway,

potentiates amygdala function and enhances aversive conditioning. This is achieved by presynaptic modulation of GABA release in two areas. In the lateral amygdala, dopamine, via presynaptic dopamine D2 receptors, suppresses GABAergic feedforward inhibition and thereby enhances LTP induction by conditioned fear (Fig. 42.3). Various other modulators likewise affect the induction of LTP by targeting the GABA neurons. At the thalamo-LA synapses, besides dopamine, noradrenaline and μ -opioids reduce feedforward GABA inhibition and enhance LTP (Tully et al., 2007). Conversely, other modulators such as 5-hydroxytryptamine (5HT) or gastrin-related peptide enhance GABA inhibition and constrain the induction of LTP (Ehrlich et al., 2009).

A second target for dopamine is the intercalated cell cluster (ITC), a network of paracapsular GABAergic cells that surround the basolateral complex of the amygdala (Fig. 42.2). It provides GABAergic feedforward inhibition into the basolateral and the central amygdala. Dopamine (via D1 receptors) hyperpolarizes these GABA neurons and substantially suppresses their excitability, resulting in disinhibition of the basolateral and central nucleus with an increase in fear responding. Suppression of the paracapsular inhibitory system by dopamine provides a compelling neuronal mechanism for the increased affective behavior observed during stress or other hyperdopaminergic states (Marowsky et al., 2005). The ITC neurons are innervated by cortical fibers and can thus mediate the cortical feed-forward control of the BLA and the CEA (Fig. 42.2). By disinhibiting the BLA and CEA, dopamine promotes amygdala-related behavior and reduces cortical control. Indeed, focal or systemic administration of the D1 receptor antagonist SCH 23390 results in anxiolysis and blocks acquisition and expression of fear.

CENTRAL AMYGDALA: GABA CONTROL OF FEAR EFFECTOR NEURONS

The central nucleus of the amygdala (CEA) is well known as the major output station by which the amygdala determines the expression of fear-related behavior that includes immobility (freezing) and activation of autonomic and neuroendocrine responses (LeDoux, 2000). A microcircuit within the CEA has been identified to be important for both the acquisition as well as the expression of fear (Haubensak et al., 2010). The output neurons, located in the medial subdivision of CEA (CEM) are normally under tight inhibitory control from a population of spontaneously active GABAergic neurons located in the lateral subdivision (CEL) (Fig. 42.2). Diminishing this inhibitory tone through aversive stimuli leads to a disinhibition of the CEM output neurons, which trigger the execution of fear and anxiety responses.

In the CEA, GABAergic inhibition operates largely if not exclusively through α_2 GABA_A receptors, the receptor subtype known to mediate benzodiazepine-induced anxiolysis (Löw et al., 2000). Electrophysiologically, diazepam-induced changes in synaptic currents in mouse CEA were found to be exclusively carried by α_2 receptors without a significant contribution from α_1 or α_3 receptors (Marowsky et al., 2004). Immunohistochemically, α_2 receptors, being by far the predominant receptor subtype throughout most of the amygdala

(Fig. 42.3), are almost exclusively expressed in the CEA, with no α_1 receptors being detectable and only a modest amount of α_3 receptors in this nucleus (Marowsky et al., 2004). This pattern of receptor distribution in the mouse was largely confirmed in post-mortem human amygdala. The α_2 receptor is again predominant throughout the amygdala. The CEA and the basal nucleus contain almost exclusively α_2 receptors. The lateral nucleus contains, in addition, α_1 GABA_A receptors. The α_3 receptors are a minor subtype (personal communication, J. Sung and H. Waldvogel, University of Auckland, NZ) (Fig. 42.3). Thus, dampening the output of the CEA via α_2 GABA_A receptors seems to be a major anxiolytic microcircuit, which illustrates the relevance of this particular GABA_A receptor subtype.

Furthermore, both CEL and CEM express high levels of neuropeptides that modulate anxiety and stress-related behavior (Huber et al., 2005). For instance, oxytocin (OT), besides its hormonal functions, exerts strong anxiolytic activity (e.g., in social anxiety), and the CEA has recently been identified as target for its ability to suppress fear. Axonal projections from OT neurons in the hypothalamus reach the CEL. Presumably, by releasing glutamate in addition to OT, a subpopulation of GABA neurons in CEL activates and thereby enhances the inhibition of CEM output neurons (Tovote and Lüthi, 2012). Thus, the anxiolytic activity of OT is based on enhancing the GABAergic inhibition to attenuate the CEA output neurons, an effect mediated by α_2 receptors. There is also an opposing interaction pointing to a convergence of the anxiolytic circuitries of OT and benzodiazepines. A subpopulation of CEL neurons express presynaptic CRF receptors type 1, which respond to the stress hormone CRF (corticotropin releasing factor), suggesting that GABA circuits within the CEA may be a point of convergence of stress and stress-coping (anxiolytic) systems (Ehrlich et al., 2009). In summary, diminishing the activity of CEM output neurons (via α_2 GABA_A receptors) attenuates fear and anxiety responses while increasing CEM output leads to stronger fear responses.

FEAR EXTINCTION: SWITCHING FEAR OFF BY A DISTINCT NEURAL CIRCUIT

Understanding how learned fears are diminished is a valuable contribution to clinical cognitive therapy. Fear extinction is an active learning process eventually leading to the formation of a consolidated extinction memory (Herry et al., 2010). Extinction of conditioned fear is achieved through repeated presentation of the CS in the absence of an aversive unconditioned stimulus rendering the CS as non-aversive. Not only is the amygdala important for the acquisition of fear (see preceding), but also as a site of extinction-associated plasticity. Activating GABAergic neurons in the amygdala is thought to underly the process of extinction. During extinction, cortical neurons, in conveying the absence of the aversive unconditioned stimulus, are thought to suppress the amygdala output. This is largely achieved by cortical activation of the GABA neurons of the intercalated cell cluster (ITC) which surrounds the amygdala and innervates the basolateral and central nuclei (Fig. 42.2). They act as a switching circuit that can block the fear-induced LTP and guide the change in behavior (Herry et al., 2010). Molecularly, the expression of certain GABA_A receptor subunit genes (α_2 and β_2) was upregulated within hours following

extinction training as shown on the mRNA level (Heldt and Ressler, 2007). Since in both the LA and the CEA, α_2 GABA_A receptors play a major role, it might be conceivable that anxiolytics acting on α_2 receptors (sparing sedation via α_1 receptors) may also facilitate fear extinction.

Fear and fear extinction have been recognized in behaving mice to be encoded by distinct populations of basal amygdala neurons termed fear neurons and extinction neurons. After conditioning, fear neurons exhibited increased activity upon CS exposure. In contrast, extinction neurons developed CS responses only during extinction training. Indeed, a decrease in the firing activity of fear neurons and a concomitant increase in activity of extinction neurons preceded the behavioral shift from the fear to the no-fear response upon CS presentation (Herry et al., 2008, 2010). The activation of extinction neurons remained stable for at least one week. However, changing the context resulted in the immediate recovery of the previously conditioned fear response, a process called renewal. The bi-directional switch in behavior between fear extinction and fear renewal is likely to be encoded by discrete neural circuits. They comprise a distributed network with differential connections between the BLA, the mPFC, and hippocampus, the latter being relevant for conveying context information to be associated with the unconditioned stimulus in the amygdala (Ehrlich et al., 2009; see also Cain, Sullivan, and LeDoux, this volume, Chapter 41).

SHIFT FROM PASSIVE FEAR TO ACTIVE COPING

Fear-arousing stimuli elicit a constellation of fear responses through the amygdala, which acts as an interface that triggers freezing, autonomic, and endocrine responses. However, the pathways that initiate this fear behavior can be redirected. Fully fear-conditioned rats were given the option of moving to another place to avoid the conditioned stimulus. The learning of this escape response (i.e., changing the context prevents fear stimulus) engages alternative pathways in the lateral amygdala that circumvent the CEA, as shown by lesion studies. Passive fear responding is replaced by an active coping strategy (Amorapanth et al., 2000; LeDoux and Gorman, 2001). Recently, first insights into the cellular switch between freezing and active coping were made. The inhibition of a particular type of GABA interneuron (type I neuron) in the lateral subdivision of the CEA was shown to be sufficient (via disinhibition of another GABA neuron) to suppress freezing and engage active responses (Gozzi et al., 2010). These findings identify neural circuit that biases fear responses toward active coping strategies. Coping inherently entails a physiologically anxiolytic response by threat avoidance learning.

CORTICAL MICROCIRCUITS FOR ANXIOLYSIS

ANTERIOR CINGULATE CORTEX AND THE RESOLUTION OF CONFLICT

The choice between different options in goal-directed behavior requires a value arbitration. In a conflict situation, upcoming decisions are evaluated as being “good” or “bad” relative to one’s

expectation. In healthy individuals, the pregenual anterior cingulate cortex (pACC) is involved in cost–benefit evaluations. It communicates the outcome of the evaluation to other brain areas and thereby regulates the emotional response triggered by a conflict situation. The pACC has been implicated in human anxiety disorders and depression (Ressler and Mayberg, 2007).

Generalized anxiety disorder is characterized by continuous rumination and worrying. This anxiety behavior relates to risk assessment of a potential threat and crucially involves uncertainty as to the expectancy of the threat. Anxious individuals show a biased evaluation of a situation in that they pay increased attention to threat-related cues and tend to interpret ambiguous stimuli in a threatening manner. These cognitive biases are thought to underlie avoidance behavior (e.g., avoidance of social contact) as a cardinal symptom of anxiety disorders as well as depression. The implication of the pACC was recently tested in a macaque version of an approach–avoidance decision task, which is also used in humans (Amemori and Graybiel, 2012). Visual cues indicated the likelihood of positive outcome (delivery of food) or negative outcome (airpuff) at the end of the trial. The animals varied their decision to approach (reward is worth it) or to avoid (reward is not worth it) depending on the relative sizes of food rewards and airpuffs indicated by the cues at the beginning of the task. By electrical recording, the pACC was found to have an organization of neurons that represented motivationally positive (P) or negative (N) subjective value, respectively. The cost–benefit boundary was set by balanced activity of N-type and P-type neuron populations, flexibly changing depending on the average offers in each task. In one pACC subzone, neurons with negative coding were more numerous, and electrical microstimulation of this subzone, but not elsewhere in the pACC, strongly increased avoidance decisions. Thus, overactivated neurons representing negative motivational values lead to a pessimistic evaluation of future outcome and increased avoidance behavior. In subsequent experiments, a bias toward avoidance persisted even in the absence of the microstimulation. These findings raise the possibility that pACC stimulation could bring about a tonic, persistent state affecting the relative evaluation of cost and benefit.

The uncertainty of a conflict situation frequently induces anxiety. In the approach–avoidance task described earlier, anxiolytic treatment of the animals with diazepam (0.25 mg/kg intramuscularly) fully blocked the negative biasing of the cost–benefit evaluation and the stimulus-induced negative decision making (Amemori and Graybiel, 2012). This result is important as it defines a cellular substrate for the ability of diazepam to reduce negative motivation and reverse a negative biasing of behavior. The diazepam-induced, dampening the stimulus-induced overactivity of N-neurons in the pACC, may possibly be mediated via α_2 GABA_A receptors. In a conflict situation in mice (light/dark test), the anxiolytic action of diazepam was found to be exclusively mediated via α_2 GABA_A receptors (Löw et al., 2000). These results on value arbitration are of major interest not only for anxiety disorders but also for depression, where negative biases in cost–benefit evaluations are part of the pathophysiology. Besides providing a microcircuit for anxiolysis, the results also add support to the GABA hypothesis of major depression where the pACC plays

a critical role (Lüscher et al., 2010; Möhler, 2012; Ressler and Mayberg, 2007).

FEAR LEARNING IN THE AUDITORY CORTEX: A DISINHIBITORY MICROCIRCUIT

Fear memory acquisition (tone/shock association) depends on the amygdala but, depending on the stimulus complexity of the tone, can also engage the auditory cortex. It receives thalamocortical feedforward information and may act as a relay for tone information to down-stream structures such as the amygdala. Fear conditioning causes long-lasting plasticity of CS responses in auditory cortex, which critically involves GABA interneurons (Letzkus et al., 2011). After experiencing the CS, acetylcholine is rapidly released from cholinergic basal forebrain afferents, which activate GABA interneurons in layer 1 (L1) of auditory cortex, which, in turn, inhibit fast-spiking parvalbumin-positive (PV) interneurons in L2/3 of auditory cortex. These PV basket cells in turn provide strong perisomatic inhibition to local pyramidal cells in the L2/3 layer. When stimulation by tone and shock was combined, the activity of pyramidal cells was strikingly enhanced (visualized by Ca-imaging). Disinhibition of PV interneurons by foot shock probably gates the induction of activity-dependent plasticity in the auditory cortex. The convergence of stimuli and the concomitant auditory cortex disinhibition are essential for fear learning (Letzkus et al., 2011). The GABA interneurons in L1 are responsive to dopamine and 5HT, indicating that modulatory systems can feed into the cortical microcircuit.

Although an anxiolytic drug was not tested in this paradigm, the disinhibition of the microcircuit in auditory cortex offers a conceptual role for drugs acting on α_2 GABA_A receptors. Being located perisomatically and at the axon initial segment, a drug-induced enhancement of α_2 GABA_A receptors would permit an attenuation of the overactivity of the pyramidal cells without causing sedation via α_1 receptors.

NOVEL DRUGS ACTING ON GABA_A RECEPTOR SUBTYPES

NOVEL ANXIOLYTICS ACTING ON $\alpha_{2,3}$ GABA_A RECEPTOR SUBTYPES

Based on the functional differentiation of GABA_A receptor subtypes *in vivo* by genetic means, the anxiolytic activity of benzodiazepines was attributed to circuits expressing α_2 and α_3 receptors, while sedation was attributed to circuits expressing α_1 receptors (see previous section). These findings gave rise to a new pharmacology based on ligands targeted to the benzodiazepine site of the respective GABA_A receptor subtype. A striking confirmation of the hypothesis that sedation was mediated via α_1 receptors was provided by the sedative hypnotic drugs Zolpidem, Zaleplone, or Zopiclone (Z hypnotics). They invariably show a preferential affinity for α_1 GABA_A receptors (Table 42.2).

Ligands acting at α_2 and/or α_3 GABA_A receptors, sparing α_1 receptors, were expected to act as anxiolytics without inducing sedation. The search for novel nonsedative anxiolytics of this type is ongoing with major challenges for medicinal chemistry. So far, a differentiation of the respective

receptor subtypes by affinity (i.e., high affinity for α_2 and/or α_3 receptors versus α_1 receptors) has not yet been achieved. Nevertheless, new ligands have been developed that differentiate between α_1 and α_2 and/or α_3 GABA_A receptors by efficacy although not by ligand affinity (for review, see Möhler, 2011, 2012; Table 42.2). For instance TP003, which displays selective efficacy at α_3 receptors, showed anxiolytic activity, albeit only at high receptor occupancy (Table 42.2) (Dias et al., 2005; see previous section). Major attention was, rather, focused on compounds that act as partial agonists at α_2 and α_3 receptors, sparing α_1 receptors such as L-838417, TPA023, and NS11394. Their anxiolytic activity is mediated primarily via α_2 receptors with α_3 receptors as backup at higher receptor occupancy (see previous section). The best characterized compound is TPA023, for which anxiolytic activity without sedation was firmly demonstrated in a multitude of rodent and monkey models (Atack et al., 2006b; Atack, 2009; Table 42.2). In addition, this compound showed little or no dependence liability, largely by failing to enhance α_1 receptors and possibly also by its partial efficacy (Ator, 2005; Ator et al., 2010; Licata and Rowlett, 2008; see previous section).

Clinical proof of concept

Among the compounds mentioned, TPA023 (MK 0777) reached the stage of clinical development as an anxiolytic drug. In volunteers, TPA023 (0.5 and 1.5 mg) did not affect alertness, postural stability, and memory in contrast to lorazepam (2 mg), which is in line with the absence of overt sedation for TPA023. In patients with generalized anxiety disorder, the anxiolytic activity of TPA023 was validated in proof-of-concept studies (Atack, 2009). TPA023, given over four weeks, was effective with a significantly superior HAM-A scale reduction compared with placebo. TPA023 had a time of onset within the first week of treatment. Unfortunately, due to the formation of cataracts in rodents following long-term treatment, the clinical development of TPA023 was discontinued. Nevertheless, the clinical proof of concept, established for TPA023, is expected to encourage further efforts in developing α_2/α_3 GABA_A receptor modulators as anxiolytic drugs. They are expected to be largely devoid of the side effects of classical benzodiazepines such as sedation and dependence liability.

ANXIOLYTIC ACTION VIA NEUROSTEROIDS

Neuroactive endogenous steroids (neurosteroids) such as the progesterone metabolite allopregnanolone or the corticosterone metabolite $3\alpha,5\alpha$ -THDOC, synthesized in both glia and neurons, are able to directly enhance GABA_A receptor function through a neurosteroid binding site present on practically all GABA_A receptors. Neurosteroids, consequently, have anxiolytic, sedative-hypnotic and anticonvulsant properties (Belelli and Lambert, 2005). In patients with panic disorder, neurosteroids were decreased in blood plasma. Stimulating the neurosteroid synthesis was therefore expected to be a novel anti-anxiety treatment strategy. The rate limiting step of neurosteroid synthesis is the transport of cholesterol through the outer mitochondrial membrane, mediated by the translocator protein (18 kD) (TSPO, formerly termed peripheral or mitochondrial benzodiazepine receptor). When a TSPO agonist

(XBD173) was administered to human volunteers undergoing an anxiety challenge (cholecystokinin-tetrapeptide i.v.), panic anxiety behavior was suppressed. The anxiolytic effect was indeed mediated by the induction of neurosteroidogenesis since, in rodents, the anxiolytic effect of XBD173 was blocked by finasteride, a 5α -reductase inhibitor of neurosteroid synthesis (Rupprecht et al., 2009). Thus, TSPO as well as the neurosteroid site of GABA_A receptors directly are potential targets for novel types of anxiolytics.

DRUGS ENHANCING MEMORY BY REDUCING α_5 GABA_A RECEPTOR FUNCTION

The ability to learn and remember is thought to be encoded at the synaptic level and involves the ability of synapses to undergo long-term changes in synaptic strength. Tonic GABAergic inhibition appears to contribute to this process. Hippocampus-dependent learning and memory was improved when tonic inhibition was reduced based on a partial or full deficit of α_5 GABA_A receptors in transgenic mice (see previous section). This finding pointed to α_5 GABA_A receptors as a potential pharmacological target for the enhancement of cognitive performance (Fig. 42.4). Ligands with only partial efficacy (partial inverse agonists) were considered to be devoid of potential side effects such as proconvulsant activity.

One of the first drugs to be developed was L-655708, a partial inverse agonist with preferential affinity for α_5 GABA_A receptors (Table 42.2). It reduced tonic inhibition, facilitated LTP, induced γ -oscillations in hippocampal CA3, and enhanced performance in the Morris maze without being proconvulsant (Table 42.2). However, its anxiogenic activity, presumably due to its inverse agonistic activity at GABA_A receptors other than α_5 receptors, prevented its use in humans.

Another partial inverse agonist, α_5 IA, displayed preferential efficacy (but not affinity) for α_5 GABA_A receptors. It lacked anxiogenic activity and enhanced spatial memory (encoding and recall) in the Morris water maze (Table 42.2) (Atack, 2010). Preclinical renal toxicity prevented further development of this compound.

RO4938581 was the first partial inverse agonist with high selectivity in both affinity and efficacy for α_5 GABA_A receptors (Table 42.2) (Ballard et al., 2009). Behaviorally, RO4938581 fully rescued a scopolamine- or diazepam-induced spatial working memory deficit (delayed match to position task or Morris water maze paradigm) in rodents. Furthermore, in monkeys, the performance in an object retrieval task, which is thought to require executive functions, was enhanced by the drug even beyond the physiological level of responding. Thus, such agents hold the promise of novel treatments for various disorders afflicted with learning and memory deficits. They include Down syndrome, Alzheimer's disease, and other neurological and psychiatric disorders.

Indeed, in Ts65Dn mice, a well-characterized murine Down syndrome model, α_5 IA improved cognitive performance to the level of euploid controls, as demonstrated in associative and declarative memory tasks. The deficit in spatial learning (Morris water maze) in the Ts65Dn mice was likewise normalized by α_5 IA as was the deficit in object recognition (Braudeau et al., 2011). Based on such results, an analogue of RO4938581

was entered into clinical trials with the aim of counteracting the cognitive disabilities of subjects with Down syndrome (<http://www.clinicaltrials.gov>; drug RG1662; last searched April 7, 2012). Since cognitive deficits are apparent across several disease categories, this type of drug may possibly find multiple indications in psychiatric disorders (Möhler, 2012a).

GABA_A RECEPTOR DRUGS FOR DEPRESSION?

In line with the comorbidity of anxiety disorders and depression, a marked deficit in GABA transmission was not only found in anxiety disorders but also in patients with major depression. It includes a deficit of GABA_A receptors in parahippocampal and in temporal cortex areas, a reduction of GABA neurons in the orbitofrontal cortex, and a reduced level of GABA in occipital brain and cerebrospinal fluid (for review, see Möhler, 2011). In transgenic mice, a partial deficit of GABA_A receptors, which was manifest mainly in hippocampus and cerebral cortex, showed enhanced behavioral inhibitory depression-like responses in tests sensitive to antidepressant drug treatment (novelty-suppressed feeding, forced swim test, tail suppression, sucrose consumption test) concomitant with a deficit in adult hippocampal neurogenesis and a hyperactivity of the HPA (hypothalamic-pituitary-adrenal) axis (Lüscher et al., 2011; Shen et al., 2010). Importantly, the behavioral alterations induced by the partial deficit of GABA_A receptors were reversed by treatment with the antidepressant imipramine, pointing to a close functional link between the GABA- and the monoaminergic system (Lüscher et al., 2011). A partial α_2 GABA_A receptor deficit was recently proposed to contribute to a depression-like phenotype (Vollenweider et al., 2011). Thus, a deficit in the GABA system seems to be a common denominator of both anxiety disorders and depression-like behavior, and the GABA system may therefore offer new therapeutic opportunities for depression. Classical benzodiazepines fail in this respect due to sedation and abuse liability. However, largely lacking these side effects, modulators of α_2, α_3 GABA_A receptors such as TPA023 offer new opportunities to achieve clinically relevant antidepressant activity with the expectation of a rapid onset of action based on alleviating the GABAergic deficits. A major impetus comes from the ability of GABAergic drugs to reverse negative motivation and pessimistic biases by influencing the cost–benefit arbitration in pACC (Amemori and Graybiel, 2012; see previous section), a brain area that is strongly implicated in anxiety disorders and major depression (Ressler and Mayberg, 2007) (for review, see Lüscher et al., 2010, Möhler, 2012b).

43 | PREFRONTAL CORTEX REGULATION OF EMOTION AND ANXIETY

BRONWYN M. GRAHAM AND MOHAMMED R. MILAD

Emotion regulation encompasses the ability to initiate fight/flight responses to actual threat in the environment. It also encompasses the ability to appropriately inhibit defensive responses when no longer faced with potentially threatening stimuli in order to successfully adapt to and thrive in one's environment—to forage, to seek a mate, and so forth. The adaptive significance of emotion regulation is highlighted by the consequences of instances in which such ability fails. A prime example is anxiety disorders, which affect roughly 30% of the population. People with anxiety disorders exhibit pathological avoidance of perceived threatening situations and cues due to unrealistic beliefs about the probability and cost of negative outcomes associated with such stimuli. Alternatively, they may endure situations with significant distress and typically with the aid of safety behaviors, which serve to maintain irrational beliefs and diminish the person's sense of self-efficacy. At the opposite end of the scale, failures in emotion regulation can also lead to impulsiveness and risky decision making, as is often the case in childhood and adolescent behavioral disorders. Rather than experience too much fear, as observed in anxiety disorders, children with various behavioral disorders exhibit a deficient sense of threat or danger. Despite their differing behavioral profiles, the long-term consequence of both examples of failed emotion regulation is the failure to thrive in one's environment (Fig. 43.1). The normalization of these two extremes of emotion deregulation requires that we first understand how fearful emotions are processed and regulated at a neural level. Once accomplished, advancements can be made toward improving current treatment approaches, as well as developing novel approaches.

The experience and processing of emotion, and its underlying neurobiological substrates, has been a focus of many decades of psychological research. We now have a much more advanced understanding of the mechanisms underlying the perception of fear-relevant stimuli, as well as the induction of species-specific defensive responses in turn. The amygdala is a critical limbic structure underlying these processes in mammals, and several downstream structures have been identified to mediate specific defensive responses (Orsini and Maren, 2012). However, emotion regulation goes beyond mere stimulus–response relationships. Rather than select the best response on the basis of presently available information, emotion regulation (at least in the context of fear and anxiety) involves gauging the extent of potential threat on the basis of present and past experience/knowledge, and integrating such information with short- and long-term motivational goals to decide the most appropriate

response. Thus, successful emotion regulation involves the constant updating of threat “schemas” on the basis of learning episodes across time. What are the neurocognitive underpinnings of this ability? Answering this question is not only theoretically important from an evolutionary perspective, but it is also clinically important. If we understand the processes underlying normal/successful emotion regulation, then we can investigate ways to rectify these processes when regulation fails, as described in the previous examples.

As emotion regulation is often considered a “top-down” process involving conscious inhibition over more automatic threat responses, cortical areas like the prefrontal cortex (PFC) have long been suspected to play a crucial role in this ability. With the introduction of neuroimaging to psychiatry research, later reports of deficient PFC activations during presentations of emotional stimuli in various anxiety-disordered cohorts led to hypotheses that the exaggerated fear responses observed in anxiety may be due to failures in PFC inhibition over emotional responses (Etkin and Wager, 2007). However, direct evidence that the PFC was specifically involved in the regulation (not just the processing) of emotions was lacking. More recently, researchers have developed emotional tasks that measure specific aspects of emotion regulation. These tasks have been combined with brain imaging methods in humans, along with lesion, stimulation, and pharmacological manipulations in nonhuman animals, to greater elucidate the contribution of the PFC to emotion regulation. In this chapter we review research on these tasks that explicitly assess the ability to change one's emotional state, either behaviorally through alteration of environmental contingencies, or through cognitive exertion. We discuss how these studies have provided evidence that the PFC plays a regulatory role in the emotions of fear and anxiety, and also how these studies have begun to delineate the exact nature of this role. It is acknowledged that emotion regulation may implicitly occur in many other tasks that simply expose subjects to emotion-eliciting stimuli, and that this research contributed to the push to study PFC contributions to emotion regulation, as noted previously. However, due to the difficulty in interpreting the exact contribution of regulation strategies to the neural activations associated with such tasks, we have largely restricted our discussion to the former tasks. In addition, it is noted that structures other than the PFC have also been implicated in emotion regulation; however, this chapter will focus on the role of the PFC and its interactions with other cortical and subcortical structures involved in emotion processing.

PREFRONTAL CORTEX AND FEAR EXTINCTION

One commonly used method of examining fear and inhibition of fear in the laboratory is Pavlovian conditioning and extinction. In such procedures fear is acquired to an initially neutral conditioned stimulus (CS; e.g., tone or light) through repeated pairings with an aversive unconditioned stimulus (US, e.g., mild electrical shock), until the CS comes to elicit species-specific conditioned fear responses (CRs) on its own. Fear can then be inhibited via extinction training, which involves repeated presentations of the CS without any reinforcement. Subjects typically exhibit long-term retention of extinction memories when again presented the CS at a later

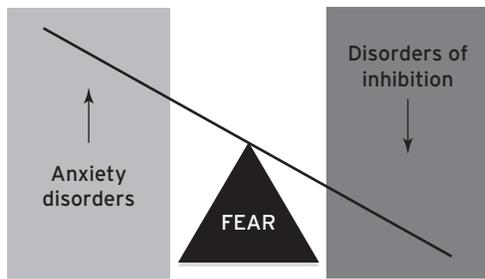

Figure 43.1 Emotion deregulation can result in too much fear, as is the case in anxiety disorders, or it can result in too little fear, as is the case in disorders of inhibition.

time (i.e., they exhibit low levels of CRs), although certain manipulations (e.g., change of testing context, exposure to mild stressor, or the mere passage of time) can elicit recovery of fear. Extinction is likely to result from a combination of processes; however, it is widely accepted that extinction largely involves the formation of a new context-dependent memory that coexists and competes with the original fear-conditioning memory (Orsini and Maren, 2012). Thus, when the subject is presented with the (now ambiguous) CS, it must decide the most appropriate course of action on the basis of conflicting past learning episodes (Fig. 43.2). Hence, extinction provides a useful model of emotion regulation, the underlying mechanisms of which can easily be explored across species.

For the past two decades, extinction research has largely centered on the following questions: When the subject is presented with the extinguished CS, what regulates which memory is recalled? How is it determined which response (to fear or not to fear) is elicited (Fig. 43.3)? There are several lines of evidence that support the notion that the ventromedial PFC (vmPFC) is critical to this regulation process, and furthermore, that distinct regions of the vmPFC exert opposing influences on fear expression. Specifically, the prelimbic (PL) division of the vmPFC appears to be necessary for the expression of learned fear. PL inactivation reduces fear responses to conditioned cues and contexts, whereas microstimulation increases conditioned freezing and impairs extinction, and PL neurons exhibit potentiated responses to conditioned cues, the persistence of which is associated with extinction failure (see Milad and Quirk,

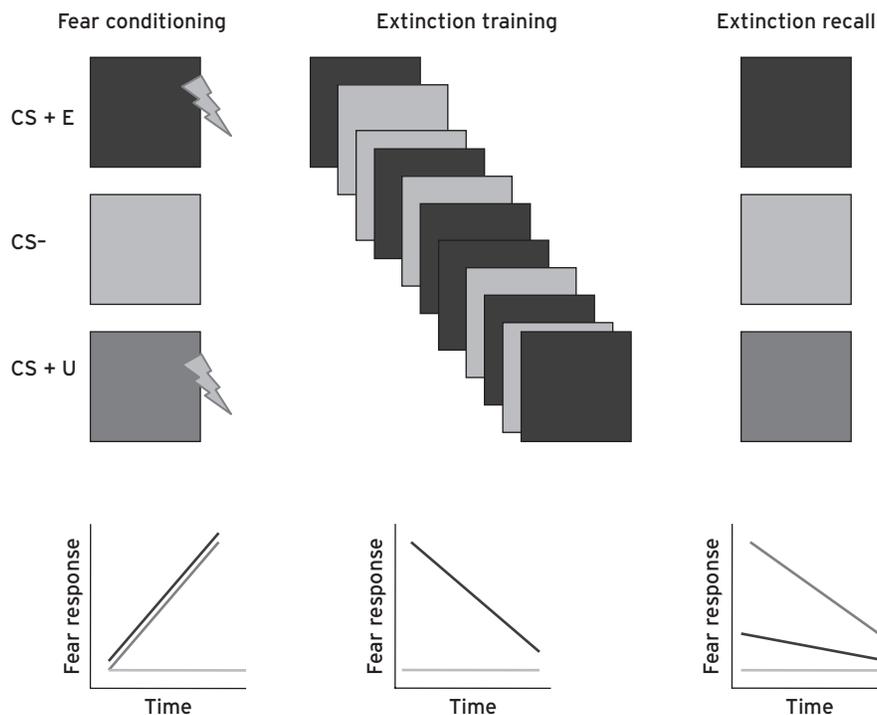

Figure 43.2 Fear conditioning and extinction protocol. During fear conditioning two stimuli are paired with an aversive outcome (CS+'s), and the third stimuli is unreinforced (CS-). Fear responses generally increase to the CS+'s and remain low to the CS-. During extinction training, one of the CS+'s is extinguished (CS+E) by being repeatedly presented in the absence of the aversive outcome. The other CS+ remains unextinguished (CS+U). Fear responses to the CS+E decrease across training and eventually are comparable to those expressed in the presence of the CS-. During extinction recall, all three CSs are presented. In healthy populations, fear responses are low to the CS+E and the CS-, whereas they are high to the CS+U.

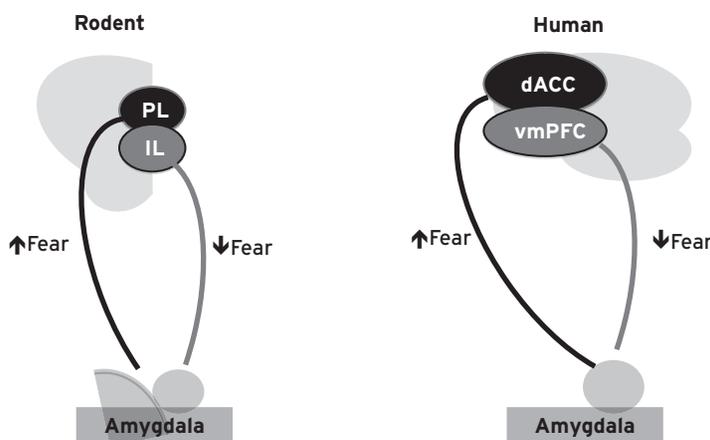

Figure 43.3 Distinct regions of the rodent (prelimbic and infralimbic) and human (ventromedial and dorsal anterior cingulate cortex) PFC increase and decrease expression of conditioned fear, respectively, via interactions with the amygdala.

2012, for review). In contrast, the infralimbic (IL) division of the vmPFC appears to be involved in extinction and/or the expression of extinction memories. Morgan et al. (1993) initially examined the effect of vmPFC lesions (encompassing IL, PL, and some orbital cortices) on acquisition and extinction of conditioned fear. They reported that while vmPFC-lesioned rats exhibited no differences in the acquisition or retention of conditioning, they took a significantly greater number of days to reach the extinction criterion (5 s or less time spent freezing in the presence of the CS). Subsequent studies that have more closely examined the within-session acquisition of extinction reported that vmPFC lesions do not affect the ability to reduce fear within a session but impair the retention of such inhibition the following day (e.g., Lebron et al., 2004; Quirk et al., 2000). Additionally, Quirk et al. (2000) reported that lesions that did not encompass the IL region spared extinction retention, suggesting that the IL region might be necessary to extinction recall. Some studies, however, have reported no effect of vmPFC lesions on fear extinction (e.g., Gewirtz et al., 1997).

The disadvantages of examining the contribution of various structures to a task using lesions are that (a) the role of the structure in the discrete phases of the task is difficult to isolate and (b) there may be some recovery of function or compensation that changes the circuitry involved in the task. To overcome these disadvantages, a second line of studies has used temporary inactivation or inhibition of protein synthesis in the vmPFC at specific points before or after fear extinction. These studies have, by and large, consistently reported impairments in retrieval of extinction memories and, again, have suggested a specific role for the IL in this regard (Orsini and Maren, 2012). While initial studies suggested no effects of vmPFC lesions on the acquisition of extinction learning, a recent study reported that when the IL (but not PL) region of the vmPFC was temporarily inactivated prior to extinction training, rats exhibited a significantly slowed rate of extinction, along with impairments in recall the following day (Sierra-Mercado et al., 2011).

A third line of evidence from rodents has used electrophysiology to measure neural responses to conditioned cues during

extinction training and its recall. Milad and Quirk (2002) demonstrated that neural responses to a tone CS increased in the IL region only during the extinction recall, and not the extinction training, phase. Moreover, freezing responses during extinction recall were inversely correlated with IL CS responses, whereas no relation was found for PL CS responses, suggesting a specific role for IL activation in dictating the strength of extinction recall. To provide more direct evidence for this hypothesis, a fourth line of evidence has examined the effects of vmPFC stimulation on extinction. Milad and Quirk (2002) reported that combining CS presentations with IL stimulation reduced freezing during extinction training, and the reduced freezing persisted during extinction recall the following day in the absence of any stimulation, suggesting that IL stimulation enhanced extinction learning or consolidation. Similar results have also been reported in studies that have stimulated thalamic (Herry and Garcia, 2002) or hippocampal (Farinelli et al., 2006) inputs to the vmPFC. In addition, Thompson et al. (2010) demonstrated that IL activation, combined with short exposure to a conditioned context, enhanced the rate of extinction to that context over subsequent days, without inducing extinction in and of itself (i.e., when tested in the context the day after IL activation, all groups exhibited comparable initial levels of freezing). Moreover, the enhanced rate of extinction was also observed when IL activation was combined with exposure to a different aversive context, but not a neutral context. Thompson et al. (2010) suggested that IL activation in the presence of a conditioned context nonspecifically “primes” the extinction circuitry in a way that allows extinction to be acquired more rapidly. In line with this suggestion, Rodriguez-Romaguera et al. (2012) recently demonstrated that deep brain stimulation (DBS) of the ventral striatum in combination with extinction training enhances extinction recall. Interestingly, although DBS without extinction training was ineffective in reducing fear, DBS alone induced plasticity within the IL and PL regions of the vmPFC, as well as regions of the amygdala, leading the authors to suggest that DBS may prime the development of plasticity within the extinction circuitry. It is yet to be

determined whether the development of such plasticity within the vmPFC is necessary for the enhancing effects of DBS on extinction.

With the advent of functional magnetic resonance imaging (fMRI) techniques, and spurred on by knowledge advancements from rodent research, the neurocircuitry underlying fear extinction has become a popular target of investigation in humans. Striking cross-species similarity in the networks mediating fear extinction in rodents and humans has been revealed. Humans exhibit increased amygdala and dorsal anterior cingulate (dACC, which appears to be functionally analogous to the PL) activations during fear acquisition and recall (Knight et al., 2004; Phelps et al., 2004), and cortical thickness of the dACC is positively correlated with fear responses during fear conditioning (see Milad and Quirk, 2012, for review). Earlier fMRI studies examining extinction of conditioned fear reported increased orbitofrontal cortex (OFC) activation during extinction training for an aversively conditioned olfactory cue (Gottfried and Dolan, 2004), as well as increased vmPFC activation during recall of an extinguished visual cue (Phelps et al., 2004). Later studies have consistently demonstrated that extinction recall is associated with increased activity in the vmPFC (Milad et al., 2007), and one study reported increased vmPFC activation to an extinguished cue only when it was presented in the extinction context, but not when presented in the original conditioning context (Kalisch et al., 2006). Furthermore, several structural MRI studies have reported a positive correlation between extinction recall and vmPFC thickness (Milad and Quirk, 2012).

Assuming a role for the vmPFC in expression of learned fear and extinction, how exactly does it up- and downregulate fear responses? Anatomically, the vmPFC is well positioned to regulate the activation of limbic structures that are involved in the expression of defensive responses, with the IL sending glutamatergic projections to the amygdala (Quirk et al., 2003), and dorsal regions of the PFC exhibiting positive connectivity with the amygdala (Etkin et al., 2011). One recent study demonstrated a positive functional connectivity between the dorsomedial (dm) PFC and the amygdala during the processing of emotional faces (Robinson et al., 2012). The dmPFC–amygdala coupling strength increased when participants were exposed to fearful faces and told that they may receive a shock, and there was a positive correlation between coupling strength and reaction times in identifying the emotion of the face. Finally, participants with high trait anxiety exhibited greatest dmPFC–amygdala coupling during processing of fearful faces under threat of shock. This suggests that the dorsal regions of the PFC may activate amygdala regions to enhance defensive responses.

With respect to PFC regulation of fear extinction, rodent studies have proved useful in identifying the specific interactions between vmPFC and specific subnuclei of the amygdala due to the ability to record from, stimulate, or lesion anatomically precise areas. Quirk et al. (2003) were the first to demonstrate that mPFC stimulation (on the border between IL and PL) inhibits central amygdala (CeA) neuronal activity in response to insula or basolateral nucleus of the amygdala (BLA) activation. The mPFC is unlikely to inhibit CeA activity

via activating inhibitory BLA interneurons, as was originally thought, given that IL projections onto inhibitory interneurons are sparse. Rather, the mPFC may activate the intercalated cells (ITCs) between the BLA and CeA, which send inhibitory projections to the CeA. Indeed, ITC lesions after extinction prevent extinction recall (Likhtik et al., 2008). As these findings from rodent experiments indicate the existence of contrasting contributions of specific amygdala subnuclei in extinction, future fMRI studies will need to make use of high-resolution imaging techniques that can better identify anatomically precise areas to determine the circuits by which vmPFC regulates fear responses during extinction and its recall in humans.

A different line of research that may help inform as to the role of the PFC in fear extinction (and fear regulation more generally) is that which has examined PFC activations during unexpected omissions of the US following presentations of a previously reinforced CS. We reported that whereas an expected shock that eventuates was associated with a decrease in vmPFC activation, an unexpectedly omitted shock was associated with increased dACC activity (Linnman et al., 2011). Another study demonstrated that an unexpectedly omitted shock was associated with ACC and dorsolateral (dl) PFC activations (Dunsmoor and LaBar, 2012). Together with findings from reversal learning paradigms (see next section), these results suggest that the PFC may provide a neural signal for outcome expectancy or further, error detection and signaling. Interestingly, it has been reported that opioid signaling in the periaqueductal gray, which is purported to regulate error detection necessary to extinction paradigms (McNally et al., 2004), mediates mPFC activation during extinction (Parsons et al., 2010), suggesting that the PFC may recruit such information (or be directly involved in processing it) to determine the most appropriate fear response. Furthermore, this research again demonstrates the opposing roles of dorsal from ventral regions of the PFC in emotion regulation.

PREFRONTAL CORTEX AND REVERSAL LEARNING

In addition to the typical Pavlovian conditioning paradigms, investigators have utilized a different experimental approach to examine emotion regulation, namely, reversal learning. This paradigm is useful because it allows for the assessment of how the subject is able to determine the most appropriate response in an ambiguous situation. Reversal learning has been extensively studied in the context of decision making in instrumental (usually rewarding) tasks, in which two different stimuli and/or responses are associated with reward or punishment, respectively, and then halfway through the task the contingencies switch. More recently a variant of this task using fear conditioning has been employed to further explore the processes underlying fear regulation. A typical fear reversal-learning task involves the presentation of two stimuli, one of which is reinforced (CS+, typically paired with shock), while the other is not (CS–). This is termed the “acquisition phase.” Halfway through the paradigm, the reinforcement contingencies switch, such that the old CS+ now becomes the CS– (i.e.,

it is extinguished), whereas the old CS– now becomes the CS+ (i.e., it is now paired with shock). This is termed the “reversal” phase. Fear reversal provides another approach with which to understand flexibility in emotion regulation, and it also allows the examination of two dissociable processes (i.e., fear acquisition and inhibition) in parallel (Fig. 43.4). Schiller et al. (2008) investigated the neural correlates of fear reversal in healthy humans using faces as CSs, and mild electric shock as the US. They reported that during both the acquisition and reversal phases vmPFC activity was slightly and significantly increased during the CS– relative to the CS+ presentations, regardless of whether the stimuli were “new” or “old” CS–’s. However, the increase in vmPFC activity in response to the CS– was significantly greater during the reversal (i.e., extinction) phase than during the acquisition phase. Schiller et al. (2008) suggested that the vmPFC might provide a selective safety signal to indicate which environmental stimuli are safe to ignore. Interestingly, an earlier study using a very similar model of reversal learning reported the exact opposite results, where vmPFC activity increased during presentations of the CS+ compared with the CS–, during both acquisition and reversal phases (Morris and Dolan, 2004). Distinct regions of the right anterior cingulate exhibited segregated patterns of opposing activity: one region that decreased activation when the CS+ became a CS– (i.e., exhibited reversal) and one region (lateral to the previous region) that continued to exhibit increased activation to the CS+ even when it became a CS– (i.e., exhibited nonreversal, or perseveration). Importantly, both studies implicate the vmPFC in switching responses to signal a change in stimulus contingencies; however, the reason for the

discrepancy between the studies in terms of the direction of vmPFC activation is unclear.

BEHAVIORAL VERSUS COGNITIVE EMOTION REGULATION

The chapter thus far has focused on tasks that may be considered “behavioral regulation,” which involve forming new, or updating existing, representations of CS–US contingencies on the basis of direct experience of the organism. This type of emotion regulation is sometimes conceptualized as “automatic,” seeming to occur without input from a declarative (explicit) memory system (Öhman and Mineka, 2001, but see Lovibond and Shanks, 2002). The advantage of such tasks is that they can be easily modeled in the laboratory in both humans and nonhuman animals, and they also reflect the behavioral components of cognitive behavioral therapy (CBT) used to treat a range of disorders with underlying difficulties with emotion regulation. However, emotion regulation in humans can and often does stem from cognitive resources. In such instances, alterations in emotional output can arise without direct experience, merely from altering one’s perceptions through reasoning. The next part of this chapter examines cognitive aspects of emotion regulation.

THE PFC AND REAPPRAISAL

Cognitive reappraisal involves the conscious attempt to alter the meaning of an emotionally significant stimulus/event, typically with the goal of downregulating a negative affective

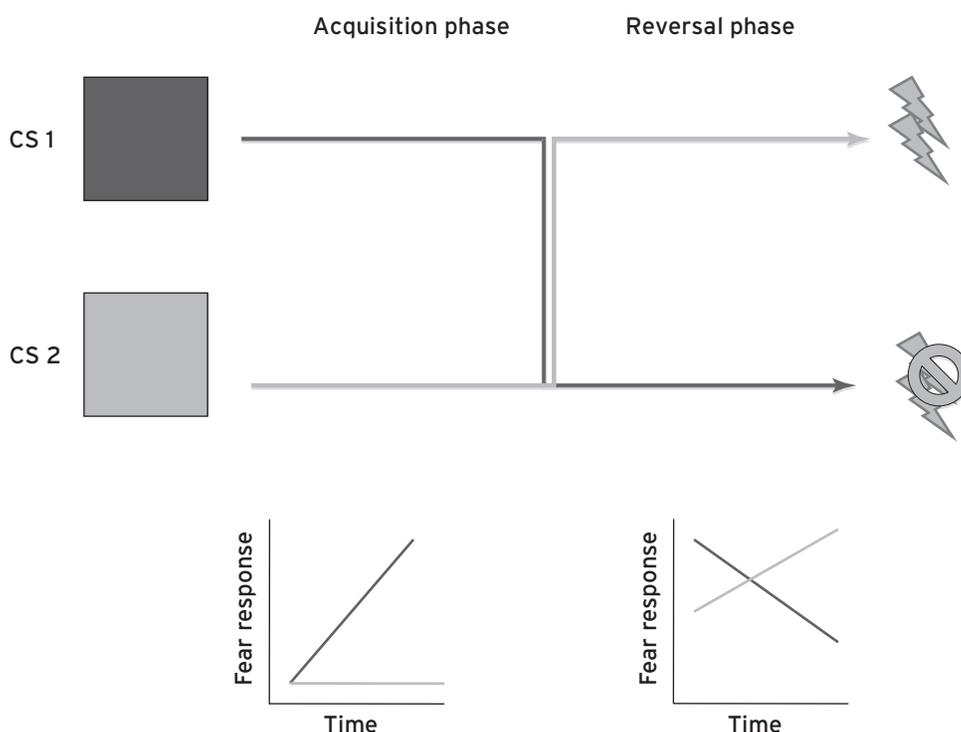

Figure 43.4 Reversal learning protocol. In the acquisition phase, CS1 is paired with an aversive outcome whereas CS2 is unreinforced. Fear responses increase to CS1 and remain low to CS2. In the reversal phase, CS1 is unreinforced (i.e., is extinguished), and CS2 is now paired with an aversive outcome. Fear responses decrease to CS1 and increase to CS2.

response (Gross, 2002). For example, when confronted with an anxiety-provoking stimulus such as a dangerous snake, an individual may attempt to reduce his or her fear by noting that the snake is in an enclosure and therefore very unlikely to escape. Reappraisal is frequently employed in CBT for a range of psychopathologies and often involves the evaluation of all available evidence for one's initial (usually unrealistic) thought, followed by a substitution of the initial thought with one that is more realistic (Smits et al., 2012). Reappraisal capitalizes on humans' unique ability to verbally reason and so is likely to be regulated by higher level cortical structures. It is an indirect means of emotion regulation, in the sense that the emotional response is altered as a consequence of directly modifying attributions of the meaning associated with emotionally relevant stimuli/events. Thus, it fits with the underlying principles of CBT, which holds that emotions are merely reactions to thoughts, by modifying the thought; the emotion is modified in turn.

During the past decade, several studies have started to examine the neurobiological mechanisms underlying cognitive reappraisal. One study examined the use of reappraisal strategies toward classically conditioned cues (images of neutral shapes; Delgado et al., 2008). Following conditioning, participants received nonreinforced presentations of the cues, along with instructions to either attend (pay attention to their natural feelings) or reappraise (imagine something calming in nature, prompted by the color of the cue: e.g., an ocean scene in response to a blue cue). Reappraise trials were associated with reduced skin conductance responses and heightened dlPFC and vmPFC activity relative to attend trials, and a positive correlation was observed between reappraisal success (indexed by reduced skin conductance responses) and dlPFC activation. Interestingly, the vmPFC region activated in this reappraisal task was the same region activated in a previous study that used the same conditioning paradigm but subjected participants to extinction trials rather than reappraisal instructions (Phelps et al., 2004), suggesting the existence of a common neurobiological route for the two different methods of emotion regulation.

Other studies of reappraisal have involved the presentation of innately negative or threatening images with instructions to attend (i.e., pay attention to the image without attempting to control the emotional reaction) or "reappraise"/"decrease" (i.e., think about the image in a more neutral or positive manner). Such studies have revealed that in addition to the vmPFC region that is implicated in fear extinction, reappraisal appears to recruit more lateral regions of the PFC, as also reported by Delgado et al. (2008). For example, a recent meta-analysis concluded that reappraisal use is associated with increased activation of the lateral (including the superior, middle, and inferior frontal gyri, and lateral orbital gyri) and medial (including the superior frontal gyrus and anterior cingulate cortex) prefrontal cortices (Kalisch, 2009; see also Etkin et al., 2011, for review).

Accepting that the PFC is involved in reappraisal, what is the nature of its involvement, and how exactly does it modulate emotional responses? Wager et al. (2008) noted that the PFC may influence emotional responding directly (direct hypothesis), or it may regulate activity of subcortical structures

implicated in emotional learning and expression (mediation hypothesis). In support of the mediation hypothesis, several studies have reported that reappraisal success is associated with increased PFC, but decreased amygdala and/or nucleus accumbens, activity (Delgado et al., 2008; Goldin et al., 2008; Phan et al., 2005). Wager et al. (2008) extended these findings in a mediation analysis of the ventrolateral (vl) PFC as a predictor of reappraisal success. They demonstrated that increased amygdala activity was associated with reduced success, whereas increased nucleus accumbens/ventral striatum activity was associated with increased success, and both areas were positively associated with vlPFC activity. Independently, both regions accounted for a part of vlPFC-associated reappraisal success while controlling for the effects attributable to the other. Wager et al.'s (2008) results support the existence of two distinct networks mediated by the vlPFC—one that generates negative affect, and one that downregulates negative affect during reappraisal. The authors therefore concluded that the PFC might be involved in the appraisal process and subsequent recruitment of subcortical regions that up- or downregulate emotional responses, rather than being a constant "dampener" on negative affect as is often assumed.

Other evidence that supports the role of a PFC–amygdala network in reappraisal comes from studies that have exploited individual differences in emotion regulation strategy preference and/or ability. One recent study demonstrated that individuals who were more successful at downregulating emotion exhibited greater inverse functional connectivity between the amygdala and areas of the PFC including the pregenual ACC, OFC, and dm/dlPFC (Lee et al., 2012). Similarly, a different study by Drabant et al. (2009) exposed participants to negative images in the absence of any explicit instructions; thus, participants were free to spontaneously engage in whatever emotion regulation strategy (if any) they chose. The results showed that a greater tendency to use reappraisal in everyday life (as indexed by the Emotion Regulation Questionnaire) was associated with decreased amygdala activation, and increased dl/dmPFC, and lateral OFC activation. These results demonstrate that spontaneous recruitment of reappraisal strategies is associated with similar involvement of neural regions to those involved following instructed recruitment. These results also fit with more recent structural findings demonstrating that high scores on trait measures of cognitive reappraisal positively correlate with dACC, but not ventral ACC, thickness (Giuliani et al., 2011). Emotion regulation is more likely to arise spontaneously rather than in response to explicit cues in everyday life. Thus, these findings provide evidence for the validity of using instructed modes of emotion regulation in the laboratory as a model of such processes as they occur in more natural settings.

From the studies reviewed in this section, it is apparent that while PFC–amygdala (and other subcortical) interactions appear to mediate cognitive reappraisal, lateral and medial, as well as dorsal and ventral, PFC regions have also been implicated in this regard. A focus of more recent research, therefore, has been to disentangle the relative contributions of distinct PFC regions to emotion regulation and their interactions with subcortical structures. It is unlikely that the lateral PFC modulates

emotion regulation via direct influence on amygdala activity as robust monosynaptic connections between these two brain regions have not been previously reported (Urry et al., 2006), suggesting an indirect route via additional brain regions. The vmPFC is likely to serve as an intermediate structure given that reciprocal anatomical and functional connections between the lateral PFC and vmPFC have been reported, and the vmPFC has direct anatomical connections with different subnuclei within the amygdala (Kim et al., 2011b; Urry et al., 2006). In view of this, several researchers have suggested that the vmPFC may function as a gateway between phylogenetically newer cortical structures and phylogenetically older subcortical structures to modify emotional responses using higher level cognitive strategies (Delgado et al., 2008). Urry et al. (2006) provided support for this idea by demonstrating that successful reappraisal was associated with greater vmPFC and reduced amygdala activity. Additionally, greater medial frontal gyrus (MFG) activity was associated with greater vmPFC activity when downregulating emotion, and subjects with higher MFG activity showed lower amygdala activity. In a test of mediation, the vmPFC was a significant mediator of the relationship between the MFG and amygdala, whereas the MFG did not mediate the relationship between the vmPFC and amygdala. In other words, the MFG indirectly controlled amygdala activity via the vmPFC, suggestive of the vmPFC's role as a gateway between other cortical areas and the amygdala.

THE PFC AND CONTROLLABILITY

A consistent finding in the clinical anxiety literature is that while many people experience highly traumatic events, only 15–20% of these will ultimately develop an anxiety disorder like PTSD. This highlights the apparent existence of large individual differences with respect to people's response to trauma, or more broadly, people's ability to regulate their emotions following high levels of stress. By examining the differences between people who experience trauma and develop PTSD on the one hand, and people who experience trauma but do not develop any psychopathology on the other, research has identified several factors that may protect against the development of anxiety. Of these, one consistent protective factor relates to perceptions of control. Individuals who hold the belief that they had some amount of control during a traumatic event, or that they have control over their emotional reactions to reminders of the event posttrauma, are far less likely to develop PTSD than are individuals who perceive the traumatic event and/or their reactions to posttrauma reminders to be entirely uncontrollable (Ehlers et al., 2000). In this framework, beliefs of controllability can be viewed as an effective cognitive strategy for emotion regulation.

Although the *perception* of controllability is a cognitive process, much preclinical research has investigated the behavioral and neurophysiological consequences of controllable versus uncontrollable stress in animal models of emotion regulation. In a typical paradigm examining this phenomenon, two groups of subjects are exposed to a series of electrical tail shocks. One group has the ability to terminate the shocks by turning a wheel that is fixed in the chamber. Another group, whose chambers

are yoked to that of the first group, is unable to terminate the shocks, and so receives the same number and duration of shocks as determined by the first group. Despite the fact that both groups receive identical shock experiences and that both procedures induce significant release of stress hormones, the behavioral and neurophysiological characteristics of the two groups differ substantially postshock. Subjects that receive inescapable shock fail to learn how to escape subsequent stressful situations, exhibit potentiated fear during and after fear conditioning, and show large effluxes of serotonin in the dorsal raphe nucleus (DRN; see review by Maier and Watkins, 2010). In contrast, escapable shock does not produce any of these consequences. Moreover, previous experience with escapable shock prevents the behavioral and neurophysiological consequences of later inescapable shock, a phenomenon known as "behavioral immunization" (Maier and Watkins, 2010).

The effects of inescapable shock are dependent on DRN activation, as pharmacological blockade of DRN activity either during inescapable shock or during subsequent behavioral testing prevents escape learning deficits and potentiation of fear conditioning (Maier and Watkins, 2010). Conversely, the effects of escapable shock require the animal to recognize that there is a contingency between its actions and the outcomes, and thus are unlikely to be mediated in the brainstem DRN. Maier and Watkins hypothesized that as the DRN receives almost all its cortical input from the IL and PL, these regions of the vmPFC may regulate the perception of controllable shock. In a series of experiments, they demonstrated that temporary inactivation of the vmPFC during escapable shock increased DRN 5-HT efflux during the procedure, potentiated contextual fear conditioning, and led to deficits in subsequent escape learning (Amat et al., 2005). In other words, inactivation of vmPFC during escapable shock led to all of the consequences of inescapable shock. Importantly, inactivation of the vmPFC did not prevent rats from learning to turn the wheel to terminate the shock. Thus, even though rats did, in fact, learn to escape the shock, they later behaved as if they had received inescapable shock.

In addition to regulating the effects of controllable stress, activation of the vmPFC is also necessary for the immunizing effects of prior experience with control on later consequences of uncontrollability. In a typical behavioral immunization protocol, rats are exposed to escapable shock and then one week later are exposed to inescapable shock, followed by tests for fear conditioning and escape behavior. Amat et al. (2006) demonstrated that inactivation of the vmPFC during escapable shock prevented its immunizing effects on subsequent DRN 5-HT efflux during inescapable shock, potentiated fear conditioning, and escape deficits. In addition, when the vmPFC was inactivated during inescapable shock, this also prevented the immunizing effects of previous exposure to escapable shock.

Perhaps even more convincing, in a later series of experiments, Amat et al. (2008) demonstrated that enhancing vmPFC activity by picrotoxin infusion during inescapable shock prevented the increase in DRN 5-HT efflux, potentiated fear conditioning, and deficits in subsequent escape learning. That is, these rats behaved as if the shock were controllable, despite never being able to actually control the shock during the procedure. In the next experiment, rats were given two sessions

of inescapable shock one week apart, followed by behavioral testing. During the first session, half the rats received vmPFC infusion of picrotoxin, thus enhancing vmPFC during the initial inescapable shock session. Remarkably, vmPFC activation during initial inescapable shock abolished the effects of later inescapable shock on 5-HT efflux, fear conditioning, and escape learning. That is, these rats “behaved” as if they had previously been exposed to an escapable stressor. Importantly, vmPFC activation had no effect on wheel-turning behavior during escapable shock.

Together, this experimental series suggests that vmPFC activity is necessary and also sufficient to produce the behavioral and neurophysiological consequences of controllability, and to produce the immunizing effects of prior experience with control. Later, the same group used retrograde tracing to demonstrate that escapable shock, or inescapable shock that was preceded by escapable shock, activates DRN-projecting neurons in the PL of the vmPFC (Baratta et al., 2009). As glutamateric DRN-projecting PL neurons synapse on GABAergic DRN neurons, this suggests that escapable shock may cause vmPFC inhibition over DRN activity, not only during escapable shock, but also during subsequent stressful experiences regardless of their ability to be controlled.

Does the lesser fear exhibited by animals that have previously experienced control indicate that they experience/express less fear, or that they have reduced memory for the fear-conditioning episodes? Fear expression (i.e., the frequency with which a fear behavior is exhibited) is often taken to index the strength of the associative memory. In this sense, the decreased fear conditioning displayed by rats exposed to escapable shock could suggest some blunting of associative memory caused by the vmPFC. However, two findings from Maier and Watkins contradict this interpretation. First, when inescapable shock occurred 24 hours after fear conditioning, these rats still exhibited potentiated freezing at test, even though it is unlikely that the stress procedure could have modulated the memory at such time point (Baratta et al., 2007). Second, inactivation of vmPFC prior to a contextual fear conditioning test in rats that had previously been exposed to escapable shock abolished the blunting effects of escapable shock on fear conditioning (Baratta et al., 2008). These findings suggest that vmPFC activity during controllable/uncontrollable stressful events does not impact the associative strength of subsequent learning episodes; rather, it modulates the expression of fear for any given associative strength. This conclusion fits nicely with research on the role of the vmPFC in fear extinction, which has suggested that the vmPFC may be important in the expression of the fear extinction memory.

The main implication drawn by Maier’s group is that the consequences of controllable/uncontrollable shock are not determined by the ability to exert behavioral control over stress per se, but rather by whether vmPFC activity is increased during the time of stress. Subsequent work in humans has demonstrated that individuals who exhibit greater vPFC activation in anticipation of an uncontrollable painful stimulus report less pain in response to that stimulus and show greater tendencies to engage “acceptance” over “denial” styles of coping,

suggesting that the neural circuitry mediating perceived control has been preserved across species (Salomons et al., 2007). These findings therefore provide strong evidence for the role of the PFC in mediating emotion regulation via enhancing the perception of control. Moreover, the preclinical findings parallel nicely with clinical reports in humans that it is the perception of control over a traumatic event that seems to confer protection from psychopathology rather than the actual ability to exert control (Ehlers et al., 2000).

INTERIM SUMMARY

Though fear extinction, reversal learning, reappraisal, and studies on controllability represent seemingly distinct experimental tools, the involvement of the PFC in these tasks leads to one common behavioral outcome: regulation of inappropriate fear responses. This can be achieved via interactions with the amygdala as in fear extinction, with more lateral and dorsal prefrontal regions during reappraisal, or through the DRN in the case of controllability. The common involvement of the PFC, therefore, leads the organism to make the most advantageous decision to guide its behavior. It can also be argued that there may be some element of reappraisal during fear extinction, and that both reappraisal and fear extinction may confer some element of controllability, and all three involve the altering of perceived or actual contingencies, as modeled by reversal learning. Thus, while investigators often attribute the role of this brain region to a specific task (i.e., PFC and fear extinction), it should be clear to the reader that the PFC is critical for emotion regulation and behavioral choice optimization in a much broader sense (Fig. 43.5).

WHEN REGULATION FAILS

We have so far examined the PFC’s involvement in emotion regulation as it occurs in a normally functioning subject. However, there are many instances in which emotion regulation fails. Examining how the PFC functions in circumstances during which emotion regulation fails provides another means of investigating the nature of its involvement in this ability. If the PFC truly is the gateway for successful emotion regulation, then failures in this ability must be associated with aberrant PFC structure and/or function. In the following section, we briefly review rodent and human research that has examined the functioning of the PFC during times of emotion regulation failure, and highlight some of the factors that may influence this process, such as stress and sex hormones. Our review of the clinical studies related to emotion regulation will be very brief as a more thorough examination of this topic will be reported in Chapter 45 by Goodkind, Gyurak, and Etkin.

ANXIETY DISORDERS

Anxiety disorders are characterized by the failure to appropriately regulate fear and anxiety. Neuroimaging tools have

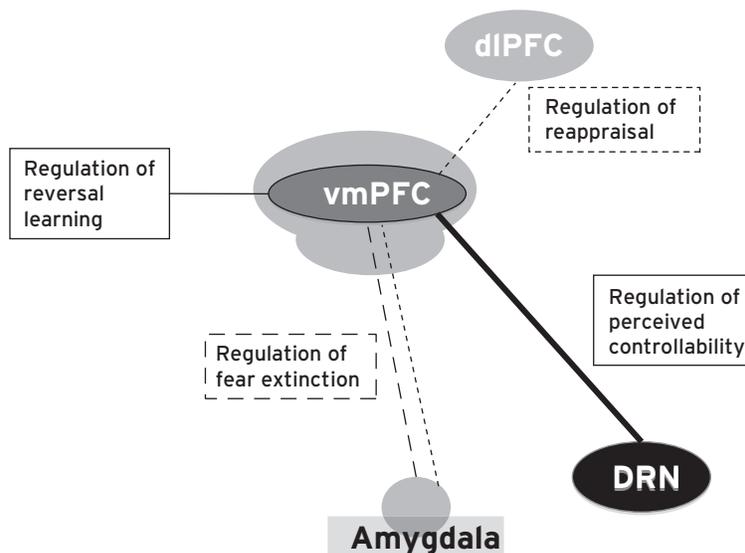

Figure 43.5 The vmPFC may act as a gateway between phylogenetically newer cortical structures (e.g., dorsal lateral PFC) and phylogenetically older limbic and brainstem structures (e.g., amygdala and dorsal raphe nucleus) to regulate many forms of emotion regulation.

been used to investigate the underlying pathophysiology of the inappropriate control of fear, in parallel with preclinical investigations that are able to use more invasive means of investigation to gain a more anatomically precise understanding of the mechanisms of emotion regulation. These efforts have led to the identification of a number of brain regions that may contribute to symptoms of anxiety. Not surprisingly, aberrant functioning of regions of the PFC has been identified as a key contributor to the development and maintenance of anxiety. Earlier neuroimaging research examined PFC activations in people with anxiety disorders while viewing fear-relevant and irrelevant images. Such research, known as “symptom provocation studies,” has typically reported altered PFC activity in anxious subjects relative to controls; however, the direction of the difference (i.e., increased or decreased activity) has been somewhat inconsistent (Etkin and Wager, 2007). One reason for the variability between studies may be that in the absence of explicit instructions, participants may or may not spontaneously engage in emotion regulation, and if they do, they may differ with respect to the specific emotion regulation strategy engaged, as well as its relative success. We will focus the following discussion on research that has specifically examined neural activations during emotion regulation tasks.

Emotion regulation deficits have been reported in people with anxiety disorders in a range of tasks, including those that tap into behavioral/automatic, as well as cognitive, regulation abilities (Cisler et al., 2010). With respect to the former, conditioning and extinction of fear have been widely examined in clinically anxious populations because the paradigm is thought to reflect the etiology, symptoms, maintenance, and treatment of anxiety disorders to varying degrees. A meta-analysis of earlier studies that focused on fear conditioning and extinction to simple, single cues revealed evidence for moderately enhanced fear responses during both conditioning and extinction in anxious subjects relative to healthy controls (Lissek et al., 2005). Later studies used discriminative conditioning, in

which participants’ conditioned responses in the presence of a reinforced cue are compared with those exhibited in the presence of a nonreinforced (safe) cue. Relative to healthy controls, people with PTSD often exhibit heightened fear responses to both types of cues, as well as delayed extinction, suggesting a reduced ability to discriminate between dangerous and safe cues, and another study reported a specific failure in extinction learning in people with panic disorder (see Graham and Milad, 2011, for review). The most recent studies have focused on the ability to retain extinction memories over a longer period (typically 24 hours after extinction training). For example, we have reported that people with PTSD exhibit normal conditioning and extinction learning, but impairments in extinction recall (Milad et al., 2009a).

Similar to extinction, deficits in cognitive reappraisal have also been reported in clinically anxious populations. Such studies typically instruct participants to downregulate their emotional responses to disorder-relevant or innately threatening/negative images. Less success in emotion downregulation, as indexed by self-reports, has been reported in people with PTSD (New et al., 2009) and spider phobia (Hermann et al., 2009).

Might there be common neurobiological underpinnings of anxiety disorder-associated failures in emotion regulation across these tasks? In the case of extinction, there is evidence that heightened activity within the dACC and reduced activity within the vmPFC may be responsible for the enhanced conditioning and reduced extinction observed in PTSD, respectively. For example, using positron emission tomography, Bremner et al. (2005) demonstrated that people with PTSD exhibited heightened behavioral responses during fear acquisition and extinction that were associated with increased resting metabolic activity in the left amygdala and decreased resting metabolic activity in the vmPFC, respectively, compared with healthy controls. We reported that the impaired extinction recall observed in PTSD populations is associated with reduced activity in the vmPFC and hippocampus, but heightened dACC

activity to conditioned cues (Milad et al., 2009a) and contexts (Rougémont-Bücking et al., 2011). Replication of these findings in other cohorts/subtypes of anxiety is required to determine whether vmPFC deregulation is characteristic of anxiety as a dimension.

In the case of cognitive reappraisal, the deficits in downregulation among people with PTSD were associated with reductions in lateral PFC activity compared with healthy controls (New et al., 2009). Similarly, participants with spider phobia exhibited decreased rostral ACC and vm/dmPFC activity (but normal vlPFC activity) when attempting to downregulate emotional responses to phobic-relevant fearful images, compared with phobic-irrelevant fearful images (Hermann et al., 2009). Interestingly, no differences in self-report of emotion downregulation via reappraisal were found in people with social anxiety disorder (SAD) compared with healthy controls, but reappraisal was associated with reduced dlPFC and dmPFC activation in SAD participants in response to images of social threat, but not images of physical threat (Goldin et al., 2009).

FACTORS THAT MODULATE EMOTION REGULATION SUCCESS

PERSONALITY

Examining how well variance in emotion regulation ability can be predicted by individual difference factors may potentially lead to the identification of risk factors for disorders associated with emotion regulation failure. To this end, several studies have examined the neural correlates of trait anxiety at rest and during emotion regulation tasks. For example, using diffusion tensor imaging it was shown that high levels of trait anxiety were associated with weaker reciprocal connections between the amygdala and vmPFC (Kim and Whalen, 2009). A later study reported that amygdala resting state activity was positively coupled to vmPFC activity in low-anxious subjects, and negatively coupled to vmPFC activity in high-anxious subjects (Kim et al., 2011c). Together these studies suggest that altered PFC–amygdala functional and structural connectivity may indicate susceptibility to anxiety; however, do these factors covary with emotion regulation success? One recent study examined vmPFC–amygdala activity during cued and contextual fear conditioning tasks in participants with varying levels of trait anxiety (Indovina et al., 2011). High trait anxiety was positively associated with skin conductance responses (i.e., greater arousal) and amygdala response to the conditioned cue, and negatively associated with vmPFC response to both the conditioned cue and context. Moreover, variance in trait anxiety was best accounted for by a model that included amygdala and vmPFC responses (either during the cue or the context). As this task did not include a component of instructed emotion regulation, the authors suggested that low–trait anxious individuals might spontaneously engage the vmPFC–amygdala circuitry involved in emotion downregulation during times of stress. Another study reported that while people high and low in trait anxiety exhibited similar success in reducing negative emotions, reappraisal in high-anxious participants was associated with *greater* engagement of lateral and medial PFC,

suggesting the requirement for greater neural effort to attain the same level of regulation (Campbell-Sills et al., 2011).

STRESS

Stress activates a number of hormones, one of the primary targets of which is the PFC. Numerous studies have demonstrated that chronic stress influences PFC structure and neuronal function in rodents, with chronic stress or corticosterone treatment causing retractions in dendritic length and branch numbers, dendritic spine loss, and reduced neuronal responses to serotonin or dopamine application (see review by Holmes and Wellman, 2009). In light of this, investigations have now turned to the examination of the functional implications of stress effects on the PFC. Several researchers have reported that in rodents chronic stress leads to impairments in fear extinction acquisition (Izquierdo et al., 2006) or extinction recall (Garcia et al., 2008; Knox et al., 2012; Miracle et al., 2006), without altering the acquisition of fear conditioning. The stress-induced impairment in extinction is accompanied by reductions in dendritic branch length in the IL (Izquierdo et al., 2006), reduced mPFC neuronal excitability in response to hippocampal stimulation (Garcia et al., 2008), and a change in the quality of IL–amygdala plasticity (from long-term potentiation to long-term depression; Akirav and Maroun, 2007). Evidence that the chronic stress-induced dendritic remodeling or changes in IL–amygdala pathway plasticity actually causes impairments in extinction, however, is lacking. One recent study reported that IL lesions in rodents prior to chronic stress prevented the impairment in extinction (Farrell et al., 2010), suggesting that IL activity during the stressful experience is necessary for mediating stress effects on subsequent learning episodes. It will be important for future research to investigate whether preventing the impact of stress on PFC morphology and function also prevents extinction impairments, and/or to determine whether a recovery interval following stress (which often reverses the neuronal effects of stress) reduces the impact of stress on extinction. In addition, it will also be useful to extend investigations of stress effects to other modes of emotion regulation, in both rodents and humans.

SEX HORMONES

In addition to stress hormones, sex hormones also appear to modulate emotion regulation. The influence of sex hormones on extinction is receiving increased attention, most likely due to the recognition that women are more vulnerable to anxiety disorders than men (Lebron-Milad et al., 2012). Studies in naturally cycling adult female rodents have revealed that extinction retention is optimal when cycling hormones (e.g., estradiol, progesterone) are high (the proestrus phase of the rat estrous cycle), and extinction retention is significantly impaired when cycling hormones are low (the metestrus phase of the rat estrous cycle) (Chang et al., 2009; Milad et al., 2009b; Zeidan et al., 2011). Similar findings have been reported in healthy, naturally cycling women, where extinction retention is optimal during the midluteal (high estradiol and progesterone) phase of the menstrual cycle, but reduced during the follicular (low-estradiol, progesterone) phase (Milad et al., 2010; Zeidan et al., 2011). A more recent study reported that

estradiol levels were negatively correlated with extinction ability and symptom severity in women with PTSD (Glover et al., 2012). We have demonstrated that estrogen's influence on fear extinction appears to be modulated via PFC activation (Zeidan et al., 2011). We reported that the impaired extinction in metestrus female rats is associated with reduced IL, but increased BLA, immediate early gene activity at the time of extinction recall. Moreover, the impaired extinction in follicular women was associated with reduced vmPFC, hippocampal, and amygdala neural responses during extinction recall. A recent fMRI study also found significant differences in vmPFC responding between men and women during extinction recall, supporting the likely influence of sex hormones on the functional responsiveness of this brain region during emotion regulation (Lebron-Milad et al., 2012). The impact of sex hormones on the functioning of the PFC during more cognitive forms of regulation, like reappraisal or perceived control over stress, is unknown. However, other research has demonstrated that gender and/or menstrual cycle phase affects recall for emotional films (Ferree et al., 2011), activity of the neural circuitry underlying the stress response (Goldstein et al., 2010), and OFC activity during emotion processing (Protopopescu et al., 2005). Together, these findings suggest that sex hormones may modulate emotion regulation abilities more generally, possibly by altering top-down cortical control over limbic structures.

INFLUENCE OF DEVELOPMENT

Although much is known about the neural and molecular mechanisms underlying fear extinction in adults, much less is known about extinction across development. This is surprising given that anxiety disorders often emerge during adolescence, which is a time of neuronal reorganization within the PFC that is characterized by heightened emotionality and reduced impulse control (Casey et al., 2010). Recent studies have revealed that although adolescent rats exhibit normal acquisition of conditioning and extinction, they exhibit elevated recovery of fear responses the following day (Kim et al., 2011a; McCallum et al., 2010). This deficit can be overcome with extensive extinction training, which has also been observed in adult rats with PFC lesions (Lebron et al., 2004), suggesting that the impaired extinction in adolescent rats may be similarly due to reductions in PFC function during this phase of development. Evidence for the latter idea comes from Kim et al. (2011a), who demonstrated that extinction recall in adolescent rats was associated with reduced phosphorylation of mitogen-activated protein kinase (pMAPK) in the IL compared with adult rats. Moreover, when adolescent rats were overtrained during extinction to prevent impairments in recall, this resulted in increased IL pMAPK at the time of recall.

GENETIC INFLUENCES

In an attempt to determine genetic predispositions to anxiety disorders, several studies have examined the influence of various genetic profiles on tasks of emotion regulation. Conditioning and extinction ability is moderately heritable, accounting for around 35–45% of the variability in conditioning and extinction in a cohort of monozygotic and

dizygotic twins (Hettema et al., 2003), which is equivalent to the percentage of variance associated with PTSD that is accounted for by a heritable component. A number of studies have demonstrated that single-nucleotide polymorphisms (SNPs) associated with the serotonin transporter gene (Hartley et al., 2012), the *BDNF* gene (Soliman et al., 2010), and the pituitary adenylate cyclase-activating polypeptide (PACAP; Ressler et al., 2011) are associated with impaired fear extinction and/or discrimination of safety cues. How does genetic variation mediate extinction impairments at a neural level? Preclinical studies that have taken advantage of considerable between- and within-strain differences in extinction abilities have assisted in addressing this question. Hefner et al. (2008) reported that extinction impairments in 129S1 mice were associated with reduced immediate early gene activity in the IL and BLA, and enhanced activity in the CeA, compared with C57BL/6J mice that exhibit normal extinction. Similar findings have been reported for Wistar rats selectively bred for high- and low-anxiety-related behavior (Muigg et al., 2008). High-anxiety rats exhibited impaired extinction learning and recall, and reduced immediate early gene activity in IL and lateral amygdala, and increased activity in the CeA, compared with low-anxiety rats. The neural basis for genetic-associated impairments in rodents may be common in humans, as people with *BDNF*-SNP associated extinction impairments also exhibit reduced vmPFC, but increased amygdala, activation during extinction (Soliman et al., 2010). Together, these studies suggest that extinction impairments of genetic origin may be due to reduced vmPFC control over subcortical afferents.

FUTURE DIRECTIONS

A focus of future research in the domain of emotion regulation will be to increase the understanding of how the different regions of the PFC interact to mediate emotion regulation and the subcortical structures responsible for emotion processing. Some progress has been made in this area in the study of fear extinction, with different roles for the PL and IL regions becoming increasingly well defined. Similar progress will need to be made in the study of reappraisal. It will be important to address, for example, whether different regions of the PFC are involved in different kinds of reappraisal and/or reappraisal for different types of emotions, and in turn, whether these regions recruit a common mediator, such as the vmPFC, to influence subcortical aspects of emotion processing and expression.

Moving beyond the PFC, it will also be critical for future research on emotion regulation to study the neural circuits involved rather than the activations and contributions of single neural structures in isolation. Such an approach may assist in resolving some inconsistencies in the literature where, for example, some studies have reported decreased activity in the vmPFC in participants with anxiety disorders, whereas others have reported increased activity in the same type of cohort. From the more recent research reviewed here, it is apparent that it may not be the overall activation of distinct neural regions that dictates the emotional output but, rather,

the connectivity, or the strength of coupling between two or more regions (in whichever direction), that determines the emotional response. Future research will need to examine structural and functional coupling between proposed circuitries, and how coupling strength changes according to task demands. In addition, it will be useful to examine how the various modulating factors discussed earlier (psychopathology, personality, development, sex, genetics, etc.) affect coupling at a baseline level as well as during various emotion regulation tasks.

DISCLOSURES

Dr. Graham has no conflicts of interests to disclose.

Dr. Milad has received fees from MircoTransponder Inc. in a project not related to the present work. This work was supported by an R01MH081975 (subcontract) and a 1R01MH097880-01 to M. R. M., and an American Australian Association Neurological Fellowship to Dr. Graham.

44 | DEVELOPMENTAL COMPONENTS OF FEAR AND ANXIETY IN ANIMAL MODELS

SIOBHAN S. PATTWELL, ANNE-MARIE MOULY, REGINA M. SULLIVAN, AND FRANCIS S. LEE

INTRODUCTION

Modern advances in psychiatry and neuroscience have uncovered a wealth of knowledge about the underlying neural circuitry implicated in anxiety- and stress-related disorders. As the majority of research has focused on characterizing inappropriate and exaggerated fear responses in the mature adult brain, current clinical treatments have been implemented based on their efficacy in a physiologically mature neural framework. While existing behavioral and psychopharmacological therapies offer significant benefit to adult patients suffering from anxiety disorders, such as posttraumatic stress disorder (PTSD), a comparative lack of knowledge about the development of fear neural circuitry may limit successful treatment outcomes in children and adolescents (Lieberman et al., 2006). In addition, early-life environmental and physiological stressors can alter the dynamic nature of this circuitry, highlighting the importance of understanding fear circuitry from early infant development, onward through adolescence, and into adulthood. Importantly, we present data indicating that the developing circuitry underlying fear and anxiety has dynamic developmental periods when fear learning or its expression is prevented. Successful treatment outcomes in children and adolescents will likely need to consider these unique developmental epochs.

NEURAL CIRCUITRY INVOLVED IN FEAR LEARNING AND MEMORY

MODELING FEAR LEARNING IN THE LABORATORY

Behavioral paradigms relying on Pavlovian principles have become standard for studying fear in both humans and nonhuman animals (Pavlov, 1927). Classical conditioning is an attractive model for studying neural mechanisms of fear because learning is rapidly acquired, the memory is long lasting, and stimuli are easily controlled by the experimenter (Sigurdsson et al., 2007). Typically, an inherently threatening and/or unpleasant stimulus, such as an electric shock or aversive noise, serves as an unconditioned stimulus (US), while a previously neutral stimulus, such as a light flicker or tone, serves as the conditioned stimulus (CS). Through pairings of the CS with

the US, an association is formed such that the CS becomes predictive of the US. Eventually, after the CS-US association has been learned, presentations of the CS alone are capable of eliciting a fear response that was developed as a result of the US. This conditioned response (CR) is often characterized physiologically by changes in autonomic arousal and behavior, or in the case of the rodent, freezing behavior. Once the CS-US association has been formed, the CR can then be extinguished by giving multiple presentations of the CS alone, in the absence of the US. The initial CS-US pairing is not forgotten during the extinction process, as the fear almost always returns after standard extinction training with renewal, reinstatement, or the passage of time (Bouton et al., 2006). Extinction learning, not to be confused with the process of mere forgetting, is an inhibitory process during which the relationship and expectancy of the CS-US pairing is modified (Sotres-Bayon et al., 2006). By presenting the CS repeatedly, in the absence of any US, one can reevaluate the predictability of the CS, thus learning that a stimulus that was once associated with threat has become safe. Uncovering information behind the mechanisms involved in fear acquisition, and extinction in particular, has wide clinical implications, as the most common and validated treatment for anxiety disorders involves exposure-based therapy, which relies heavily on extinction principles for reevaluating existing contingencies (Rothbaum and Davis, 2003). Strong cross-species preservation of the neural circuitry implicated in fear extinction learning is supported by human and nonhuman animal extinction studies, further bolstering the translational credibility of rodent models for studying fear regulation and extinction.

ACQUISITION AND EXPRESSION OF CONDITIONED FEAR

Decades of probing into the neural circuitry underlying fear learning have yielded data from specified lesion, inactivation, electrophysiological, molecular, and pharmacological studies, confirming the amygdala to be a key structure involved in acquisition of conditioned fear (Milad and Quirk, 2012). During standard auditory cue fear conditioning, both somatosensory and auditory thalamic inputs converge on the lateral nucleus of the amygdala (LA) simultaneously or in close temporal proximity (Collins and Pare, 2000; Sotres-Bayon et al., 2006),

such that after repeated pairings, the CS presentations alone are capable of eliciting activity within the LA. See Figure 44.1 for schematic representation of neural circuitry implicated in fear learning and memory.

While the basal (BA) and lateral (LA) nuclei are considered to make up the primary sensory interface involved in fear learning and acquisition, the central (CE) nucleus is the amygdala's interface to fear response systems (Maren, 2001). After integration via the BLA (basolateral amygdala), relevant sensory information responsible for eliciting a behavioral or autonomic response is relayed to the CE through both direct and indirect thalamic and interamygdalar projections (Milad and Quirk, 2012; Sotres-Bayon et al., 2006). After the intraamygdaloid message has been relayed to CE, the CE elicits physiological responses via its divergent projections to downstream efferent structures that target various hypothalamic and brain stem nuclei responsible for engaging autonomic responses such as increased heart rate, blood pressure, respiration, freezing behavior, acoustic startle, and glucocorticoid release (Maren, 2011). Auditory tones or distinct sensory cues are not experienced in isolation, and surrounding contextual and environmental factors have a profound effect on the acquisition of conditioned fear and the resulting fear memory. Projections from the hippocampus, specifically the CA1 region, to the basal nucleus of the amygdala (BA) are implicated in contextual information processing during fear acquisition (Bouton et al., 2006; Phelps and LeDoux, 2005), and lesions to dorsal hippocampus disrupt both acquisition and expression of contextual fear (Kim and Fanselow, 1992; Phillips and LeDoux, 1992). While the CE remains the prime amygdalar site responsible for eliciting autonomic responses and fear behaviors, hippocampus-BA

integration of contextual information can alter downstream CE activity and affect subsequent behaviors. The hippocampus can modulate fear expression by altering contextual fear directly or by influencing amygdala-specific cued fear as animals are capable of using contextual cues to retrieve the meaning of a CS appropriate to a given context (Maren, 2011).

Increased spike firing in amygdala neurons, and long-term potentiation (LTP), or enduring synaptic plasticity, have been shown to occur at synapses in the hippocampus and amygdala during fear conditioning and expression (Milad and Quirk, 2012). Glutamate receptor signaling in the amygdala and hippocampus, through both NMDA and AMPA receptors, has also been shown to be crucial for fear acquisition and expression, further confirming the role of these two structures in fear acquisition and expression. Disruption of various downstream signaling cascades, including protein kinase A (PKA) (Bourtchouladze et al., 1998), mitogen-activated protein kinase (MAPK), and phosphatidylinositol 3 kinase (PI3K) in the amygdala and hippocampus, has also been shown to disrupt learning in both contextual and auditory fear conditioning paradigms (Chen et al., 2005; Schafe et al., 1999).

EXTINCTION OF CONDITIONED FEAR

After CS-US associations have been acquired and consolidated, modifications of the initial fear memory are possible. For example, repeated presentations of the CS (in the absence of any US) may ultimately result in a decreased conditioned fear response and reinterpretation of a formerly threatening cue, transitioning the CS into a nonnoxious stimulus. Through multiple presentations or sessions, this new form of inhibitory

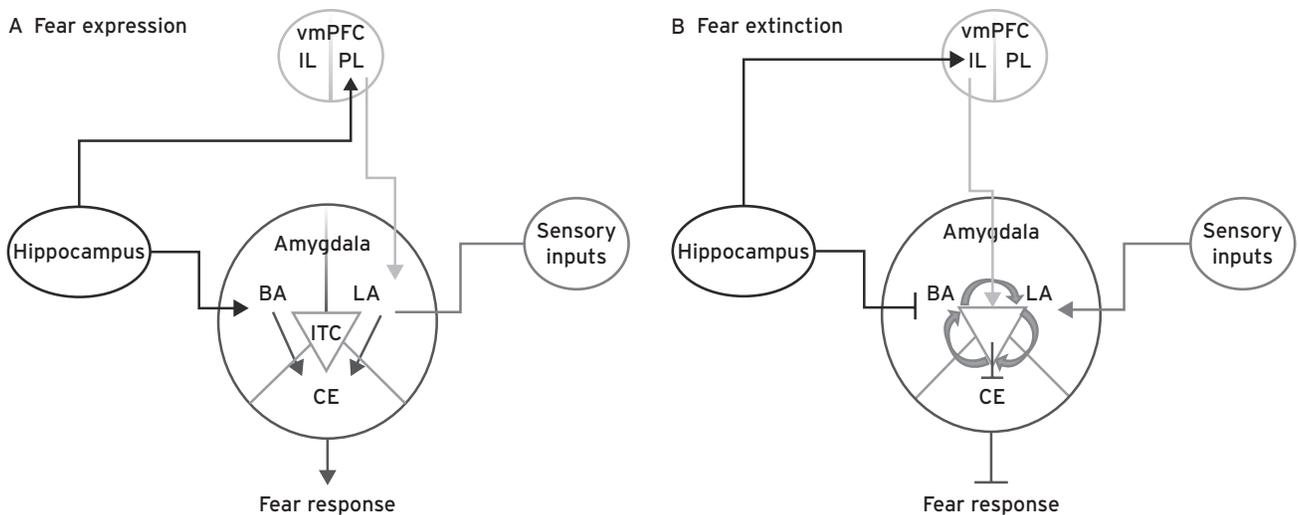

Figure 44.1 Neural circuitry of fear expression and extinction. (A) During acquisition and expression of conditioned fear, projections from PL and thalamic nuclei (mediating converging sensory information) excite LA neurons, while hippocampal projections (mediating contextual inputs) lead to excitation of BA neurons directly or indirectly via connections with PL. LA and BA neurons activate CE output neurons, which project to downstream brain stem and hypothalamic nuclei responsible for mediating physiological responses, resulting in fear expression. (B) During extinction of conditioned fear, hippocampal projections (mediating contextual inputs) lead to divergent excitation of IL neurons and inhibition of BA neurons. IL projections directly activate GABAergic ITC cells within the amygdala. Integration of ITC, BA, and LA inputs during extinction result in a suppression of CE output neurons, resulting in a lack of physiological response and suppression of fear expression. Arrowheads delineate pathway excitation; straight ends delineate pathway inhibition. (BA, basal amygdala; LA, lateral amygdala; CE, central amygdala; vmPFC, ventromedial prefrontal cortex; PL, prelimbic cortex; IL, infralimbic cortex; ITC, intercalated cells). For simplicity, connection arrows are delineated as being unidirectional, although bidirectional projections exist. (Figures adapted from *Hormones and Behavior*, in press, Pattwell et al.)

learning results in an extinction of the initial conditioned fear memory. While the amygdala itself plays a significant role in extinction learning, lesions to cortical areas have also been shown to interfere with extinction learning, demonstrating that the extinction processes require top-down control and interactions between both cortical and subcortical regions (LeDoux, 2000; Maren and Quirk, 2004).

The prefrontal cortex has been widely accepted to play a role in extinction of conditioned fear, as it is important for adjusting behaviors appropriately when the emotional salience of a given stimulus changes (Sotres-Bayon and Quirk, 2010). The ventromedial prefrontal cortex (vmPFC), in particular, has been shown to be important for making the switch from fear expression to fear inhibition during fear extinction learning and retention of extinction memory (Phelps et al., 2004). Further subdividing this cortical area, distinct subregions within the vmPFC have been differentially implicated in the expression and extinction of conditioned fear in the rodent (Sotres-Bayon and Quirk, 2010). Specifically, the dorsally located prelimbic (PL) cortex is associated with production of conditioned fear responses and expression of conditioned fear behaviors, whereas the more ventrally located infralimbic (IL) cortex is associated with inhibition of conditioned fear responses typically seen during successful extinction learning and upon recall of extinction memory (Myers and Davis, 2007). Importantly, the vmPFC–hippocampus network can modulate extinction learning by picking up on contextual cues present in the surrounding environment (Maren, 2011) and lead to appropriate alterations in plasticity. During repeated presentations of a previously negative CS, in the absence of a US, the vmPFC exerts inhibitory effects on amygdala circuitry, particularly through its excitatory glutamatergic projections to intra-amygdalar inhibitory GABAergic interneurons (Milad and Quirk, 2012; Sotres-Bayon et al., 2006). These inhibitory interneurons, or intercalated cells (ITC cells), receive projections from PL or LA neurons during fear conditioning to relieve inhibition on inhibitory CE neurons, thus resulting in expression of fear and associated autonomic responses. During extinction learning, however, a subset of these ITC cells can be activated by inputs from IL, which together with its modulation by the hippocampus can lead to downstream active inhibition of CE output neurons, thus decreasing fear expression and the associated physiological responses. These complex interactions between the vmPFC, amygdala, and hippocampus during extinction of previously conditioned fear memories are necessary for adjusting behavioral and autonomic responses in rapidly changing environments, and vmPFC–hippocampus–amygdala circuitry is altered in patients with impairments in extinction learning associated with PTSD (Mahan and Ressler, 2011).

DEVELOPMENTAL TRANSITIONS IN FEAR ACROSS THE LIFE SPAN: ECOLOGICAL SIGNIFICANCE

In children and other species, fear responses are developmentally delayed and seemingly emerge when fear expression fits the ecological niche of a particular developmental stage.

The developing fear response continues to be modified and sculpted throughout ontogeny to fit the dynamic needs of the immature organism transitioning to adulthood. This delayed emergence and modification of fear expression has been documented in myriad species, including humans and rodents, for both natural and learned fears. More recently, the neural basis for developmental changes in fear learning has been described in rodents, some of which will be reviewed here. First, we describe the emergence of amygdala-dependent learned fear to the CS odor cue around postnatal (P) day 10, along with its control by corticosterone (CORT) through P15. Second, we describe the emergence of hippocampal-dependent context fear learning around weaning. Together, these results indicate that the emergence of learned fear depends upon the developmental emergence of new brain circuit capabilities. These circuits provide animals with a nervous system and behavioral repertoire adapted to their changing ecological niche from the nest to independence. This approach of defining increased learning ability as the brain matures has been enormously helpful in providing insight into brain function.

More importantly, current developmental research has highlighted the importance of modification of existing fear circuitry to alter the developing animals' behavior to fit the dynamic ecological niche associated with development. We highlight two examples. First, we review literature showing the importance of maternal presence in suppressing fear learning through suppression of amygdala plasticity. Second, we review the surprising recent demonstration of suppressed contextual fear during a brief period during adolescence. These results illustrate the importance of developmental adaptations as animals' move through different ecological niches ranging from a helpless, essentially poikilothermic neonatal pup to the weanling developing skills for independence to the adolescent embarking on an independent life.

DEVELOPMENT OF CUE FEAR: INFANCY TO SEMI-INDEPENDENCE

Research over the past few decades has provided a basic understanding of the ontogeny of fear learning in infant rat pups. It is a history of slowly discovering the importance of assessing learning through pups' ecological niche rather than an immature version of the adult. In the case of infant animals, it is critical to assess fear development within the context of attachment and the infant's dependency on the caregiver for survival.

EARLY-LIFE LIMITATIONS ON FEAR/AVOIDANCE LEARNING: CUE FEAR CONDITIONING

Across species, infant fear learning is characterized by limitations and constraints. For example, during the temporally limited imprinting period in chicks, a moderate electric shock paired with the surrogate caregiver actually enhances following of the surrogate, although this same procedure supports avoidance learning after the imprinting critical period closes. Similarly, pairing of an odor and pain (moderate intensity shock, tail pinch, or rough handling by the caregiver) in rat

pup results in a strong learned approach to the odor present during the pain (Camp and Rudy, 1988; Sullivan et al., 2000). This paradoxical preference learning occurs despite a robust pain response in pups. Thus, rat pups have an attenuated-cue fear-learning circuit, but more paradoxically, pups learn to approach odors previously associated with moderate pain. We refer to this early period in pups' life as the Sensitive Period for attachment, which ends at P10, and is illustrated in Figure 44.2. As is discussed in the following, this odor-pain learned approach response seems to have relied not only on a suppressed fear system but also activation of the rat pups' attachment system and learning about the caregiver.

AMYGDALA AND EARLY-LIFE LIMITATIONS ON FEAR/AVOIDANCE LEARNING

Evidence suggests that a lack of amygdala plasticity plays a leading role in pups' attenuated fear learning during the Sensitive Period. Specifically, the amygdala is not recruited during infant learning in controlled classical fear conditioning outside the nest nor within natural learning paradigms with an abusive mother used to deliver the aversive stimuli within the nest (Rainekei et al., 2012; Rainekei et al., 2010b). As was reviewed previously, in older animals including rodents and humans, the amygdala is a critical brain area for fear learning. At least in very young neonatal pups, lack of amygdala plasticity in early-life learning is due in part to amygdala immaturity, with peak neurogenesis and nuclei subdivision occurring as early as the first week of life, which is quickly followed by peak synaptogenesis at P10-20 (Berdel et al., 1997). Importantly, significant synaptic plasticity, as indicated by amygdala basolateral LTP, emerges at the same age as the emergence of amygdala-dependent fear learning (reviewed in Sullivan and Holman, 2010).

ECOLOGICAL PERSPECTIVE ON EARLY-LIFE LIMITATIONS ON FEAR/AVOIDANCE LEARNING

From an ecological perspective, an attenuated fear-learning system appears to have adaptive value since young rat pups rely on odor learning to support attachment to their mother.

Specifically, in early life, rat pups cannot see or hear and rely on their sense of smell to interact with the mother and attach to her nipples, using the maternal odor. The diet-dependent maternal odor is learned. An evolutionary explanation that we have suggested for this paradoxical learning proposes that it is better for an altricial infant to have a bad caretaker than no caretaker, as an altricial infant rat is dependent upon access to the mother's milk, her warmth, and protection. We further suggest that the fear-learning system is suppressed in early life and that a very broad range of both painful and nurturing stimuli function as a reward to support the learning that is critically important for pup survival (for review, see Sullivan and Holman, 2010).

It should be noted that pups can learn to avoid odors if paired with malaise, such as that produced by a LiCl injection or strong 1.0 mA shock, although unlike the adult, this learning does not depend upon the amygdala (Shionoya et al., 2006; Smotherman, 1982). Together, decades of research indicate that amygdala-dependent fear (cue learning) is not learned by infant rats during the Sensitive Period, although nonamygdala odor avoidance can be learned in perinatal rats provided the aversive stimuli produces malaise (strong shock, LiCl). This failure to engage amygdala plasticity for fear learning is coincident with engagement of the attachment circuitry and paradoxical support of approach/preference learning, despite pups experiencing pain.

DEVELOPMENTAL TRANSITIONS IN CUE FEAR: ROLE OF CORTICOSTERONE

While the developmental emergence of cue fear learning parallels amygdala plasticity and maturation, pharmacological manipulations of pups' CORT proved to be a critical factor in amygdala's functional emergence. Specifically, CORT manipulation uncovered a learning circuit that is malleable by the early environment, which further sculpts the fear learning circuitry to fit pups' ecological niche. As we outline the effects of CORT on pup fear learning, it is important to know that, unlike adults, which mount a robust CORT increase when stressed, infant rats have a Stress Hyporesponsive Period (SHRP) where painful and stressful events typically fail to increase pups'

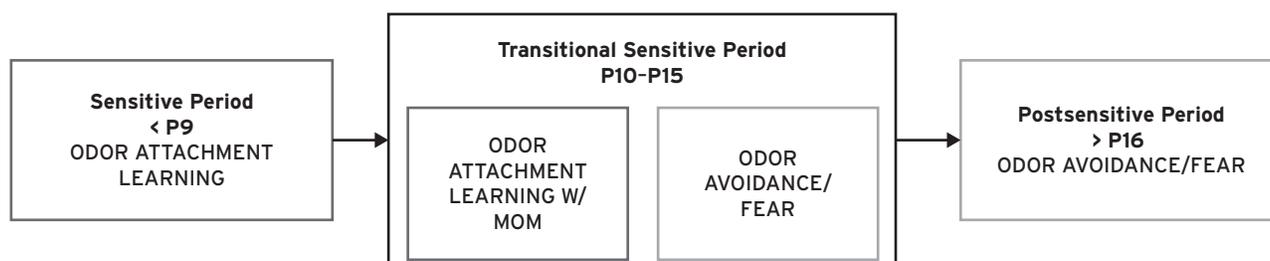

Figure 44.2 This schematic represents rat pups' developmental transitions associated with odor-0.5mA shock conditioning. Pups have a sensitive period for attachment learning through P9: odor-0.5mA shock conditioning results in a learned odor preference and a new maternal odor used by pups for attachment (illustrated by Dark gray box), regardless of maternal presence. Fear cue learning emerges at P10 but also begins the Transitional Sensitive Period (from P10 to P15) when CORT level can determine whether fear is learned: decreasing CORT either pharmacologically or naturally through maternal presence prevents fear learning and supports attachment learning (Dark gray box), while increasing CORT permits fear learning (Light gray box). Pups P16 and older learn to fear odors previously paired with shock (Light gray box), regardless of maternal presence and represents the Postsensitive Period.

CORT (Dallman, 2000). Sensory stimulation provided by the mother during nursing and grooming seems to control the pups' SHRP, with prolonged removal of the mother's stimulation (i.e., maternal deprivation procedure) causing increasing CORT, although replacement sensory stimulation returns CORT to normal SHRP levels (VanOers et al., 1998). The SHRP is hypothesized to protect the developing organism from the negative influences of stress hormones, such as reduced brain size that is associated with decreased mitosis, myelination, and granule cell genesis. More recent data outlined here also suggests that the SHRP protects pups from learning to avoid or fear their caregiver during the normal, periodic rough treatment pups receive from mothers as she enters and leaves the nest.

Recently, stress-induced heightened rough maternal care has proven to be an ecologically relevant paradigm that produces a premature elevation in pups' CORT (Gilles et al., 1996). This model relies on insufficient bedding material for the mother's nest building and is a continuous stressor for the mother and pups. The mother repeatedly engages in nest building, which causes her to spend longer time away from her pups, but also to trample on and transport pups more frequently, although pups gain weight normally (Rainekei et al., 2012).

CORT modifications and stress have immediate effects on pups' brain and behavior, including determining pups' odor-shock learning: if CORT is elevated, pups learn avoidance/fear, but with low CORT pups learn odor approach/attachment. Specifically, a systemic or intra-amygdala injection of CORT during 0.5mA odor-shock conditioning is sufficient to support amygdala-dependent fear learning in Sensitive Period pups (Moriceau and Sullivan, 2006). Conversely, decreasing CORT, either systemically or when restricted to the amygdala in older pups (P10-16), is capable of reinstating attachment learning and blocking fear. This is in sharp contrast to the modulatory role of CORT in adult fear conditioning, where fear/avoidance learning is simply strengthened or weakened by the level of CORT.

The critical importance of CORT has also been demonstrated in an ecologically significant manner. Specifically, being reared by a mother handling her pups roughly (i.e., insufficient bedding paradigm) can prematurely increase pups' CORT and ends the SHRP early. Specifically, pups reared with this aberrant rearing have early termination of the SHRP but also premature termination of the Sensitive Period and access to amygdala-dependent fear learning (reviewed in Sullivan and Holman, 2010).

Naturalistic suppression of the CORT system is also able to block fear learning in young pups and provides ecological relevance to the important role of CORT. Specifically, attenuation of the shock-induced CORT release has been demonstrated by maternal presence in older animals, a phenomenon known as social buffering. This naturalistic maternal social buffering not only blocks amygdala-dependent fear learning but also reinstates the attachment odor learning of a new maternal odor (Moriceau and Sullivan, 2006). After P15, only fear will be learned during an odor-shock conditioning with maternal presence, and social buffering is no longer sufficient to either block fear or support attachment learning. Furthermore, we have verified the causal

relationship between maternal presence and suppression of a shock-induced CORT release in pups' odor aversion learning by systemic and intra-amygdala CORT infusions, which then permit pups to learn odor aversions even in the presence of the mother (Moriceau and Sullivan, 2006).

DEVELOPMENT OF CONTEXT FEAR LEARNING: WEANING TO PERIADOLESCENCE

Previous work has shown that, in rats, contextual fear learning ontogenetically emerges at weaning age when pups are beginning independent life (Rainekei et al., 2010; Rudy, 1993). Other hippocampal-dependent behaviors, such as latent inhibition, spontaneous alternation, and spatial navigation, have been assessed in rat pups and appear to emerge at a slightly younger age (reviewed in Rainekei et al., 2010a). It should be noted that contextual fear conditioning is not a unitary phenomenon, nor is the hippocampus the sole supporter of this learning and memory. Indeed, context can be broadly characterized by configural (the environment as a whole or the relationship between environmental elements) and elemental (isolated or specific features or cues in the environment) conditioning, with the latter more dependent upon hippocampus-amygdala interactions. The complexity of context learning and its interaction with the hippocampus and amygdala remains controversial and has received little attention developmentally.

Furthermore, developmental studies have rarely directly assessed the causal relationship between context learning and the hippocampus, which is problematic because contextual fear learning involves structures other than the hippocampus. However, by weaning, the hippocampus seems sufficiently mature for learning-associated plasticity (Benes et al., 1994), and silencing of the hippocampus in postweanling rats abolishes contextual fear learning (Rainekei et al., 2010a). The hippocampus is divided into distinct sections and basically a trisynaptic circuit relaying information through the dentate gyrus (DG), CA3, and CA1, with each hippocampal subdivision implicated in different aspects of context fear learning and unique developmental trajectories that continue through adolescence. Importantly, at least a few important neuronal characteristics associated with plasticity do not emerge until the second to third week of life, including LTP and glutamatergic synapses (reviewed in Rainekei et al., 2010a). The implications of infant fear memories formed before maturation of the hippocampus and contextual learning has yet to be explored. However, this lack of context constraint on learning likely has implications for fear behaviors that might be appropriate in one place but not another.

ENDURING EFFECTS OF INFANT ODOR-SHOCK AND MATERNAL ODOR LEARNING: CUE AND CONTEXT

Basic and clinical research has long recognized the importance of early-life experience, especially trauma within attachment,

in producing particularly pronounced vulnerability to later life psychiatric disorders in humans, as well as rodent and non-human primate animal models (Monk et al., 2003). However, onset of most psychopathologies does not occur until later in life, generally around periadolescence, although possibly expressed as deficits in social behavior early in life (Letcher et al., 2012), which has been modeled in the rodent (Rainecki et al., 2012).

The questions of *how* early disruptions to infant attachment effects later behavior remains largely unclear, although nonhuman animal models (maternal separation/deprivation, rearing environment alteration, CORT manipulation, neonatal handling, etc.) have provided a clear link between infant experience, stress, and later life neurobehavioral deficits that appear to target many brain areas, including the amygdala, cerebellum, prefrontal cortex, hippocampus, and stress axis. Since the amygdala and hippocampus are targets of the early life stress, later life fear conditioning is impacted.

The infant odor-shock manipulation described here also appears to target the amygdala. Specifically, experience with paired odor-shock in early life appears to cause not only accelerated maturation of the amygdala and termination of early-life attachment learning sensitive period (Rainecki et al., 2012; Rainecki et al., 2010b), but also enduring effects related to depressive-like behavior. Importantly, unpaired odor-shock conditioning, which does not produce cue or context learning, producing later life heightened anxiety (reviewed in Sullivan and Holman, 2010), does not alter either early-life attachment learning or later life fear learning (Sevelinges et al., 2011). Thus, the pain of shock is not the critical factor producing many of the enduring effects of infant experience; rather, it is the pairing of the odor-shock and activation of the learning attachment circuitry that is critical for enduring effects. Additional literature, which has modeled early-life adversity using infant shock, suggests that the predictable versus unpredictable manner of early shock influences emotional outcome and learning.

ODOR VALUE: THE IMPORTANCE OF THE INFANT ODOR IS RETAINED INTO LATER LIFE BEHAVIOR—IMPLICATIONS FOR FEAR AND ANXIETY

The attachment odor learned by infants continues to be approached into adulthood, even when it was learned through odor-pain pairings. The odor continues to be used in attachment through reproduction, consistent with other species and imprinting. The infant-learned attachment odors, including those associated with pain, also continue to elicit both enhanced olfactory bulb neural responses and attenuated amygdala activation and conditioned fear into adulthood.

The clinical literature suggests that cues associated with early-life trauma are not always avoided. Indeed, a strong attraction and comfort can sometimes be elicited by the cues associated with early-life maltreatment (Haynes-Seman, 1987). We have begun to explore the value of the odor associated with early-life maltreatment and questioned whether this odor could restore or rescue (bring to control levels) brain and behaviors

in animal models of psychiatric disorders. Specifically, a recent study showed that infant experience with a maltreating mother rat or odor-shock conditioning produced later life depressive-like behaviors, as indicated by performance in the forced swim test and sucrose consumption test (Sevelinges et al., 2011). These depressive-like behaviors were associated with a deficit in paired pulse inhibition in the amygdala, suggesting altered synaptic function. Interestingly, presentation of the shock-associated conditioned maternal odor during both the forced swim test and sucrose test brought performance and amygdala functioning to control levels. We speculated that the odor may have acquired the value of a “paradoxical safety signal,” since safety signals reduce conditioned fear responses, normalize forced swim tests (decrease immobility), and normalize amygdala activity. A “safety signal” is typically formed when it predicts the absence of the aversive event in a fear conditioning paradigm and subsequently produces a reduction in fear and/or anxiety and amygdala activity in both humans and rodents (Pollak et al., 2008; Sevelinges et al., 2011). We speculate that, since the mother or her attributes are viewed as a safety signal, and the rat pups’ natural maternal odor or learned (odor-shock) maternal odor normalizes their adult depressive-like behavior and amygdala paired pulse inhibition deficit, this odor could be functioning as a safety signal.

BRAIN MATURATION, ANXIETY, AND ADOLESCENCE

The transition between the dependence of childhood to the independence of adulthood is a dynamic developmental period, known as adolescence, associated with emotional, psychological, social, and physical changes, and hormonal fluctuations ultimately leading toward sexual maturity (Schulz et al., 2009; Sisk and Zehr, 2005). The very nature of adolescent development serves to launch an organism toward reproductive success and survival and is associated with increased exploratory behavior and emotional reactivity (Spear, 2000). As such, it is probable that within this adaptive and necessary developmental transition exist neural and behavioral characteristics divergent from those of dependent children and independent adults, which are uniquely specific to the adolescent.

Adolescence, in particular, is a period of increased prevalence of psychopathology (Monk et al., 2003), and it is estimated that over 75% of adults with fear-related disorders met diagnostic criteria as children and adolescents (Kim-Cohen et al., 2003). Prevalence of emotional disorders, and anxiety disorders specifically, is heightened during adolescent years, occurring in as many as 1 in 10 adolescents (Kessler et al., 2005); yet, due to insufficient or inaccurate diagnosis and a dearth of pediatric and adolescent specialized treatments, fewer than one in five anxious children or adolescents are expected to receive treatment for their disorders (Merikangas et al., 2010), leaving a vast number with inadequate or no treatment (Lieberman et al., 2006). The inflated frequency of anxiety disorders in pediatric and adolescent populations highlights the importance of recognizing neural mechanisms of fear regulation from a developmental perspective. This

increased prevalence for anxiety and affective disorders during adolescence coincides with a period of massive cortical rearrangement that is normatively accompanied by drastic cognitive and behavioral changes (Spear, 2000), and longitudinal studies of brain maturation illustrate a nonlinear process that is not complete until early adulthood (Giedd et al., 1999; Gogtay et al., 2004).

ADOLESCENT FEAR—BEHAVIORAL AND MOLECULAR FINDINGS IN MICE AND HUMANS

As previously outlined in earlier chapter sections, responses in the amygdala and medial prefrontal cortex are inversely related, and decreased functional connectivity between the two regions has been associated with anxiety in adults (Milad and Quirk, 2012). Advances in the developmental neurobiology of emotion regulation have yielded substantial evidence of protracted development of prefrontal regions relative to phylogenetically older regions (Casey et al., 2005). Consistent with developmental changes in structural maturation, immature prefrontal functioning and top-down control of subcortical regions have been observed in adolescents relative to adults during emotional contexts (Hare et al., 2008).

The investigation of learned fear acquisition and extinction across development in humans has previously been limited due to the nature of aversive conditioning paradigms, which often utilize an electric shock as the US. As this US is not as feasible for use with children, various groups have recently employed techniques incorporating loud tones (Craske et al., 2008), aversive airpuffs to the larynx (Grillon et al., 1998), or airpuffs paired with loud screams and aversive faces (Schmitz et al., 2011). Because variations with US delivery and behavioral assessment in humans yield inconsistent results (Glenn et al., 2011), animal models have more recently been relied upon for studying developmental effects of fear learning.

Studies examining the mechanisms of hippocampal-dependent contextual fear and amygdala-dependent cued fear acquisition and extinction in rodent models have traditionally excluded adolescent ages, choosing to focus on earlier developmental ages and adults (Moriceau and Sullivan, 2006; Rudy, 1993). Recently, these previously excluded intermediate ages have been investigated due to the translational relevance of studying fear during adolescent development, when increased prevalence of fear-related disorders typically emerges.

DEVELOPMENT OF CUE FEAR EXTINCTION AND PFC

Building upon studies of structural and functional human brain maturation, a number of translational studies have begun to explore extinction of amygdala-dependent cue fear in rats across development. While cue fear learning emerges during early infancy (Sullivan et al., 2000), adult-like extinction fails to develop until much later. For example, while the mPFC is critical for adult extinction, inactivation of the mPFC

fails to disrupt long-term extinction in preadolescent, P17 rats, suggesting that a system more similar to forgetting may underlie early-life behavioral decrement during an extinction paradigm. Indeed, adult-like mechanisms of extinction appear intact around weaning. Specifically, inactivation of the mPFC fails to disrupt long-term extinction in preadolescent, P17 rats, yet inactivation of mPFC does disrupt this memory in P24 rats (Kim et al., 2009). Extinction training in these young age groups leads to increased levels of pMAPK in both the prelimbic and infralimbic cortices, suggestive of nonspecific, global mPFC activity, as opposed to the inverse pattern of IL/PL activity typically seen with successful adult extinction retention. A similar diffuse activation pattern, with less focal activity, has also been observed in the prefrontal cortex of human children and adolescents during tasks requiring cognitive control (Durstun et al., 2006). Developmental studies of innate fear regulation in rodents demonstrate that during innate fear, the mPFC of infant rats is neither active nor responsive while the prelimbic cortex becomes active in preadolescence but does not yet regulate freezing behavior, whereas the PL in adolescents becomes functional, and activity corresponds to an appropriately expressed cued fear response (Chan et al., 2011). These developmentally altered roles in the mPFC are independent of amygdala activity, which suggest that mPFC neural circuitry develops enhanced capacities for fear regulation as an animal matures. In addition, injections of anterograde tracers placed into the BLA of developing rats show that amygdalocortical connectivity is late maturing, with fiber density reaching a plateau circa P45, thus confirming that maturation of this circuit continues into adolescence (Cunningham et al., 2002).

Despite demonstrating equivalent anxiety-like behavior, as assessed by open field, adolescent mice have been shown to exhibit increased acquisition of cued fear compared with preadolescent and adult mice (Hefner and Holmes, 2007). This heightened fear response during adolescence, typically defined in the rodent as the phase surrounding the 10 days prior to sexual maturation at postnatal day P40 (Spear, 2000), has been found to be resistant to extinction (McCallum et al., 2010). Adolescent rats require either twice as many extinction trials or a pharmacological intervention, such as the NMDA-agonist D-cycloserine, to achieve reductions in fear expression comparable to younger or older rats (McCallum et al., 2010). Attenuated fear extinction learning during adolescence is associated with a lack of activity in prefrontal cortex, specifically infralimbic cortex, as assessed by pMAPK immunohistochemistry (Kim et al., 2011) and c-Fos immunohistochemistry (Pattwell et al., 2012) compared with younger and older ages. Electrophysiological recordings at IL and PL synapses across development reveal that a fear conditioning-induced potentiation of PL synapses present in adult mice is absent in adolescent mice. Furthermore, extinction-induced enhancement of IL synaptic plasticity in adult mice is lacking in adolescent mice (Pattwell et al., 2012). Diminished fear extinction, relative to children and adults, has been shown in adolescent humans, with a cued fear-conditioning task involving aversive sounds (Pattwell et al., 2012), and parallels rodent findings as shown in Figure 44.3. Additionally, behavioral tasks using fearful or

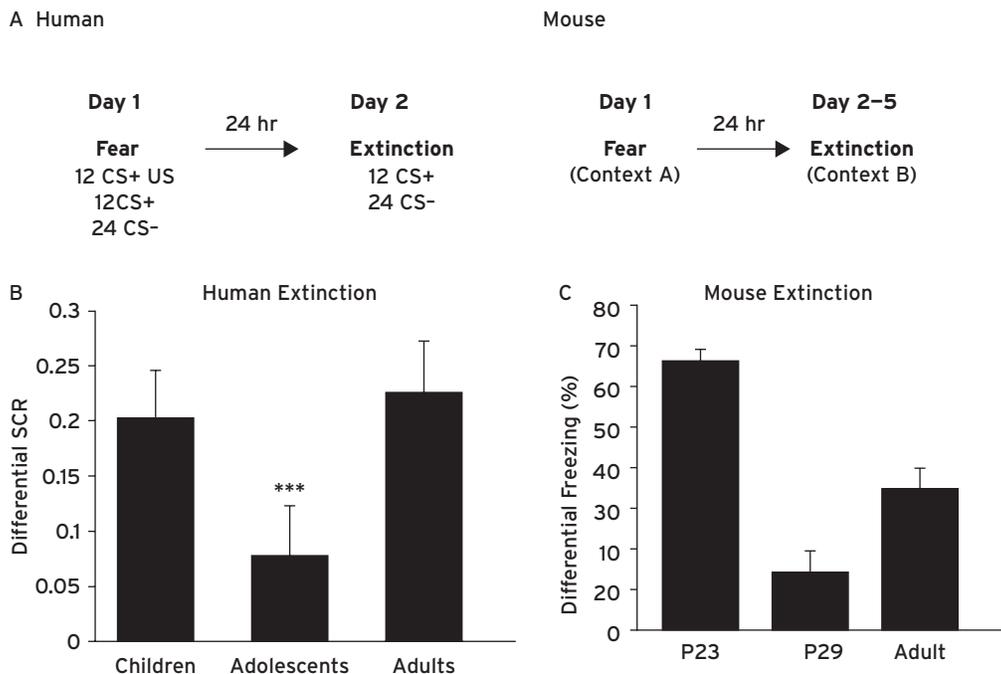

Figure 44.3 Cued extinction learning and spontaneous recovery across development in mice and humans. (A) Behavioral paradigms for parallel fear conditioning experiments in humans and mice. (B) Analysis of extinction indices ([Averaged first two extinction trials]—[averaged last two extinction trials]) reveals a main effect of age group for humans, such that adolescents display attenuated fear extinction learning compared with children and adults (adolescent 0.05916 ± 0.06904 ; children 0.25435 ± 0.04839 ; adults 0.22510 ± 0.05931). (C) A lack of extinction learning and retention of extinction memory is observed in adolescent mice, as displayed by a significantly decreased differential extinction indices ([Day 1, Tone 1] – [Day 4, Tone 5]) compared with older and younger ages (P23 $66.5\% \pm 2.75$; P29 $14.72\% \pm 4.79$; P70 $35.17\% \pm 4.89$). (Adapted from Figure 1 of Pattwell et al., 2012.)

screaming faces result in heightened amygdala activity (Hare et al., 2008) and fear learning (Glenn et al., 2011) in adolescent humans, compared with younger children. Taken together, these studies reveal a nonlinear pattern in fear extinction learning and blunted regulation of amygdala-dependent fear responses during fear extinction in adolescents, which may help provide novel insight into the heightened prevalence of anxiety disorders during this period and on treating developing populations with anxiety, as the main form of CBT relies on extinction principles.

The importance of the mPFC in cued extinction learning and extinction retention is widely accepted, and inactivation of the mPFC alone is enough to impair the retrieval of cued extinction memory (Sierra-Mercado et al., 2006). Importantly, and often disregarded, however, is that inactivation of the hippocampus alone before extinction training also leads to impaired retrieval of cued extinction memory the following day, suggesting that mPFC may be an important target of the hippocampus for modulating extinction learning and recalling extinction memory in rodents and humans (Quirk and Mueller, 2008). Furthermore, contextual modulation of amygdala activity requires the hippocampus (Maren, 2011).

It is important to note that in cases where cued extinction retention and the degree of successful extinction are assessed in the same context as where conditioning took place, it may be difficult, even impossible, to claim that poor extinction learning solely results from insufficient vmPFC regulation. Many

of the extinction paradigms in the existing literature fail to account for important hippocampal contributions associated with contextual information. Distinct populations of neurons exist in the BA for triggering the activation of neuronal circuits responsible for integrating sensory and contextual information (Herry et al., 2008). These populations of “fear neurons,” and “extinction neurons,” as they are called, are differentially connected with the hippocampus and mPFC. Particularly, hippocampal inputs to BA preferentially target the “fear neurons,” over the “extinction neurons,” suggesting that hippocampal input to these neurons may override the retrieval of cued or contextual extinction memory, a likely contributor to the phenomenon of fear renewal. Fear renewal, or the fear that returns upon experiencing a reminder outside of the extinction context, remains a major obstacle for clinical treatment of anxiety disorder in humans (Mahan and Ressler, 2011) and may be the result of tipping the balance between activation between specific neuronal circuits in the hippocampus and amygdala. This clinical observation lends support for finding better treatment methods, perhaps through further investigation of hippocampally mediated techniques, such as contextual-based extinction.

DEVELOPMENT OF CONTEXTUAL FEAR AND CONTEXTUAL EXTINCTION

From a developmental perspective, the notion of hippocampal involvement in mediating both contextual and cued fear

processing is a promising one. While the hippocampal cytoarchitecture is well established by 34 weeks *in utero* in the human (Arnold and Trojanowski, 1996), as is noted earlier, development of this structure has been shown to continue through adolescence in both rodents and primates (Benes et al., 1994). Longitudinal scans of children and adolescents, between the ages of 4 and 25 years, reveal that postnatal hippocampal development is not homogenous and that distinct maturational profiles exist for specific subregions (Gogtay et al., 2006). While overall hippocampal volume remains constant throughout these ages, posterior subregions of the hippocampus show volumetric enlargement over time while anterior regions undergo substantial volumetric reductions. The cause of these heterogeneous volume changes remains unknown, but it is hypothesized that they may be due to differences in neuronal proliferation, synaptic production and/or pruning, myelination, or glial alterations and may parallel differences in functional development (Gogtay et al., 2006). Of note, the anterior region of the hippocampus, which exhibits decreases in volume as a function of age, is reciprocally connected to the prefrontal cortex (Cavada et al., 2000), amygdala (Pitkanen et al., 2000), and hypothalamic-pituitary-adrenal axis (Bannerman et al., 2004)—regions implicated in fear and anxiety. This heterogeneous postnatal development of hippocampal subregions, specifically the volumetric decreases observed in the anterior region, correlates with contextual fear data showing that contextual fear expression during preadolescent ages is intact, is temporarily suppressed during adolescence, and then reemerges again during adulthood (Pattwell et al., 2011) (Fig. 44.4), supporting the notion that development is not a linear process in which neural maturation occurs uniformly in one direction or another. Rather, an intricate reciprocal balance

between neural development in one brain region may lead to alterations in another region. Convergent adolescent and adult rodent contextual fear data further highlight the importance of the developing hippocampus in mediating fear responses. The aforementioned literature on human and nonhuman primate hippocampal development suggests a developmentally sensitive fear circuitry model, depicted in Figure 44.5.

A PROPOSED MODEL OF ADOLESCENT NEURAL CIRCUITRY IN FEAR LEARNING AND MEMORY

Crosstalk between CA1 and CA3 regions of the hippocampus is required for contextual fear expression and cued fear extinction in the adult brain. The adult brain integrates specific hippocampally mediated contextual inputs, thalamic sensory inputs, and prefrontal cortical inputs within intra-amygdalar circuits to produce an appropriate behavioral response. As shown in Figure 44.5C and D, the successful retrieval of cued fear memories across preadolescence, adolescence, and adulthood (McCallum et al., 2010; Pattwell et al., 2011, 2012) suggests that sensory inputs to the lateral amygdala (LA) are functional across postnatal development. As adolescent mice are impaired on contextual fear tasks, one possibility is that preadolescent mice rely more heavily on available sensory inputs and are relying solely on elemental cues of odor, texture, and so on, to retrieve the contextual memory rather than its more complex configural elements. The successful retrieval of contextual fear memories during early, preadolescent ages, as previously shown in Pattwell et al. (2011), also suggests that aforementioned age-dependent volumetric decreases in the CA1 region of the hippocampus have yet to occur and a

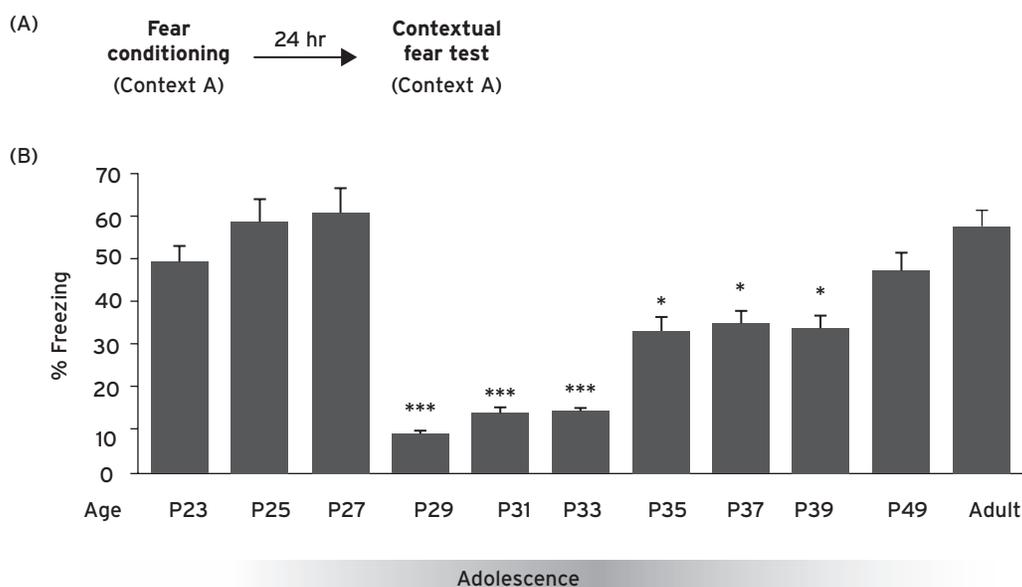

Figure 44.4 Hippocampal-dependent contextual fear memory across adolescent development. (A) Mice of all ages were fear conditioned (fear cond) with three tone–shock pairings. Twenty-four hours later, they were returned to the conditioning context (Context A) and freezing behavior was scored. (B) Adolescent mice (P29–P39) froze significantly less than both younger (P23–P27) and older (P49–P70) mice. All results are presented as a mean ± SEM, determined from analysis of 7–10 mice per group (fear conditioning) and 28 mice per group (novel object placement) (* $p < 0.05$, *** $p < 0.001$). (Adapted from Figure 1, Pattwell et al., 2011.)

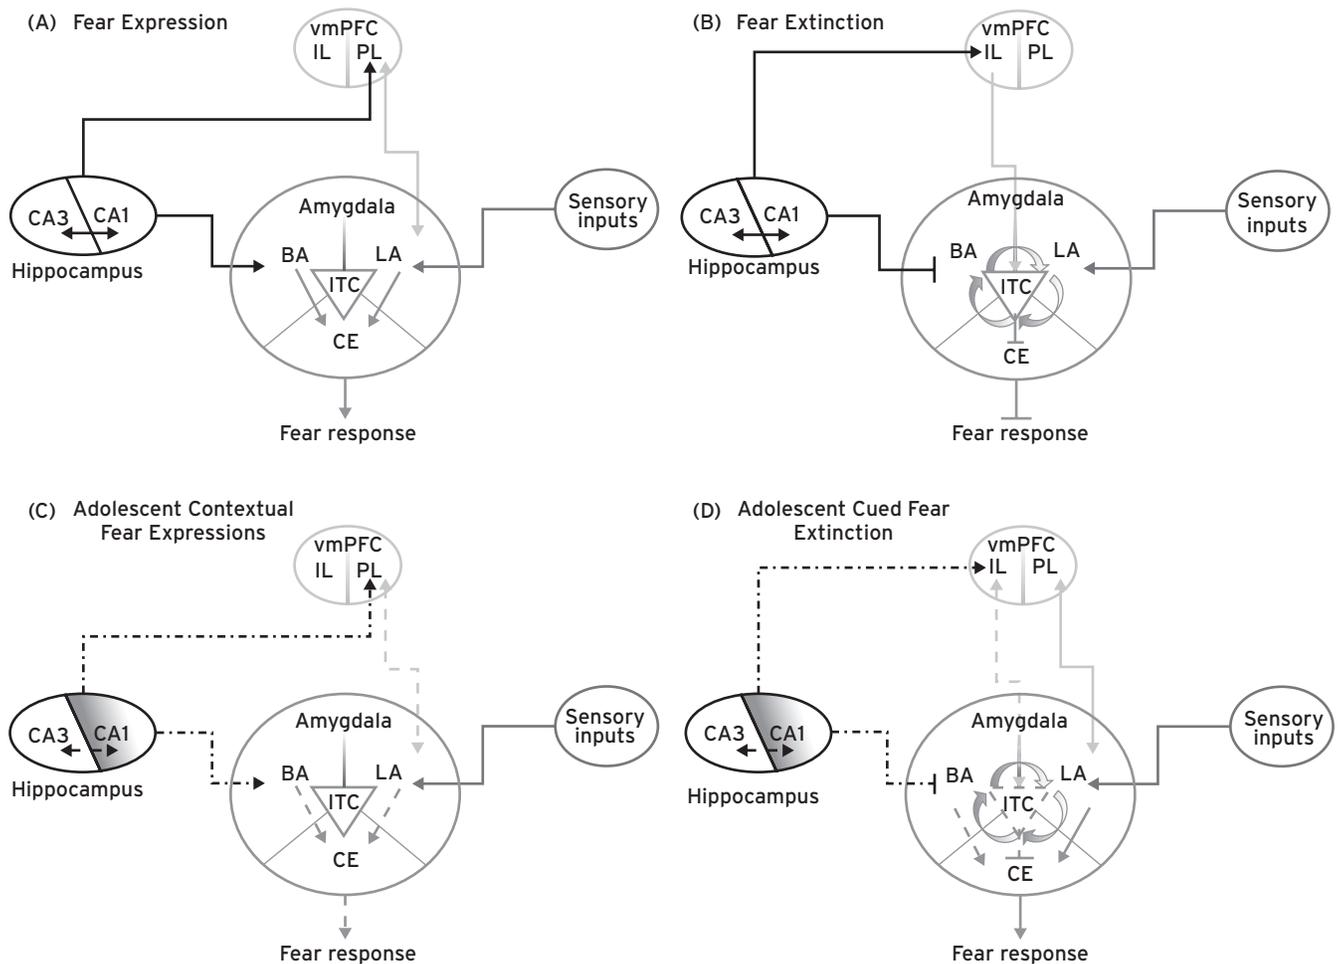

Figure 44.5 Developmental neural circuitry of fear expression and extinction. Diagrammatic representation of adult neural circuitry implicated in (A) fear expression and (B) fear extinction. (C) A lack of contextual fear expression in adolescent mice can be traced to immature CA1. Without proper CA1–PL and CA1–BA inputs, there is a lack of downstream activation of CE output neurons, resulting in a diminished or suppressed fear response. (Weak signals and low functional connectivity represented by dotted lines.) (D) A lack of CA1 excitatory input to IL combined with a lack of CA1 inhibitory input to BA, typical in cued fear extinction, results in reduced inhibition of CE output neurons, resulting in fear expression and a lack of extinction. Arrowheads delineate pathway excitation; straight ends delineate pathway inhibition (BA, basal amygdala; LA, lateral amygdala; CE, central amygdala; vmPFC, ventromedial prefrontal cortex; PL, prelimbic cortex; IL, infralimbic cortex; ITC, intercalated cells). For simplicity, connection arrows are delineated as being unidirectional, although bidirectional projections exist. (Figures adapted from *Hormones and Behavior*, in press, Pattwell et al.)

potential overabundance of active synapses between CA1–PL and CA1–BA allow for successful retrieval and expression of contextual fear. Because rodent data has also shown that bidirectional IL–amygdala synapses are later maturing than PL–amygdala synapses (Chan et al., 2011), it could also be a possibility that the amygdala has not yet received any conflicting IL inputs during preadolescence on contextual fear tests, allowing for PL–amygdala synapse activation. During adolescent development in both rodents and humans, however, vmPFC maturation can be observed (Cunningham et al., 2002; Gogtay et al., 2004), and as IL–amygdala synapses are refined, activity in PL–amygdala circuits must override IL–amygdala inputs, allowing for fear expression. Because CA1–PL connectivity is necessary for this interaction, and because CA1 undergoes volumetric decreases throughout adolescent development (Gogtay et al., 2006), which may be indicative of changes in synaptic pruning or myelination, CA1 inputs to BA and PL are not sufficient for fear expression in adolescent mice

(as represented by the shading out of CA1 and the resulting dotted arrows in Fig. 44.5C and Fig. 44.5D). This hypothesis is also supported by blunted responses in synaptic neurotransmission in BA of P29 mice upon contextual fear tests, as shown via electrophysiological experiments (Pattwell et al., 2011). Importantly, CA1 is responsible for retrieval of fear memories, while CA3 is responsible for fear acquisition and encoding of fear memories. Consistent with behavioral findings, adolescent mice acquire and consolidate contextual fear memories, despite showing impairments in retrieval and expression. Preliminary c-Fos data suggests that CA3 is active during retrieval in adolescent fear-conditioned mice (Pattwell et al., unpublished data), supporting the notion that the fear memory has been encoded and retrieved, allowing for retrieval at later, postadolescent ages when the neural circuitry underlying fear learning and memory has reached stabilized, adult-like structural and functional maturation. Further, it has been shown that inactivation of CA1 can interfere with CA3 communication with

extrahippocampal regions (Lee and Kesner, 2004), such as the amygdala. With little or no fear expression and corresponding CA1-PL or CA1-BA inputs, contextual extinction and contextual reconsolidation updates appear to work remarkably well in adolescent mice to persistently attenuate fear memories, possibly due to a lack of CA1 inputs, allowing for intra-amygdalar activation of ITC cells with little or no competing input from CA1 or PL. CA1-vmPFC connectivity has also been shown to be important for retrieval of cued fear extinction, and it is possible that the lack of extinction learning and retention of extinction memory in adolescent mice (McCallum et al., 2010) may result from a similar mechanism, consistent with the developmental role of CA1 maturation in fear learning and integration with IL/PL circuits. Furthermore, due to delayed developmental maturation of cortical GABAergic transmission that extends into adolescence, it is plausible that an imbalance in inhibitory synaptic transmission during adolescence interferes with synaptic plasticity in the mPFC-hippocampus-amygdala network (Kilb, 2011).

CONCLUDING REMARKS

Here we outlined the development of the neural circuitry implicated in fear learning and discussed developmental transitions in fear learning beginning with its emergence and modifications throughout infancy and adolescence. Together, the clinical and basic research suggested that animal models may provide a plausible developmental model of fear neural circuitry that may underlie infant and adolescent fear behaviors. In particular, the development of amygdala-dependent cue fear learning first emerges in midinfancy and followed the emergence of hippocampal contextual fear learning as the infant transitions to independence. Importantly, the fear circuitry of early life needs to be explored within the context of the unique attachment circuitry of early life, where pups must learn an attachment to the caregiver. This highlights the unique importance of social cues from the mother suppressing amygdala-dependent cue learning (Barr et al., 2009; Moriceau and Sullivan, 2006; Sullivan et al., 2000). We also highlighted a unique developmental transition when the contextual fear learning is suppressed during adolescence and reemerges during adulthood (Pattwell et al., 2011). Finally, we review literature on cued fear extinction learning, which appears intact during early ages in both mice and humans, but attenuated during adolescence, and intact again in adulthood (McCallum et al., 2010; Pattwell et al., 2012). Together, these findings suggest a nonlinear pattern in the development of fear learning during infancy and adolescence, which differs from prototypical fear responses associated with both younger and older ages (Casey et al., 2008), and illustrate the importance of assessment of neurobehavioral development within the ecological niche and developmental demands of each developmental period. Infants transition from complete dependence on the caregiver with a gradual transition to independence and learning about the world. The developing organism undergoes multiple transitions during this early-life development with each transition likely requiring some unique features to adapt to the environment. For example, infancy is developmental period

of complete dependence on the caregiver, when attachments must be formed for survival and access to food and protections. We suggest that cue fear learning suppression ensures that the infant only learns to approach the caregiver, despite periodic painful interactions with the caregiver. Next, as the animal transitions to the extraneust environment, contextual fear learning may become important as the animal learns about spatial characteristics of the environment. However, as the animal approaches adolescence, the suppression of contextual fear learning may provide benefits since increased exploration becomes critical for reproductive success and access to additional resources. Thus, leaving the safety and stability of its environment in search of reproductive success is likely facilitated by a suppression of contextual fear to contribute to the fearlessness required for exploring new environments, typically seen with this age group (Spear, 2000). As specific danger cues are still relevant during this novelty-seeking period, cued fear expression remains intact and resistant to extinction during adolescence. Combined, these behaviors allow the adolescent to remain both exploratory and cautious, thus optimizing chances for survival and success.

As one considers how these transitions in fear learning and expression apply to psychopathology, it is important to understand that aberrant fear behaviors are associated with traumatic situations. Indeed, both infancy and adolescent traumatic experiences have been shown to alter these developmental fear transitions in both basic and clinical studies. The animal literature described here provides insight and clues to potential mechanisms unique to infancy and adolescence, with implications for unique needs for assessment and treatment across development. For example, in infancy, the failure to avoid an abusive caregiver or the failure to show immediate aberrant behavior may not be relied upon as an index of well-being during early life. Another example, in adolescence, notes that the same features of adolescent brain development required for survival may contribute to treatment resistance for disorders such as PTSD or anxiety. If nonlinear development of the neural circuitry implicated in fear learning has evolutionarily primed the adolescent to exhibit attenuated fear extinction, CBT relying on exposure therapy may need to be reconsidered as a treatment option, and new avenues may need to be explored to develop novel treatments for this developmentally distinct period to determine when, during development, specific treatments may be most effective.

45 | FUNCTIONAL NEUROCIRCUITRY AND NEUROIMAGING STUDIES OF ANXIETY DISORDERS

MADELEINE S. GOODKIND, ANETT GYURAK, AND AMIT ETKIN

INTRODUCTION

Fear and anxiety serve adaptive survival functions, signaling to the organism the presence of potential danger in the environment. Fear is the immediate response triggered by a potentially harmful event or object, and anxiety is characterized by prolonged heightened vigilance for looming danger in the environment. The circuitry supporting fear responses is remarkably well preserved phylogenetically across species. Anxiety and fear reactions encompass a wide range of subjective, physiological, behavioral, and cognitive responses that are often experienced subjectively as unpleasant. While the line between functional and pathological fear and anxiety can be vague, once these reactions are present chronically, and to a heightened degree that generalizes to signals beyond those that are objectively dangerous, one sees emergence of clinical anxiety disorders.

Anxiety disorders are among the most common psychiatric disorders, with an estimated one-year prevalence of 18% and a lifetime prevalence of nearly 30% (Kessler et al., 2005). They negatively impact everyday functioning and quality of life (Mendlowicz and Stein, 2000). Anxiety disorders impose a considerable burden on society in terms of both treatment and workplace costs related to absenteeism and lost productivity. Meta-analyses of randomized clinical trials of CBT (cognitive-behavioral therapy) in anxiety yield medium to large effect sizes (e.g., Stewart and Chambless, 2009), however, with a negative correlation between the representativeness of the sample and the effect sizes (Stewart and Chambless, 2009). These data suggest that while in well-controlled situations we are able to provide effective treatment, the effectiveness wanes as situations become more complicated. We are also not yet able to predict who is likely to respond to treatment and why. Thus, given the enormous burden of anxiety disorders to the individual and the community, and the inability of current treatment options to sufficiently alleviate this burden, it is important to bring new tools to bear on understanding the underlying pathophysiology of anxiety disorders to inform and direct treatment. An important route to understanding pathophysiology of anxiety disorders is neuroimaging.

Pathological fear and anxiety responses have traditionally been characterized as resulting from alterations in brain systems that normally control negative emotions, especially fear. Thus, investigating the neural underpinnings of anxiety disorders begins with discussion of fear-related circuitry (see also Graham and Milad in Chapter 43 of this volume for a more

in-depth discussion). However, because some anxiety disorders also involve a broader range of emotional disturbances, such as an absence of positive affect or perturbations of other negative emotions (e.g., anger), the constellation of emotional dysfunctions indicates a wider abnormality in emotional systems beyond fear circuitry. Thus, our goal is to present an updated and expanded version of our previously published integrative framework of emotional functioning in anxiety disorders that encompasses disruptions in *emotional reactivity* and highlights deficits in circuits *regulating emotional responses* (Etkin, 2009).

We organize the chapter as follows: we start by introducing the neural circuitry relevant for fear conditioning and extinction, and emotional reactivity and regulation more broadly, by reviewing relevant neuroimaging studies. We then review neuroimaging studies of social anxiety disorder, specific phobia, generalized anxiety disorder, panic disorder, and posttraumatic stress disorder. We exclude obsessive compulsive disorder from our discussion because it appears to have a distinct neural signature from the other anxiety disorders (Etkin, 2009) and is extensively covered elsewhere in this book (see Ahmari and Simpson, Chapter 48). In each disorder, we highlight areas of disruption or preservation in emotional reactivity and emotion regulation. Although anxiety disorders are highly comorbid with each other (Kessler et al., 2005), they are differentiated by the type of cues that lead to anxious responses, the magnitude of exaggerated fear responses, and whether negative or positive affect are more generally dysregulated. To further diagnostic differentiation, we highlight disorder-specific perturbations within our integrative framework. Similarly, where there are overlaps between disorders, these are also highlighted. With a cross-diagnostic framework in mind, we examine the potential neural markers common to many or all anxiety disorders. This approach is consistent with recent research that finds single disruptions in neural circuitry often cut across many distinct syndromes.

CORE PROCESSES IN ANXIETY DISORDERS: EMOTIONAL REACTIVITY AND REGULATION

CONDITIONED FEAR AS A MODEL OF ANXIETY DISORDERS

Classical conditioning models, extensively studied in experimental animals, have elucidated how emotionally significant

events are learned and remembered. In fear conditioning, a neutral stimulus that is paired with an aversive unconditioned stimulus eventually comes to signal the imminent onset of something aversive. Although fear conditioning serves an adaptive and self-preserving function, it is also believed to be implicated in the development of anxiety disorders. Fear extinction is another critical aspect of the conditioning process and refers to diminishing fear response after repeated presentations of the conditioned stimulus alone, without the unconditioned stimulus. This process is thought to reflect fear inhibition rather than unlearning (Phelps et al., 2004). Fear extinction has important implications for understanding both how an adaptive fear response transitions into an anxiety disorder and also for understanding exposure-based psychotherapeutic treatments.

Classical conditioning was first proposed as important for anxiety disorders by Watson and Rayner in their case of “Little Albert” (Watson and Rayner, 1920). In fact, relative to participants without anxiety disorders, people with anxiety disorders show greater conditioned fear responses during both acquisition and extinction phases (Lissek et al., 2005). Moreover, patients with anxiety disorders also show greater subjective and physiological fear reactivity to cues signaling safety (in addition to those that signal an aversive stimulus; Mineka and Oehlberg, 2008), consistent with the hypothesis that these patients are less able to inhibit fear responses when presented with safety signals. As such, a fear conditioning/extinction-based model explains many of the core symptoms of anxiety disorders, such as the hypervigilance for danger and avoidance of cues that provoke anxious cognitions and behaviors. However, many anxiety disorders involve emotional dysfunction beyond simply fear learning. As such, we now consider a broader view of emotion and its regulation.

EMOTIONAL REACTIVITY AND REGULATION

In the previous section, we reviewed fear responsivity. In this section, we expand on this and also include subjective, physiological, and behavioral responses to other negative emotions and to positive emotions. Emotional reactivity refers to the type and magnitude of a response to emotion-eliciting events. Processing emotional information and reacting emotionally involves a large number of cortical and subcortical regions, which have been summarized in recent meta-analyses (Kober et al., 2008; Phan et al., 2002). Emotional reactivity disturbances in anxiety disorders may include excesses of other types of negative emotions (e.g., anger in posttraumatic stress disorder) or diminished positive emotion (e.g., in social anxiety disorder a failure to attend to positive feedback).

Emotion regulation encompasses a wide range of processes. Described by Gyurak and colleagues (2011) as an attempt to influence or modulate the intensity, duration, and type of emotion experienced, regulatory processes include those that happen deliberately and consciously as well as those that occur reflexively and outside of conscious awareness. Examples of the former include changing emotional responses through distraction, reappraisal, distancing, or suppression. In this case, emotion regulation can be antecedent focused, altering

emotions before they begin, or response focused, voluntarily modifying the expression of emotions. Antecedent-focused strategies are typically cognitive and include reappraising, detaching from, or distracting oneself from emotional stimuli; response-focused strategies include voluntary suppression of positive or negative emotional reactions. Studies of this type of regulation require participants to deliberately modify how they think about a given situation (e.g., “try to change how you view the situation to feel less negative emotion”) or what emotions they express (e.g., “hide your emotional reactions to the situation”).

Emotion regulation that occurs automatically (i.e., implicit emotion regulation) is characterized by the lack of a deliberate and conscious emotion regulatory goal, but it results in adaptive changes in behavior and emotional responding. This type of emotion regulation has received less study than explicit regulation. One way implicit emotion regulation has been measured is by using an emotional modification of the traditional Stroop conflict paradigm, in which participants view fear or happy emotional faces with the words “Fear” or “Happy” written across the front. In this task, participants identify the emotion on the face, disregarding the word that is written. Incongruence between the emotion on the face and the written word creates conflict, thereby slowing reaction time to identifying the emotion. This conflict is lessened (and reaction times are quicker) when an incongruent trial is preceded by an incongruent trial, suggesting that a regulatory mechanism is activated in the first incongruent trial and utilized in the second.

CORE STRUCTURES IN EMOTIONAL REACTIVITY AND REGULATION

AMYGDALA

The amygdala is an almond-shaped structure that sits below the temporal lobes and is associated, albeit not exclusively, with the experience of fear and anxiety (see Fig. 45.1). The human amygdala is activated in response to negative emotional stimuli and to unpredictability—cues that lead to feelings and behaviors associated with anxiety in both humans and nonhuman animals (Davis, 2002). Across species, the amygdala signals danger to an organism and provides a basis for avoiding such stimuli in the future. Lesions in the amygdala result in failure to avoid stimuli previously associated with danger (reviewed in Davis, 2002).

The amygdala is activated during the presentation of stimuli indicating fear and, more generally, when organisms are presented with salient, biologically relevant information. Suppression of neuronal activity in the amygdala leads to decreased expression of fear and anxiety across multiple species (Davis, 2002). In human participants, the amygdala is activated when participants view fearful expressions (Phan et al., 2002). Adolphs and colleagues (1995) describe a patient with bilateral calcification of the amygdala who subsequently showed selective deficits in the representation and identification of fearful facial expressions. However, this patient could represent and recognize other basic emotions. Processing of fear-specific stimuli and negative emotional stimuli generally

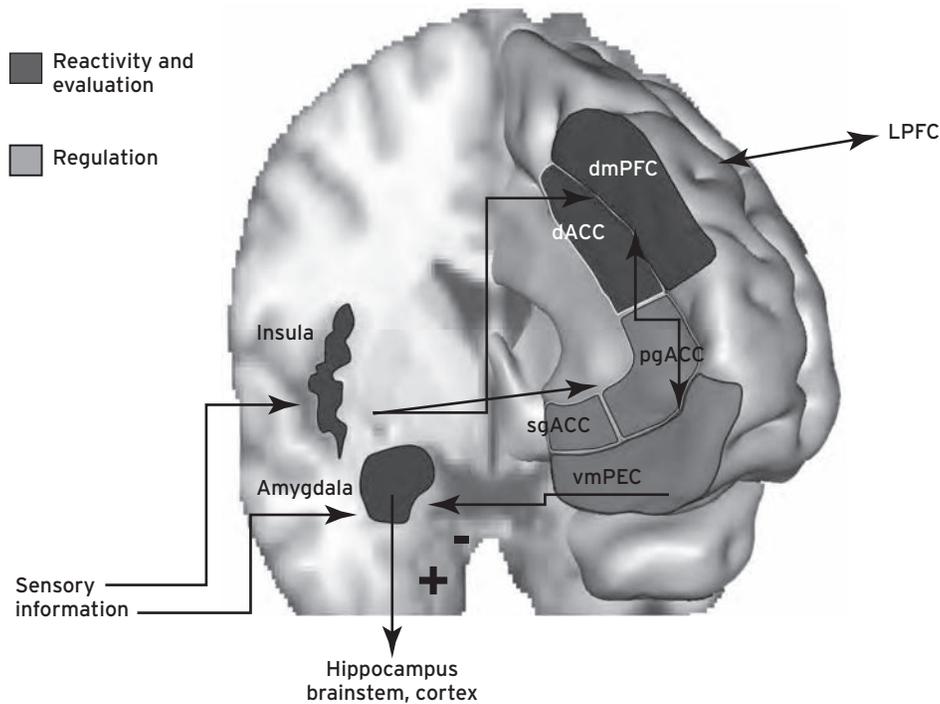

Figure 45.1 A limbic-medial prefrontal circuit view of emotional processing. Relevant structures are separated into two groups: those involved in emotional reactivity and evaluation and those important for emotion regulation.

can also occur outside of awareness and this also implicates the amygdala. When healthy participants are shown fearful facial expressions presented too quickly to be perceived, the amygdala is activated (Etkin et al., 2004). Additionally, the degree of amygdala activation correlates positively with self-reported anxiety and individual differences in anxiety (Stein et al., 2007).

The role of the amygdala in monitoring the environment for threatening (e.g., fear cues) and new information (e.g., unpredictable cues) implies a role for this region in hypervigilance, a symptom of many anxiety disorders. Amygdala activity is also associated with the physical reactions that accompany anxiety. In rats, increasing amygdala activity by injecting GABA antagonists leads to increases in blood pressure and heart rate (Sanders and Shekhar, 1991). Electrical stimulation of this region in human participants elicits feelings of fear, anxiety, and apprehension, and direct injection of benzodiazepines into the amygdala has anxiolytic effects (Davis, 2002).

The amygdala is critical in fear conditioning, as demonstrated by fear conditioning studies in experimental animals (Davis, 2002) and in humans (Phelps et al., 2004). The amygdala is activated when participants view stimuli that predict an aversive event, and amygdala lesions in human and experimental animals lead to deficits in conditioned and unconditioned fear (Davis, 2002). For example, lesions in the amygdala result in disrupted Galvanic skin responses during classical fear conditioning tasks (LaBar et al., 1995). In a neuroimaging meta-analysis, we report consistently increased amygdala activation during fear conditioning in healthy subjects (Etkin and Wager, 2007). Additionally, the amygdala is important when changes in conditioned responses occur, such as devaluation of a stimulus when it

is switched to signal aversive rather than appetitive information (Davis, 2002).

The amygdala is not a unitary structure, however, and can be partitioned into multiple subregions, each with specific efferent and afferent projections. Two subregions have been particularly well studied in the context of fear and anxiety, due to their roles in distinct aspects of the fear response. The basolateral amygdala (BLA) is the primary subregion that receives sensory information, coming in from the thalamus and sensory and association cortices, and in turn projects to thalamic and cortical regions, including those that provide input into the BLA (Davis, 2002). Research in rodents has found that the BLA evaluates and encodes the value of a threatening stimulus (Davis, 2002). In rats, the BLA responds differently to odors signaling positive versus negative stimuli and these reactions precede behavioral changes. In humans, the BLA responds to nonconsciously presented fearful emotional expressions (Etkin et al., 2004). Similarly, the lateral ventral amygdala in humans is most responsive to negative stimuli (especially if the stimuli signal impending negative information) (Whalen et al., 2008).

Cortical regions that project to and receive projections from the BLA include those involved in sensory functions and medial prefrontal regions (described in this chapter).

Another critical subregion is the centromedial amygdala (CMA) located dorsal to the BLA in humans, which has primarily subcortical projections, especially those to the brain stem hypothalamus, and periaqueductal gray (PAG) (Pitkanen, 1997). These projections may explain in part the physiological responses associated with fear, as the hypothalamus is important in sympathetic nervous system responding, and the brain stem and PAG with stereotyped species-specific defensive behavior. The CMA elicits these responses to information

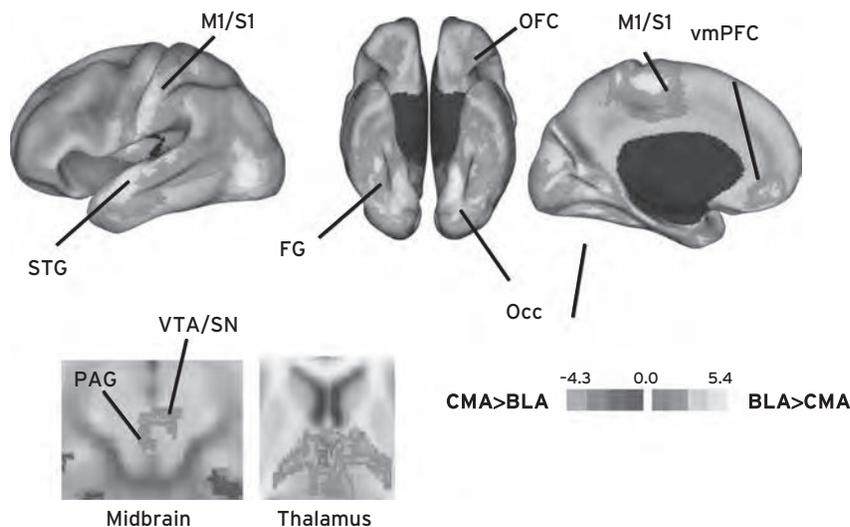

Figure 45.2 Differential connectivity of the basolateral (BLA) and centromedial (CMA) amygdalar subregions during resting-state fMRI. Findings are from a conjunction of two cohorts of healthy participants. The BLA connectivity was primarily cortical; CMA connectivity was primarily subcortical. Color scales represent *t* scores for the main effect of region in a voxelwise analysis. Red indicates that BLA connectivity is increased compared with CMA connectivity; blue, CMA connectivity is increased compared with BLA connectivity. FG, fusiform gyrus; M1/S1, primary somatosensory and motor cortices; Occ, occipital cortex; OFC, orbitofrontal cortex; PAG, periaqueductal gray; STG, superior temporal gyrus; vmPFC, ventromedial prefrontal cortex; and VTA/SN, ventral tegmental area/substantia nigra. (See color insert)

received from BLA, which represents its primary input. Stimulation of the CMA also results in increased attention, potentially through projections to cholinergic basal forebrain targets, suggesting the importance of this region in arousal in fear and in anxiety disorders. The differentiation between the mostly cortical connections of the BLA and the mostly subcortical connections of the CMA has also been recently demonstrated with human neuroimaging by Etkin and colleagues (2009) (see Fig. 45.2).

INSULA

Another core region in the limbic circuitry is the insula. Like the amygdala, the insula consistently activates in response to negatively valenced emotional stimuli (Phan et al., 2002) and in response to emotionally salient information (Craig, 2009). The positioning of the insula between both limbic and cortical targets makes it an important node in the fear circuit (see Fig. 45.1). The insula is heavily connected with the hypothalamus, PAG, and amygdala; this region receives projections from the amygdala and projects to the anterior cingulate cortex (ACC) (Craig, 2009). Moreover, functional connectivity between the BLA and anterior insula explains 40% of the variance in anxiety levels among control participants (Baur et al., 2012). Interoceptive awareness and monitoring the autonomic nervous system have been consistently linked to this region (Craig, 2009). For example, when attending to their heartbeats, insula activation is greater for individuals with higher levels of anxiety and greater sensitivity to their own bodily responses (Craig, 2009). Internal bodily responses are often perceived by people with anxiety disorders as dangerous, and the encoding of aversive interoceptive cues has been linked to the insula (Craig, 2009).

Individuals with panic disorder show heightened sensitivity to and concern about interoceptive cues, suggesting that the insula may be especially important for understanding this condition, but also of broader relevance to other anxiety disorders.

PERIAQUEDUCTAL GRAY AND HYPOTHALAMUS

These regions are also part of the core limbic circuit and are critical in the regulation of the autonomic nervous system. The PAG is important for active defensive reactions (Davis, 2002). Activation of the PAG correlates with feelings of dread in healthy control participants in the context of impending threat (Mobbs et al., 2007). Stimulating the PAG in experimental animals leads to avoidance, defensive aggression, and cardiovascular reactivity. Stimulation of the PAG in humans leads to cardiovascular reactivity similar to a panic attack. Participants also report experiencing fear and anxiety (along with a desire to stop the stimulation) (Davis, 2002). Moreover, greater activity is seen in the PAG as threats become more proximal (Mobbs et al., 2007). As such, this region is important for rallying the appropriate behavioral response to threat, an important aspect of anxiety and anxiety disorders. The hypothalamus, in particular its ventromedial portion, is heavily connected with the PAG and amygdala and is thought to coordinate and modulate defensive behaviors (Davis, 2002). Panic symptoms or behaviors can be induced by direct stimulation of the ventromedial hypothalamus in humans (Wilent et al., 2010) and experimental animals (Lammers et al., 1998). While the PAG and hypothalamus have not been the focus thus far on studies of clinical anxiety, their roles in the behavioral response to emotional stimuli suggest that they may be quite important.

HIPPOCAMPUS

Early characterization of the limbic system in animals included the hippocampus; however, in humans, this region is most often implicated in memory and has not been heavily studied in anxiety in humans. Human studies of anxiety disorders have also not consistently implicated the hippocampus. However, in a meta-analysis of emotion, Kober and colleagues (2008) found that anterior hippocampal areas contiguous with the amygdala are part of a core limbic group that was consistently activated in emotional tasks. The hippocampus itself, however, is not a unitary structure and can be split into distinct subdivisions. Animal studies have distinguished between dorsal hippocampal regions, important for memory and other cognitive functions, and ventral hippocampal regions, important for anxiety-related behaviors and heavily connected to the amygdala and hypothalamus (Bannerman et al., 2004). In humans, these regions correspond to the posterior hippocampus, which is preferentially connected to the pregenual ACC, posterior cingulate cortex (PCC), and precuneus, and the anterior hippocampus, which is preferentially connected to the amygdala, striatum, dACC, dmPFC, and precentral gyrus (Chen and Etkin, manuscript submitted). Dorsal hippocampal impairments in rodents (i.e., posterior hippocampus in humans) result in deficits in both fear memory and spatial memory (Heldt et al., 2007). Moreover, some molecular perturbations in the dorsal hippocampus can result in normal acquisition of fear memory, but a reduction in the extinction of conditioned fear (Heldt et al., 2007). Rodents with lesions in the ventral hippocampus (i.e., anterior hippocampus in humans) fail to avoid anxiety-provoking situations and show decreased stress responses (via corticosterone response; Kjelstrup et al., 2002). In anxiety disorders, the posterior hippocampus may be important for abnormalities in fear memory and extinction, while the anterior hippocampus may be important in general fear- or anxiety-related behaviors and responses.

PREFRONTAL CORTEX

The prefrontal cortex (PFC) is thought to be critical for the monitoring and regulation of emotion; this includes a very large swath of cortex, which can be meaningfully subdivided into smaller and more clearly differentiated regions. We have previously published a detailed description of prefrontal cortical areas as they relate to negative emotional processing and thus provide a more concise version here (see Etkin et al., 2011 for a review) (see Fig. 45.1).

THE LATERAL PREFRONTAL CORTEX

The dorsolateral (dlPFC) and ventrolateral (vlPFC) prefrontal cortices are commonly associated with emotion regulation (Gyurak et al., 2011). Along with their role in cognitive control and executive functioning, these regions are typically recruited in the context of deliberate, effortful, and conscious regulation of emotion (Gyurak et al., 2011). However, as described earlier, emotion regulation can occur more reflexively and outside of our awareness, and this type of

regulation implicates more medial prefrontal regions and is more directly relevant to fear- and anxiety-related regulation (Gyurak et al., 2011).

DORSAL VERSUS VENTRAL MEDIAL FRONTAL CORTEX

Regions of the medial frontal lobes, including the anterior cingulate cortex and medial prefrontal cortex (mPFC) have long been implicated in emotional processes. The original functional distinction between the dorsal and ventral ACC was that of cognitive versus emotional processing. However, consideration of more recent data suggests a more parsimonious distinction between these regions, which places the dorsal ACC (dACC) and dorsomedial prefrontal cortex (dmPFC) as important for the appraisal and expression of negative emotion and the ventral ACC (vACC) and ventromedial prefrontal cortex (vmPFC) as important for emotion regulation. Fear conditioning, and specifically fear acquisition, activates the dACC and dmPFC (Etkin et al., 2011), as does recall of fear memories and generation of fear-instructed fear responses in the absence of having undergone direct fear conditioning. Electrical stimulation of the dACC results in the subjective experience of fear. Moreover, areas of the dACC and dmPFC correlate with sympathetic nervous system activity in general and with interoceptive awareness of heartbeats. Thus, the dACC and dmPFC are critical in the appraisal, experience, and expression of fear. In terms of emotional reactivity more generally, beyond only fear, these regions are involved when participants face ambiguous or emotional conflict. Additionally, these regions are implicated in a number of other emotional situations, including those involving anger, pain, disgust, and rejection. Thus, evaluating emotional stimuli, conflict, and ambiguity involves overlapping neural circuitry as the evaluation and expression of fear. Moreover, these dorsal regions show positive connectivity with the amygdala during emotional tasks, again highlighting the role in emotional reactivity.

Many aspects of regulation draw on the vACC and vmPFC. These regions are important in fear extinction and recalling inhibitory extinction memories a day or more after training. Similarly, the vACC/vmPFC is activated when exposure to a distant threat occurs, suggesting it may be involved in planning adaptive responses, a regulatory function. In contrast to the dACC/dmPFC, the vACC/vmPFC shows a negative correlation with sympathetic activity and with PAG activation. Consistent with the role of these regions in regulating fear, the vACC and vmPFC are also involved in the regulation of other emotions and regulating emotional conflict. Similar to extinction of fear learning, the extinction of appetitive learning activates the vmPFC. Using the emotional conflict task, an incongruent trial that is preceded by an incongruent trial, during which conflict regulation has been increased, activates these ventral regions. Thus, the circuitry involved in the regulation of emotional conflict is comparable to that involved in extinction, likely reflecting a broader role for the vACC/vmPFC in implicit emotion regulation. Of note, the vACC does not regulate conflict arising from nonaffective stimuli, which instead is regulated by lateral PFC regions (Egner et al., 2008). Finally, the vACC/vmPFC shows negative connectivity

with the amygdala in a range of tasks. During explicit emotion regulation, the vACC may act as an intermediary between lateral prefrontal regions and the amygdala.

NEUROCIRCUITRY OF ANXIETY IN SPECIFIC DISORDERS

Recent neuroimaging studies have begun to characterize the distinct neural deficits associated with anxiety disorders. For example, in a meta-analysis looking across three anxiety disorders (posttraumatic stress disorder [PTSD], social anxiety disorder [SAD], and specific phobia), we find amygdala and insula hyperreactivity in all three disorders and in control participants during fear conditioning (Etkin and Wager, 2007; see Figs. 45.3 and 45.4). These results point to exaggerated engagement of fear circuitry across anxiety disorders. However, this meta-analysis also points to differences across the three disorders, for example, in regions important for emotion regulation. In the following sections, we review in greater depth the functional neuroimaging literature for similarities and differences across five anxiety disorders (SAD, specific phobia, generalized anxiety disorder, panic disorder, and PTSD). We emphasize those studies that include symptom provocation tasks (e.g., using sounds, images, or scripts to evoke disorder-specific symptoms), fear conditioning, or general emotional reactivity and regulation tasks (e.g., viewing emotional facial expressions).

SOCIAL ANXIETY DISORDER

Social anxiety disorder (SAD), also referred to as generalized social phobia, is a common anxiety disorder in the general

community, with a 12-month prevalence of 7% (Kessler et al., 2005). This condition is associated with significant functional impairments and typically has an early onset, with the majority of cases beginning before adulthood. Patients with SAD show negativity biases in terms of the interpretation and recall of social events; the condition is characterized by distorted negative beliefs about oneself and how a person believes he/she will be judged by others (Guyer et al., 2008); as a result, individuals with SAD experience an excessive and unreasonable fear of social interactions in which these individuals anticipate negative evaluation by others. Although some evidence has found that genetics and environment play important roles (Stein et al., 2007), the exact etiology is largely unknown.

Across studies that include symptom provocation tasks or stimuli involving emotional facial expressions, patients with SAD show heightened amygdala activation (Etkin and Wager, 2007). This heightened amygdala reactivity is reported in particular when individuals with SAD view negative or ambiguous (i.e., neutral) emotional expressions (for a review, see Freitas-Ferrari et al., 2010). Among negative emotional expressions, viewing angry and contemptuous emotional faces is associated with increased amygdala activation, including in both the right and left amygdala (Freitas-Ferrari et al., 2010). Results have been mixed regarding whether there are amygdala abnormalities in response to positive emotional stimuli (Phan et al., 2006). Heightened amygdala responses are also seen when individuals with SAD anticipate or perform public speaking tasks (Freitas-Ferrari et al., 2010), read stories depicting social transgressions (Blair et al., 2010), or view phobia-related words (Schmidt et al., 2010). These tasks presumably tap into the core features of the condition, namely, performing publicly and perceiving negative judgment by others.

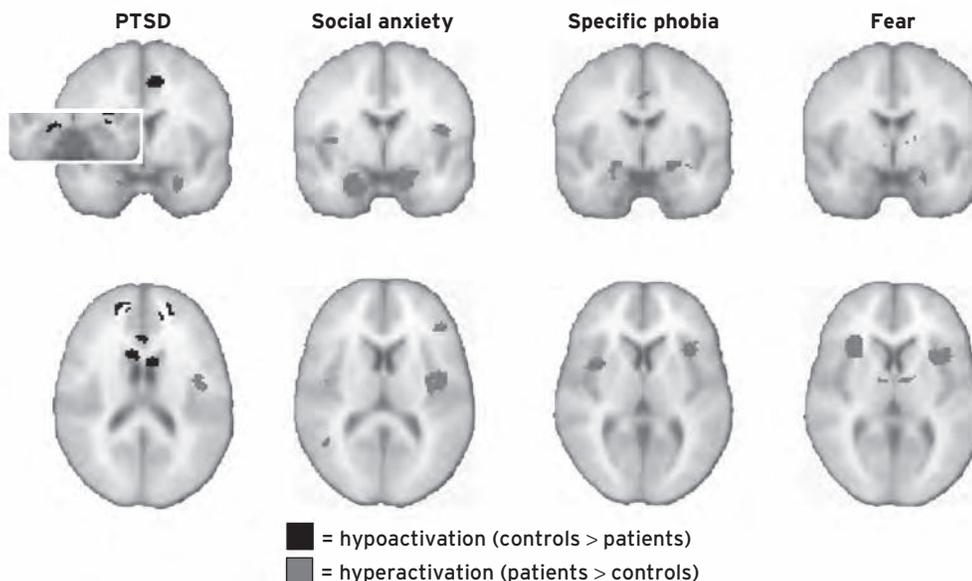

Figure 45.3 Clusters in which significant hyperactivation or hypoactivation was found in patients with PTSD, social anxiety disorder (SAD), and specific phobia relative to comparison subjects and in healthy subjects undergoing fear conditioning. Notable is common hyperactivation in the amygdala and insula. (Adapted from Etkin and Wager, 2007.)

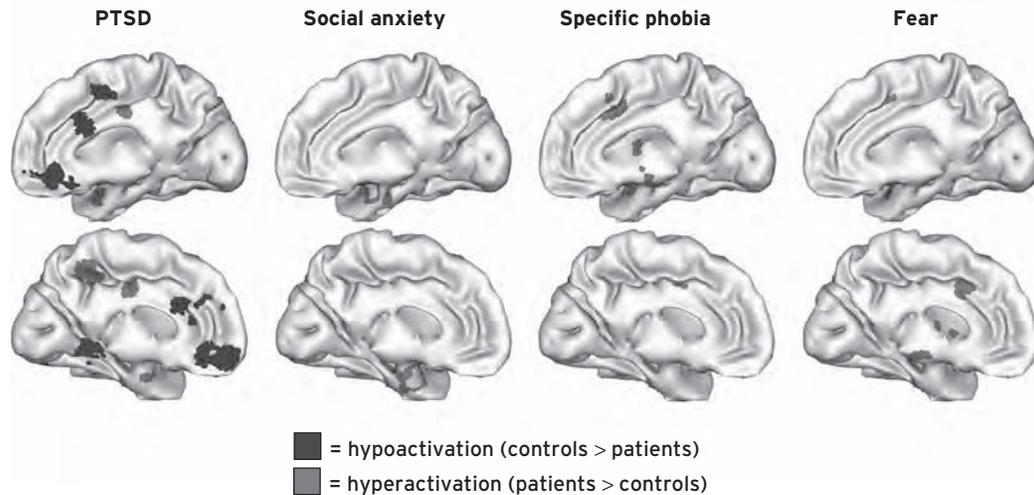

Figure 45.4 Clusters of significant hyperactivation or hypoactivation in medial prefrontal regions were found in patients with PTSD, social anxiety disorder (SAD), and specific phobia relative to comparison subjects and in healthy subjects undergoing fear. (Adapted from Etkin and Wager, 2007.)

Similar to many other anxiety disorders, patients with SAD show increased amygdala activity during aversive conditioning, with a peak response occurring later than in control participants (Freitas-Ferrari et al., 2010), suggesting less efficient and dysregulated fear circuitry. The degree of heightened amygdala activation is associated with symptom severity, including the number of DSM-IV symptoms (Battaglia et al., 2012) and the degree of trait anxiety and state social anxiety (Bruhl et al., 2011; Phan et al., 2006). Additionally, greater amygdala reactivity to social, but not physical, threat stimuli is associated with SAD symptom severity (Freitas-Ferrari et al., 2010). Following cognitive-behavioral therapy for SAD, patients show decreased amygdala activity compared with pre-treatment levels during a public speaking task (Furmark et al., 2002). The extent of amygdala decrease, along with that in the PAG and left thalamus, correlates with treatment response.

Insula dysfunction is also reported: across studies, patients with SAD show increased insula activation compared with control participants (Etkin and Wager, 2007). For example, increased insula activity has been reported when patients with SAD anticipate public speaking (Freitas-Ferrari et al., 2010), read stories of social transgressions (Blair et al., 2010), view negative emotional expressions (Freitas-Ferrari et al., 2010), and perform working memory tasks (Koric et al., 2011). Additionally, the extent of insula activation correlates with symptoms of SAD (Stein and Stein, 2008) and relates to attending to the meaning of social-phobia-related words (Schmidt et al., 2010). In connectivity analyses, patients with SAD show decreased connectivity between the anterior insula and dACC when viewing fearful emotional expressions (Klumpp et al., 2012), suggesting that exaggerated insula activity may result from insufficient downregulation by cognitive control regions. Previous work highlights the insula's role in interoception (Craig, 2009). Increased insular activation in patients with SAD is thought to reflect a heightened and persistent internal focus on interoceptive cues. For example, patients with SAD often believe that physiological responses to public performance

(such as feeling flushed, sweating, trembling hands) are pronounced and likely to be noticed by others. Treatment often focuses on teaching individuals to objectively evaluate their physiological responses and focus beyond their internal reactions (Huppert et al., 2003).

Frontal lobe differences are also seen in SAD. Specifically, there is evidence for increased vACC activation compared with control participants, particularly when viewing emotional faces (Freitas-Ferrari et al., 2010), and decreases in the vACC following CBT (Furmark et al., 2002). Stein and colleagues (2002) contrast viewing harsh versus accepting emotional faces among individuals with SAD. They report increased activation in the left inferior frontal gyrus and left parahippocampal gyrus in response to negative faces. During a stressful working memory task, patients with SAD and control participants activate lateral frontal regions important for cognitive control; only patients with SAD additionally activate right vLPFC and anterior insular regions (Koric et al., 2011), regions implicated in emotional processing.

However, despite widespread frontal activation during a number of tasks, patients with SAD are less likely to recruit the dlPFC and dACC during cognitive reappraisal tasks (Freitas-Ferrari et al., 2010) and during a measure of top-down attentional control (Blair et al., 2012). Patients with SAD show delayed dlPFC reactivity when faced with autobiographical stories of social anxiety (Freitas-Ferrari et al., 2010). When instructed to cognitively reappraise these autobiographical memories, patients with SAD fail to recruit the dACC and bilateral dlPFC and vLPFC. Greater subjective negative emotion after the reappraisal task (i.e., less successful regulation) is associated with reduced right dlPFC. Moreover, patients with SAD show reduced negative connectivity or even positive connectivity between amygdala and PFC regions (Guyer et al., 2008), suggesting ineffective regulation of the amygdala by prefrontal regions.

Taken together, neuroimaging studies shed light on the heightened and dysregulated emotion seen clinically in patients

TABLE 45.1. Summary of neuroimaging findings in anxiety disorders by brain region. The weight of the arrows reflects the strength of the supporting data. ↔ = evidence for no difference from control participants; † = evidence for both hyperreactivity and hyporeactivity.

with SAD and point to increased limbic activation without effective top-down control (see Table 45.1). Patients with SAD show hyperreactivity in the amygdala and insula both to social-anxiety-specific tasks and to emotional faces. It may be the case that for individuals with SAD, emotional facial expressions serve as phobia-specific stimuli due to an increased focus on others' reactions. Dysregulation in frontal lobe regions is also apparent. Patients hyperactivate the vACC and vIPFC when viewing emotional facial expressions and performing cognitive tasks. Thus, they show hyperactivation in regions important for regulation during emotional reactivity and nonemotional tasks. However, during explicit emotion regulation tasks, they fail to recruit lateral prefrontal regions to the extent of control participants. Moreover, these prefrontal regions do not exert sufficient control over limbic areas. Effective cognitive-behavioral treatments exist and seem to normalize many of the emotion circuit problems seen at baseline in patients with SAD.

SPECIFIC PHOBIA

Specific phobia, often called simple phobia, is an anxiety disorder defined by heightened, excessive, consistent, and irrational fear when an individual is faced with or is anticipating a phobia-evoking stimulus. The DSM-IV includes five subtypes of specific phobia: animal (e.g., spiders), natural environment (e.g., heights), blood injection injury (e.g., shots/needles), situational (e.g., flying), and other (e.g., loud sounds). The 12-month prevalence of specific phobia is estimated at 9% (Kessler et al., 2005)

Among neuroimaging studies of specific phobia, both amygdala and insular hyperreactivity are reported (reviewed in Del Casale et al., 2012). While some studies find no differences between patients and control participants in the amygdala (Straube et al., 2006), in a meta-analysis Etkin and Wager (2007) report hyperactivation in the amygdala across studies. Bilateral amygdala hyperactivation is seen when patients with spider phobia consciously view spider stimuli, including when patients view them unconsciously (e.g., using backwardly masked presentations; Lipka et al., 2011) and while simultaneously engaging in a distracting task (Del Casale et al., 2012). Across different subtypes, patients with specific phobia show more rapid time-to-peak activation in the amygdala (Del Casale et al., 2012). Amygdala hyperactivity occurs primarily with phobia-specific stimuli (Del Casale et al., 2012), although there is one report that patients with specific phobia show similar amygdalar reactivity to affective stimuli more broadly (Wendt et al., 2008).

Additional evidence exists for exaggerated emotional reactivity and diminished regulatory ability in specific phobia. Patients with spider phobia show exaggerated insula and dACC activation when faced with spider stimuli, hyperactivation that is not seen after four sessions of cognitive behavioral therapy (Straube et al., 2006). During cognitive reappraisal of emotional stimuli, patients with spider phobia show increased insula and reduced vmPFC/vACC activity (a pattern opposite to that during emotion regulation; Del Casale et al., 2012). This prefrontal disruption is seen only when individuals with spider phobia face spider stimuli and not in response to aversive stimuli generally.

Additionally, insula hyperactivation in response to and in anticipation of phobogenic stimuli is reported (Del Casale et al., 2012). Consistent with these data, after one to four sessions of CBT, patients with specific phobia demonstrate reduced hyperactivity in the amygdala, dACC, and insula compared with baseline (Goossens et al., 2007) and increased vmPFC activation not found in a wait list group over the same time period (Schienle et al., 2007).

As mentioned earlier, the diagnosis of specific phobia encompasses different types of phobias, and specific disruptions across subtypes have not been extensively explored. Two studies address differences in subtypes of specific phobia. In one, patients with the animal subtype show enhanced fear circuitry activation, including the insula and dACC, which is associated with autonomic arousal. In contrast, those with blood injection injury subtype showed activation in the prefrontal and orbitofrontal cortex (Lueken et al., 2011). In another study, patients with blood injection injury phobia have greater activity in the ventral PFC and lower amygdala response compared with patients with animal phobia during symptom provocation (Del Casale et al., 2012). Heightened emotional reactivity may be more common or pronounced in animal phobias compared with others.

Although not fully developed, research in specific phobia reveals increased activation in regions important for emotion generation, such as the amygdala, insula, and the dACC, which is primarily observed only when viewing phobia-specific stimuli. Patients with specific phobia fail to recruit prefrontal regions to effectively regulate phobia-related emotions and to reduce limbic responding to these stimuli (see Table 45.1). As such, abnormalities in processing of phobia-related stimuli resemble those seen in SAD with social evaluation-related stimuli, and in healthy subjects with fear conditioning. Thus, there is common excessive engagement of circuitry involved in fear conditioning and negative emotional processing to disorder-specific stimuli, which fits with a fear conditioning-based conceptualization of these anxiety disorders. Moreover, a small number of sessions of cognitive-behavioral therapy (which can be considered akin to extinction training) leads to decreased activation in limbic regions (e.g., the amygdala and insula) and in the dACC, coupled with increased vmPFC activation, important for emotion and fear regulation. Overall, however, neuroimaging studies indicate less extensive neural disruptions in specific phobia compared with other anxiety disorders, both in terms of the number of brain regions involved and the types of stimuli that elicit hyperreactivity; these disruptions may be more amenable to change with treatment. Although this field is incomplete, there is some evidence that different types of phobias show different neural patterns, with patients with animal phobias showing the most extensive limbic hyperactivation.

GENERALIZED ANXIETY DISORDER

Generalized anxiety disorder (GAD) is an anxiety disorder characterized by frequent worrying that is difficult to control. Over the lifetime, GAD affects nearly 6% of English speakers in the United States (Kessler et al., 2005), has a long duration of symptoms, and negatively impacts relationships, professional functioning, and general well-being (Ballenger et al.,

2001). The clinical presentation of GAD suggests deficits in regulatory abilities, specifically the ability to manage negative affect.

As with other anxiety disorders, amygdala hyperactivation is reported in GAD, though results have been mixed. Nitschke and colleagues (2009) describe exaggerated amygdala responses to the anticipation of both negative and neutral stimuli in individuals with GAD. Additionally, increased response in the amygdala is found in adolescents with GAD, during both conscious and nonconscious viewing of emotional facial expressions (Monk et al., 2008; Shin and Liberzon, 2010). When attending to their own emotional states, children with GAD show greater amygdala responses (McClure et al., 2007). Amygdala activation to nonconsciously processed negative emotional expressions positively correlates with anxiety (Monk et al., 2008), and similarly, greater amygdala activation when viewing emotional faces predicts worse treatment response (McClure et al., 2007; Shin and Liberzon, 2010). Thus, the extent of amygdala hyperactivity may signal both the severity and inflexibility of GAD, again suggesting the presence of primary deficits in emotion regulation. However, this finding may be specific to pediatric GAD as most of these studies include pediatric populations. In contrast, many of the studies in adults report no amygdala activation during symptom provocation tasks (Hoehn-Saric et al., 2004) or comparable or reduced activation in the amygdala to negative stimuli compared with healthy controls (Blair et al., 2012; Shin and Liberzon, 2010) and to patients with other anxiety disorders (Blair et al., 2012).

Patients with GAD also have disrupted amygdala functional connectivity patterns. We examined amygdalar subregion connectivity patterns in patients with GAD and healthy control participants. Within the control group, the CMA subregion of the amygdala had almost exclusively subcortical connectivity during resting state, while the BLA was associated with cortical connectivity (including regions of the occipital lobe, temporal lobe, and prefrontal cortex). Individuals with GAD have decreased differentiability between amygdalar subregions and their targets (Etkin et al., 2009). Thus, amygdalar alterations in GAD may result from abnormal subregional organization, a disruption that may be missed when collapsing across amygdalar subregions. Evidence of other alterations in limbic regions in GAD is limited, with indication that insular activation during symptom provocation declines following medication treatment of GAD and that the degree of decline is associated with symptom improvement (Hoehn-Saric et al., 2004).

Disrupted frontal lobe activation has been reported in GAD in regions important for both the evaluation and regulation of emotional information. In the dACC/dmPFC, evidence is mixed with reports of both increased activation during symptom provocation, emotional, and resting state tasks (Hoehn-Saric et al., 2004; Paulesu et al., 2010) and of decreased activation to emotional faces (Etkin et al., 2010).

Hyperreactivity is also seen in regulatory regions in GAD, such as in the vlPFC when viewing emotional stimuli (Monk et al., 2008; Shin and Liberzon, 2010). During a resting state scan, patients with GAD show greater connectivity between

the dlPFC and amygdala (Etkin et al., 2009). Prefrontal activation and prefrontal connectivity to the amygdala has been negatively correlated with symptom severity (Etkin et al., 2009; Shin and Liberzon, 2010), suggesting it may reflect a regulation-related compensation. However, patients with GAD fail to activate the vACC during an implicit regulation task and do not show the expected negative coupling of the vACC with the amygdala during this task (Etkin et al., 2010). Prior to beginning treatment, activity in the vACC to aversive cues and emotional facial expressions positively predicts treatment response (Shin and Liberzon, 2010). Stronger activity in lateral prefrontal regions is consistent with cognitive models of GAD suggesting that worry serves a compensatory function to help individuals avoid or cope with emotional arousal (Behar et al., 2009), in the context of an inability to activate medial regions important for automatic emotion regulation, such as the vACC.

GAD has received less neurobiological study than other anxiety disorders, and areas of preservation and deficit may be clarified with additional research. Thus far, neuroimaging results indicate that adolescents and adults with GAD show both overlapping and distinct neural disruptions. Specifically, limbic functioning in adolescent GAD mirrors that of adults with other anxiety disorders, in particular heightened amygdala activation. In contrast, amygdala reactivity to emotional stimuli is reduced or comparable to control participants among adults with GAD (see Table 45.1). It is unclear exactly when and why this change between adolescence and adult GAD occurs. Decreases in amygdala hyperactivity across development may indicate that individuals with GAD begin to habitually use a cognitive style intended to dampen emotional responses. In terms of the dACC/dmPFC, important for emotional evaluation, there is evidence of both hyperactivation and hypoactivation during emotional tasks in adults with GAD. This dysregulation may indicate attempts to engage cognitive control regions in order to manage excess anxiety. Indeed, worry, the hallmark of GAD, is thought to reflect a cognitive strategy that individuals employ to manage emotions (Behar et al., 2009). In adults, regions implicated in particular in automatic forms of emotion regulation are underactive during GAD, and higher activation in these regulatory regions has been linked to better prognosis. In sum, unlike other anxiety disorders, GAD is not well captured by a fear conditioning model; neuroimaging differences between individuals with GAD and control participants are best accounted for in the context of changes in emotional reactivity and regulation.

PANIC DISORDER

Panic disorder (PD) can be a debilitating condition, with a lifetime prevalence of nearly 5% (Kessler et al., 2005), and nearly 30% of people meeting criteria for having ever had a panic attack. Recurrent, unexpected panic attacks coupled with a concern that they will recur are the hallmarks of the condition, which often runs in tandem with agoraphobia. As with other anxiety disorders that can be described using a traditional fear conditioning model, the fear of the symptom-generating stimuli (in this case, internal physiological sensations) leads to

attempts at avoidance and, consequently, to a generalization of fear. A panic attack is described as intense fear and discomfort, accompanied by multiple physiological symptoms of anxiety, including heart palpitations, sweating, shaking, hot flashes, and shortness of breath. Spontaneous panic attacks are thought to arise from a fear circuitry that is hypersensitive to internal cues or cannot downregulate minor responses. These suggest heightened emotional reactivity and/or inadequate emotion regulation in PD.

Despite the enormous burden both on the individual and the community, neural circuitry research of PD has lagged behind that of other anxiety disorders. Neuroimaging studies find hyperreactivity of the amygdala in response to sensory and visceral stimuli with insufficient top-down regulation by prefrontal regions in PD (reviewed in Shin and Liberzon, 2010). One participant who had a panic attack during imaging showed increased right amygdala (along with right parahippocampal and right putamen) activation (Pfleiderer et al., 2007). In this patient, amygdala activation was associated with increases in heart rate and with insular activation. During PET scanning, patients with PD show increased glucose uptake in the amygdala (Shin and Liberzon, 2010). When presented with panic-specific negative words, patients with PD have heightened amygdala activation (Beutel et al., 2010). However, exaggerated amygdala responses are not found in all studies of PD. Inducing panic attacks pharmacologically does not consistently result in amygdala activation (Shin and Liberzon, 2010). For example, in a study of two patients who had panic attacks during scanning, only one showed amygdala activation while both had significant PFC activity (Dresler et al., 2011). Other studies find no amygdala differences compared with controls (Maddock et al., 2003) or reduced activation in the amygdala when viewing fearful emotional expressions and during anticipatory anxiety (Shin and Liberzon, 2010). These authors suggest that hypoactivity of the amygdala may result from chronic hyperresponsivity, ultimately leading to reduced emotional responses, though this interpretation remains very speculative.

Given the role of the insula in interoception and the role of interoception in panic, it is not surprising that functional imaging studies of PD implicate the insula. Activation increases at the beginning of panic symptoms (Pfleiderer et al., 2007) and is found in both spontaneous and provoked panic attacks (Dresler et al., 2011; Spiegelhalder et al., 2009). The early role of the insula in panic suggests that it may serve as an alarm, communicating information about internal bodily signals. Hippocampal hyperreactivity has been reported during rest (Sakai et al., 2006) and when individuals with PD view negative stimuli (Beutel et al., 2010). The authors suggest that this may reflect patients' preferential attention to and recall of potentially threatening stimuli. The PAG has also been implicated in PD. Electrically stimulating the PAG in patients undergoing neurosurgery results in symptoms similar to that during a panic attack, namely, heart palpitation, hyperventilation, feelings of terror, and a desire to flee (Del-Ben and Graeff, 2009); similar results are found during electrical stimulation of the hypothalamus (Wilent et al., 2010). Antidepressants, which may effectively treat symptoms of PD, are thought to do so via

serotonergic inhibition of the PAG. Due to its size and location, the PAG is difficult to image, but likely PAG activation differences have been reported in patients with PD (Shin and Liberzon, 2010). Moreover, Sakai and colleagues (2006) report a correlation between percent change in glucose utilization in midbrain areas “around PAG” during imaging and number of panic attacks over the previous four weeks.

Both neuropsychological and neuroimaging studies find disruptions in PFC functioning in PD. In two cases, damage to the dACC due to surgery or radiation led to panic attacks (Shinoura et al., 2011). Pharmacologically inducing panic leads to activation in the vACC, and middle and superior frontal gyrus (Shin and Liberzon, 2010). Among patients with primary PD, evidence exists for increased frontal lobe activation, in both dorsal and ventral ACC regions and inferior frontal cortex, during directed imagery and when viewing positive images (Shin and Liberzon, 2010). Moreover, these investigators find that responses in the dACC and vACC to happy faces are larger in patients with PD than control participants. Additionally, threat-related material may elicit greater dlPFC activation (Maddock et al., 2003). Successful cognitive-behavioral treatment for PD results in decreased glucose utilization in the left vACC (Sakai et al., 2006). By contrast, others report decreased dACC and vACC activation to fearful faces in untreated PD (Shin and Liberzon, 2010). Additionally, prior to treatment, patients with PD have decreased vlPFC activation to negative stimuli and decreased dlPFC activation to positive stimuli (suggesting widespread lateral prefrontal disruption; Beutel et al., 2010) coupled with high limbic activation; this pattern was normalized after inpatient psychodynamic treatment.

Overall, both *in vivo* symptoms of panic attacks and the condition of PD are associated with hyperreactivity of the insula and often (but not always) the amygdala. Additionally, panic symptoms and PD are associated with exaggerated activation in other regions involved in emotional reactivity that are not consistently implicated in other anxiety disorders, such as the PAG, hippocampus, and hypothalamus (see Table 45.1). The insula and PAG may be more important in PD than other anxiety disorders due to their roles in interoception and sympathetic nervous system activity, two core components of PD. Most of these studies use panic-specific stimuli or correlate activation with panic symptoms, including some that report panic symptoms that occur during scanning. These data suggest exaggerated fear responses in PD coupled with a greater focus on the physiological components of fear. Some evidence also supports hyperactivity in medial prefrontal regions to panic-specific and positive emotional stimuli, but hypoactivation in these areas to fear-specific stimuli. Evidence for lateral prefrontal disruptions is mixed, with some reporting increased activation to threat stimuli, and others reporting decreased activation to positive and negative stimuli (Beutel et al., 2010; Maddock et al., 2003). Given the small number of studies and discrepant findings across studies, further research is needed to explore frontal lobe patterns of hyper- and hypoactivation in PD. As such, it is difficult to draw conclusions about regulatory function in PD, although widespread heightened reactivity suggests deficits in regulatory function.

POSTTRAUMATIC STRESS DISORDER

Posttraumatic stress disorder encompasses a set of symptoms that develop subsequent to exposure to a traumatic event such as threat of death or serious injury to oneself or another person. In the aftermath of a traumatic event, individuals with PTSD develop a constellation of symptoms that fall into three DSM-IV-based categories: reexperiencing (e.g., flashbacks, nightmares), avoidance (attempts to avoid thoughts or situations that are reminders of the trauma), and hyperarousal (e.g., exaggerated startle response and hypervigilance). PTSD is thought to reflect exaggerated and sustained fear conditioning overlaid on a vulnerable state. From a fear conditioning model perspective, PTSD reflects rapid and exaggerated fear learning, coupled with deficient fear extinction and misinterpretation of safe contexts as dangerous. Consequently, those who suffer from PTSD often feel the world is fraught with aversive threat. Symptoms of PTSD are further maintained by a tendency to avoid situations, thoughts, and feelings related to the trauma. There are multiple symptoms of PTSD, however, that do not as readily fit into a fear conditioning framework, and which set it apart from some of the other anxiety disorders. These symptoms include numbing, irritability, anger, and guilt and can be conceptualized as dysregulated negative emotion more broadly.

Extensive research has been published on limbic and prefrontal responses to a range of emotional stimuli in PTSD. We report amygdala hyperactivation in PTSD in our meta-analysis (Etkin and Wager, 2007). Patients with PTSD show amygdalar hyperactivation when viewing emotional expressions (reviewed in Brohawn et al., 2010; Hughes and Shin, 2011), in particular fearful expressions (Hughes and Shin, 2011), including when these stimuli are presented outside of conscious awareness (Hughes and Shin, 2011). The extent of amygdala hyperactivity to emotional facial expressions is also related to symptom severity (Brohawn et al., 2010; Hughes and Shin, 2011). In symptom provocation studies, increased amygdala activity is seen to trauma-related stimuli (e.g., combat-related sounds and combat-related odors [Hughes and Shin, 2011]). Related to core symptomatology in PTSD, patients have heightened amygdala during the construction of negative autobiographical memories (St. Jacques et al., 2011). Consistent with the fear conditioning model of PTSD, amygdala habituation occurs less efficiently in patients with PTSD (Hughes and Shin, 2011), and amygdala activation is stronger during fear extinction in these patients compared with control participants (Milad et al., 2009). Following cognitive-behavioral treatment, patients with PTSD show decreased amygdala activity in response to emotional stimuli, with higher pretreatment amygdala activity relating to less symptom reduction over treatment (Hughes and Shin, 2011).

Despite considerable evidence for amygdala hyperactivation in PTSD, our meta-analysis also suggests that the picture is more complicated (Etkin and Wager, 2007). First, amygdala hyperactivation is found less frequently in PTSD than in SAD or specific phobia. Second, in contrast to SAD and specific phobia, among studies of PTSD, there is evidence for both hyperactivation and hypoactivation in the amygdala. Across

studies, a ventral amygdala cluster is hyperreactive and a dorsal cluster is hypoactive. Though precise localization is difficult in the context of a meta-analysis, we speculate that the former relates to the BLA, important for acquiring fear responses and forming emotional memories. The dorsal-posterior cluster may correspond to the CMA, which mediates autonomic and behavioral reactions to threat; hypoactivation in this area may be related to emotional blunting and numbing seen in PTSD. Additionally, these findings and examining amygdala subdivisions individually may help explain the amygdala hypoactivation that has been reported in PD and GAD.

Across studies, insula hyperactivity is seen consistently in PTSD (Etkin and Wager, 2007). Individuals with PTSD show exaggerated insula responses when viewing emotional facial expressions during emotional anticipation and script-driven imagery (Aupperle et al., 2012; Hughes and Shin, 2011) and when retrieving emotional and neutral word pairs (Hughes and Shin, 2011). Greater insula activity during emotional tasks is associated with symptom severity and with reexperiencing occurring during neuroimaging (Hughes and Shin, 2011).

Individuals with PTSD show striking abnormalities in prefrontal cortical functioning, including both hyperactivation and hypoactivation of different regions. Extensive ACC reductions, spanning both dorsal and ventral regions, have been reported in response to symptom provocation and more general emotional tasks (Hughes and Shin, 2011; Lanius et al., 2003). However, consideration of ACC subregions and their functions sheds light on the patterns of hyper- and hypoactivation seen in PTSD. For example, when faced with emotional stimuli, patients with PTSD show increased activation in the dACC and decreased activation in the vACC (Hughes and Shin, 2011). The dACC plays important roles in emotion generation and conflict monitoring, suggesting that hyperactivity here may reflect heightened emotional reactivity in PTSD. Increased dACC activation is reported across tasks in PTSD, such as during trauma-specific words, fear conditioning, and extinction, and at rest (Hughes and Shin, 2011; Rougemont-Bucking et al., 2011). Among survivors of intimate partner violence, dACC activation when viewing male faces is related to hyperarousal symptoms (Hughes and Shin, 2011). Elevated dACC activation may represent a risk factor for PTSD, which is seen in combat veterans with PTSD and their identical, combat-unexposed co-twins without PTSD (Shin et al., 2009).

In contrast, hypoactivation of the vACC in the face of affectively laden stimuli is thought to reflect insufficient regulatory systems in PTSD. Hypoactivation of the vACC and vmPFC is reported in PTSD during traumatic scripts, traumatic imagery, and trauma-related videos (Hughes and Shin, 2011), as well as during negative images generally (Phan et al., 2006). Moreover, this disruption is apparent in adolescent populations with PTSD (Yang et al., 2004). Deficits in emotional processing in PTSD may not be specific to negative emotional stimuli. Patients with PTSD have decreased activity in the vmPFC and nucleus accumbens during reward processing (Sailer et al., 2008). Decreased vmPFC activation has also been found in response to nonemotional stimuli, such as during cognitive tasks (Hughes and Shin, 2011). Activation in the

vmPFC negatively correlates with symptom severity (Hughes and Shin, 2011), and increases in vmPFC activation positively correlate with symptom improvement (Felmingham et al., 2007). Further evidence for inadequate frontal regulation of emotional stimuli comes from functional connectivity studies demonstrating reduced negative coupling between ACC regions and the amygdala (Etkin and Wager, 2007; Sripada et al., 2012).

In healthy control participants, the vmPFC (and an analogous region in experimental animals) has been linked to fear extinction (Phelps et al., 2004). PTSD patients show decreased vACC/vmPFC activation in fear conditioning studies, particularly during fear extinction (Milad et al., 2009) and recall of fear extinction (Milad et al., 2009; Rougemont-Bucking et al., 2011) and in the presence of safety signals (Rougemont-Bucking et al., 2011). Although mostly examined in the context of fear conditioning, vACC deficits likely have more far-reaching implications for emotion dysregulation in PTSD. This region is important for regulating emotional conflict (Etkin et al., 2011), and individuals with PTSD show reduced vACC activation in situations of unexpected emotional conflict (Kim et al., 2008).

Memory difficulties are often reported in PTSD, suggesting a prominent role for the hippocampus. Functional imaging studies of hippocampal activation in PTSD have been mixed. Previous research describes decreased hippocampal activation during script-driven imagery tasks (Hughes and Shin, 2011), memory encoding and retrieval (Hughes and Shin, 2011; Shin et al., 2004), and extinction recall (Milad et al., 2009). Reduction in the integrity of hippocampal function is associated with symptom severity (Hughes and Shin, 2011). However, multiple studies report heightened hippocampal activity in PTSD, including during script-driven imagery and during memory retrieval in emotional contexts (Hughes and Shin, 2011). Hippocampal activation is positively associated with amygdala activation (Brohawn et al., 2010) and symptom severity (Shin et al., 2004), and with decreases in activation following treatment (Felmingham et al., 2007). As previously described, the posterior hippocampus is critical for episodic memory, and the anterior hippocampus is involved in anxiety-related behaviors. Patients with PTSD show decreased connectivity between the posterior hippocampus and regions in the default mode network, such as vACC and PCC, which may relate to the fear memory abnormalities in PTSD, such as intrusive memories and difficulty updating fear memories (Chen and Etkin, manuscript submitted). A similar deficit is seen in activation of these patients in response to a task, which is furthermore related to the traumas being either earlier in life or multiple. By contrast, common decreased connectivity between the anterior hippocampus and dACC is seen in patients with PTSD or GAD. Anterior hippocampal connectivity deficits across these two anxiety disorders may relate to general anxiety responses that are often dysregulated in many anxiety disorders.

Taken together, individuals with PTSD show exaggerated amygdala activation to wide-ranging stimuli, including to consciously and unconsciously presented emotional stimuli, trauma-specific stimuli, autobiographical memories, and fear

conditioning. A closer examination suggests that subregions of the amygdala with cortical connections and that are important for the acquisition of fear responses are hyperactive while those with connections to the brainstem and that are important for autonomic responding are hyporeactive. Additional limbic hyperreactivity in PTSD is found in the insula. Given the disruptions in limbic activity when presented with trauma-specific stimuli, fear conditioning, and emotional stimuli more generally, disturbances in emotional reactivity appear more widespread in PTSD than other anxiety disorders. This finding is consistent with the clinical picture of PTSD that includes increased negative affect beyond fear (e.g., guilt, shame, anger, irritability) and reduced positive affect (e.g., emotional numbing or distancing).

In conjunction with limbic hyperactivity, increased responding in the dACC/dmPFC to emotional information reflects heightened reactivity and sensitivity to emotional cues in PTSD. The degree of dACC/dmPFC activation correlates with hyperarousal symptoms and may signal a predisposition to develop PTSD, as indicated by a recent twin study. In contrast, the vACC/vmPFC is consistently hypoactive in PTSD during symptom provocation and fear-conditioning tasks (especially during fear extinction) (see Table 45.1). Decreased responding in the vACC/vmPFC corresponds to inadequate regulation of emotion, such as during fear conditioning and extinction; this alteration in regulatory function tracks with both symptom severity and symptom improvement. Consistent with the clinical picture of PTSD, deficits in emotional circuitry extend beyond those implicated in and in response to fear: patients with PTSD show deficits to wide-ranging negative emotional stimuli and to positive stimuli.

CONCLUSION

The goal of this chapter is to provide a review of relevant neuroimaging findings of anxiety disorders. We introduce a new, expanded framework of our previous model (Etkin, 2009; Etkin, 2010) to catalog neuroimaging findings in the context of emotional reactivity as well as regulation in anxiety disorders. Our updated framework is guided by theory and neuroanatomy simultaneously. As such, we define emotion reactivity deficits as differences seen in behavioral manifestation of emotional responding or neural abnormalities in core limbic structures in response to emotional provocation. Similarly, emotion regulation deficits are defined as behavioral or neural abnormalities in cortical regulatory regions (see Fig. 45.1) in emotion regulation tasks.

Historically, aberrations in fear circuitry have been the guiding framework for research and treatment of anxiety disorders. While this model yields a rich understanding of the neurobiology of anxiety, our new affective science-inspired model shows that it is a minority of anxiety disorders in which disruptions in fear processing account for the entire symptom presentation. In fact, our review suggests that while fear circuit abnormalities are central to many anxiety disorders, there are other emotion reactivity, and very pronounced regulatory, deficits in anxiety pathologies.

Specifically, we found evidence of heightened reactivity in limbic structures in SAD (Etkin and Wager, 2007), but only for socially relevant and not for physical threat-related stimuli. Distinct from other anxiety disorders, SAD is associated with increased activity in the vACC (implicated in automatic emotion regulation) and decreases in lateral PFC regions (associated with deliberate emotion regulation). Neural changes associated with specific phobia are consistent with increased emotion reactivity and decreased regulation, although these deficits appear to be restricted to phobia-specific stimuli. When presented with phobia-specific stimuli, these individuals show increased amygdala, insula, and dACC (all implicated in emotional evaluation and reactivity) with decreased vACC activation (important for automatic emotion regulation). Fewer studies have addressed neural changes associated with GAD. While adolescents with GAD show heightened amygdala activation (similar to other anxiety disorders), adults with GAD often show no changes from control participants or reductions in amygdala activation. This lack of limbic hyperactivation is coupled with dysregulation in frontal regions important for the evaluation (dACC) and regulation (lateral PFC) of emotion. Patients with GAD may be able to engage those regions important for cognitive or deliberate regulation of emotion but fail to activate the vACC important for automatic emotion regulation. PD is characterized by widespread activation in diverse structures implicated in fear responding and in physiological reactivity, such as the amygdala, insula, PAG, and hippocampus, along with decreased activation in prefrontal regions involved in both deliberate and automatic emotion regulation. Finally, increased activity in both limbic and prefrontal regions important for emotional reactivity and evaluation are found in PTSD, along with decreased activation in the vmPFC, an important region in emotion regulation. These patients show heightened reactivity in the amygdala, insula, hippocampus, and dACC and across a wide range of tasks, including symptom provocation, fear conditioning, and emotional stimuli generally (both positive and negative). Within both the amygdala and the hippocampus, deficits in PTSD are more complicated than strictly hypo- or hyperactivation. Within both regions, there are subregions of hyperactivation and of hypoactivation in patients with PTSD.

Thus, it is apparent that there is great deal of variability across anxiety disorders in terms of emotional reactivity. Deficits exist in other affect dimensions than fear, such as social rejection-acceptance in SAD, and anger and numbing in PTSD. In terms of neural deficits, amygdala and insula dysfunctions cut across most anxiety disorders, while other limbic structures showed disorder specificity. We found no evidence of insula deficits in GAD, whereas there were documented cases of hyperactivation in SAD, specific phobia, PD, and PTSD. Abnormalities in the periaqueductal gray and insula appear to be most characteristic of PD due to the role of these structures in interoception.

While emotional hyperreactivity, especially to anxiety-specific stimuli, is a central feature of anxiety disorders, strong reactivity may represent an overactive emotional reactivity system, an underactive regulatory system, or both. As such, in this review we also highlighted those brain regions seen in emotional reactivity generally and those critical for the

regulation of emotion. In general, these include core limbic structures in emotional reactivity and connections between these regions and prefrontal cortical areas that play regulatory roles. In this vein, we cataloged pronounced regulatory changes in lateral PFC regions, important for effortful emotion regulation, in SAD, GAD, and PD. Increases in these regions may reflect attempts to compensate for exaggerated emotional reactivity. Strikingly, vACC/vmPFC deficits were seen across nearly all anxiety disorders. The vACC and the vmPFC are richly interconnected with limbic structures, especially the amygdala, and perform implicit emotion regulation. Deficits in activation in these regions may indicate impairments in more automatic, implicit forms of emotion regulatory operations. In summary, our hope is that this review reinforces the utility of an emotional reactivity and regulation framework for understanding and treating anxiety disorders and will inspire future researchers to grow and systematize findings within this model.

46 | NOVEL TREATMENT APPROACHES FOR ANXIETY DISORDERS

ANITA VAN ZWIETEN, GAIL A. ALVARES, AND ADAM J. GUASTELLA

Anxiety is conceptualized as a coherent structure of cognitive and affective components within the defensive motivational system that responds to perceived future threat or danger (Barlow, 2002). This complex system responds to perceived threatening information with cognitive and affective processes, physiological reactions, and behavioral responses, which relate to the well-known defensive behaviors of “freeze, fight, or flight” involved in the fear response (Sullivan et al., 2011). While anxiety is an adaptive response that serves both to alert and prepare the organism for potential threat (Barlow, 2002), pathological anxiety is characterized by its excessive expression across dimensions of duration, frequency, and/or intensity (Barlow, 2002). Anxiety disorders are thereby considered disorders of fear dysregulation (Myers and Davis, 2007).

A remarkable amount of progress has been made in the development of effective and acceptable treatments for anxiety disorders. Although evidence-based psychological and pharmacological treatments exhibit strong clinical efficacy across randomized controlled trials (RCTs), a significant number of individuals do not respond to treatment or relapse after treatment cessation. Such trials may also report overestimated effect sizes due to selection bias, with many complex or comorbid individuals excluded. These, and a number of other issues reviewed subsequently, have led to the surge of interest in recent years toward the need for efficacious and novel approaches in the treatment of anxiety disorders. Key priorities that have been highlighted are the need to identify and target the mechanisms (behavioral, cognitive, neurobiological) that underlie anxiety, as well as to develop comprehensive bio-psycho-social models that take into account factors involved in adherence and treatment response (Etkin, 2012; Taylor et al., 2012). The aim of this chapter, therefore, is to review evidence for recent and promising novel approaches to treat anxiety disorders that extend upon and augment existing best-practice interventions. After a discussion of the current state of evidence-based treatments for anxiety, evidence will be reviewed for several novel pharmacological, cognitive, and technological interventions, with reference to the specific neurobiological mechanisms of anxiety targeted in each. The interventions reviewed in this chapter are summarized in Table 46.2.

CURRENT STATE OF EVIDENCE-BASED TREATMENTS FOR ANXIETY DISORDERS

Existing psychological and pharmacological treatments for anxiety are well established in clinical settings. Although other psychotherapies (such as mindfulness-based therapy) have received some empirical support, cognitive-behavioral therapy (CBT) continues to be the gold standard for psychological treatment of both child and adult anxiety disorders (Butler et al., 2006). CBT aims to redress the maladaptive cognitive, behavioral, and affective patterns related to the focus of an individual’s anxiety. Common components of CBT packages for anxiety include psychoeducation, conscious cognitive restructuring of negatively biased thinking, and behavioral exposure (physical or imaginal) to the focus of anxiety to reduce fear and avoidance (Clark and Beck, 2010). Despite robust empirical support, a number of issues remain. CBT is not universally efficacious, nor is it acceptable to all patients, with considerable rates of non- or partial responders to treatment and treatment nonadherence (Schmidt, 2012). Nonadherence is particularly concerning given that attendance and completion of therapy homework appear to play a role in treatment outcome in treatment with CBT (Taylor et al., 2012). The quality of treatment with CBT also varies depending on the therapist, the therapeutic alliance with the client, and the extent to which the therapist’s methods reflect guidelines for evidence-based practice (Collins et al., 2004; Reger and Gahm, 2009).

Pharmacological treatment for anxiety disorders depends upon both the disorder and needs of the individual (see reviews in Bandelow et al., 2012; Ravindran and Stein, 2010). The preferred psychotropic medication across anxiety disorders tends to be selective serotonin reuptake inhibitors or SSRIs (Bandelow et al., 2012), which work to inhibit reuptake at the presynaptic serotonin transporter pump. Overall, their tolerability, efficacy, and safety are good, although drug–drug interactions and side effects during or upon termination of treatment are noted difficulties with SSRI use (Ravindran and Stein, 2010). Serotonin-norepinephrine reuptake inhibitors (SNRIs) are a more recently developed class of medications that work to inhibit the reuptake of serotonin and norepinephrine, with selectivity for the two neurotransmitters varying across dose and drug. They have adequate tolerability and efficacy to be

considered alternate first-line treatments to the SSRIs, although again side effects are still a critical limitation (Bandelow et al., 2012). Although both tricyclic antidepressants and monoamine oxidase inhibitors (MAOIs) have received support in clinical trials with certain anxiety disorders, they are generally considered third- or fourth-line treatment options because of their side effect profiles and tolerability issues (Ravindran and Stein, 2010). Benzodiazepines work to potentiate the action of the inhibitory neurotransmitter γ -aminobutyric acid (GABA) and, although generally effective, carry risks of adverse effects, tolerance, and dependence (Bandelow et al., 2012). Further, they have no recognized antidepressant effects, an important consideration given the high comorbidity between anxiety and mood disorders (Ravindran and Stein, 2010). Other psychotropic medications such as anticonvulsants, azapirones, and atypical antipsychotics do not have a sufficient evidence base at this time to justify their use over other anxiolytic agents for anxiety treatment (Ravindran and Stein, 2010). Many patients, however, refuse to undergo pharmacological treatment for their anxiety, and a substantial proportion of those who do consent fail to respond to medication or adhere to their treatment regime (Collins et al., 2004). For many, nonadherence appears to be in part a result of adverse side effects (Taylor et al., 2012).

A recent review of previous meta-analyses found mean dropout rates of 16% and 24% for CBT and serotonergic pharmacotherapy treatment trials, respectively, with mean nonresponse rates of 35% and 30% for the two treatments (Taylor et al., 2012). A common strategy in clinical settings has been to combine psychotherapy and pharmacotherapy, with the assumption that the combination will be more efficacious (Hofmann, 2007; Hofmann et al., 2009). This assumption has either been found to be not empirically supported, or supported only in the case of some disorders and not when one examines longer term outcomes (Hofmann et al., 2009).

There are also issues surrounding access to current treatments for those in need. In particular, CBT is costly to implement and requires regular meetings with a trained clinician, which reduces accessibility for patients from isolated areas, with low socioeconomic status, limited transport, time, or mobility (Collins et al., 2004). These individual psychological and practical barriers seem to contribute to failure to seek treatment and treatment nonadherence (Collins et al., 2004; Taylor et al., 2012). There is also increasing acknowledgment of the difficulty involved in ensuring that empirically supported treatments such as CBT are well disseminated by health care professionals, and the lack of rigorous training in CBT techniques among training and registration programs for psychologists (Collins et al., 2004; Gunter and Whittal, 2010). Epidemiological studies report that up to two-thirds of those experiencing an anxiety disorder in the last 12 months had not used mental health services in that time (Slade et al., 2009). There is, therefore, great potential for improvement in uptake and response rates for both psychotherapy and pharmacotherapy for anxiety. Thus, the development of novel augmentation approaches to existing anxiety treatments has the potential to further enhance the cost effectiveness, accessibility, and efficacy of treatment within the community.

NOVEL PHARMACOLOGICAL APPROACHES

As described previously, substantial research and clinical effort has been placed into the augmentation of psychotherapy with traditional anxiolytic medications, despite the lack of consistent evidence for substantive additive benefits (Hofmann, 2007). More recently, however, research efforts have been focused on the development of novel pharmacological adjuncts that capitalize on the neurobiological mechanisms involved in overcoming anxiety to augment the learning processes that take place during psychotherapy. Novel compounds that have shown such promise as cognitive enhancers for psychotherapy include yohimbine hydrochloride, glucocorticoids, and D-cycloserine (DCS; see review in Hofmann et al., 2011).

Much of our current understanding of psychological anxiety treatments, and exposure therapy in particular, is based on associative Pavlovian fear conditioning and extinction models (Sullivan et al., 2011). In brief, fear conditioning involves a harmless stimulus (*conditioned stimulus*, CS) being repeatedly paired with an innately aversive stimulus (*unconditioned stimulus*, US) that naturally elicits a fear response (*unconditioned response*, UCR). This can include the initiation of reflexes (e.g., startle and eyeblink responses), release of stress hormones, defensive behaviors, and autonomic arousal (Sullivan et al., 2011). After repeated pairings, the CS comes to elicit the same innate fear response as the US, known as the *conditioned response* (CR). This conditioned response in animal models is used as an experimental analogue of the human fear response (Barlow, 2002). In order to eliminate this learned fear response, the CS is presented repeatedly without the aversive US (Myers and Davis, 2002). This process is known as extinction and is a major component of successful anxiety reduction (Barlow, 2002).

It is likely that there are multiple neural mechanisms involved in fear extinction (Myers and Davis, 2002; see reviews in Myers and Davis, 2007). Fear conditioning involves the formation of an excitatory association between the mental representations of the CS and US (Myers and Davis, 2007). Extinction appears to involve more than a mere forgetting or even “unlearning” of this maladaptive association; rather, it additionally includes the formation of a new competing association that inhibits the excitatory association representing the learned fear response (Myers and Davis, 2002). Evidence in support of this view shows that the fear response can return after the US is unexpectedly presented again (termed *reinstatement*), when contexts change (renewal) or may spontaneously reappear after a length of time (Myers and Davis, 2007). Hence, while successful extinction alleviates fear in one context, this may only be temporary and may not generalize to other contexts.

There appear to be a number of structures involved in fear conditioning and extinction. In particular, a substantial body of evidence in animals and humans points to the amygdala (especially the basolateral complex or BLA), as well as prefrontal cortical structures including the medial prefrontal cortex (mPFC), orbital cortex, and insula in humans and the prelimbic and infralimbic cortices in rats (see reviews in

Bishop, 2007; Myers and Davis, 2002, 2007; Sullivan et al., 2011). The amygdala plays a central role in threat processing and is generally acknowledged to be critical to the acquisition and expression of conditioned fear, serving not only as the site where sensory CS and US information converges but also that from which efferent projections initiate the various (autonomic, endocrine, and behavioral) aspects of the conditioned fear response (Bishop, 2007; Sullivan et al., 2011). Animal studies implicate plasticity within the BLA in the formation of memory traces for fear conditioning and fear extinction (Charney, 2003; Myers and Davis, 2007), through the process of long-term potentiation. Neuroimaging studies have consistently demonstrated amygdala activation during fear conditioning (Etkin and Wager, 2007; Rauch et al., 2003). There is evidence to suggest that prefrontal cortical structures may modulate amygdala activity, such that the amygdala is involved in rapid fear conditioning and responses to salient stimuli while prefrontal cortical structures control more complex cognitive processing of fear stimuli, prediction of outcomes, and moderation of behavioral responses according to instrumental contingencies (Charney, 2003). *N*-methyl-*D*-aspartate (NMDA) receptors, which are activated by the neurotransmitter glutamate, play a key role in memory and learning (Hofmann et al., 2006). Extinction acquisition, and thus the overcoming of the fear response, involves activation of NMDA receptors in the amygdala, while plasticity within the mPFC contributes to extinction consolidation and inhibition of the fear response (Bishop, 2007; Sullivan et al., 2011). That is, the mPFC is crucial for short- and long-term memory of extinction learning. Although the role of the hippocampus in fear responses and fear- and extinction-related memory, particularly in relation to contextual fear conditioning and expression of extinction learning (Sullivan et al., 2011), has been well demonstrated in animals, its role in human fear has not yet been extensively investigated (Etkin, 2012).

GLUCOCORTICOIDS

Glucocorticoids (cortisol in humans and corticosterone in most animals) are a class of steroid hormones that are the major component of adaptive stress responses. Stressful situations produce a range of automatic, behavioral, and endocrine responses, including activation of the hypothalamic–pituitary–adrenal (HPA) axis. The end product of HPA axis activation is increased endogenous glucocorticoid levels that act to increase blood glucose levels, break down protein and fat, and increase inflammatory responses. Later, they also inhibit further HPA axis activity (Tsigos and Chrousos, 2002). Importantly, glucocorticoids play a critical role in learning and memory processes, particularly for emotional stimuli, through their actions at glucocorticoid receptors found in high density in the hippocampus, amygdala, and frontal lobes (Myers and Davis, 2007).

While endogenous levels of glucocorticoids increase in response to stress in both animal and human models, acutely administered glucocorticoid agonists selectively enhance and impair memory processes. In rats, glucocorticoid administration dose-dependently enhances memory consolidation of new information when given prior to or immediately after

extinction training, and impairs memory retrieval for stored aversive information (de Quervain et al., 2009). In humans, exogenous administration of cortisol facilitates extinction processes and impairs retrieval of stored fear memories. The effects of cortisol on memory are most strongly observed for emotionally arousing stimuli. Glucocorticoid administration has been shown to enhance memory consolidation and impair recall of words across a number of contexts, with strongest effects observed in the context of emotional arousal (as reviewed in Wolf, 2008).

Results of placebo-controlled clinical studies to date suggest that glucocorticoid administration may enhance the extinction of clinical fear. In one study, acute administration of cortisone to social anxiety patients prior to a psychosocial stressor reduced self-reported fear across the task (Soravia et al., 2006). For those participants given placebo, individuals with higher endogenous cortisol exhibited less subjective fear, which suggests that higher levels of cortisol may buffer fear in stressful situations. In the same article, the authors also reported that acute hydrocortisone progressively reduced fear induced by pictures of spiders among individuals with arachnophobia. Further, this effect was maintained two days after the last administration, implying a long-term memory consolidation effect. In patients with chronic posttraumatic stress disorder (PTSD), daily low-dose cortisol reduced intensity of reexperiencing symptoms, physiological distress, and frequency of nightmares (Aerni et al., 2004). Lastly, acute cortisol administered in conjunction with exposure-based therapy resulted in significantly fewer fear symptoms at both posttreatment and one-month follow-up in acrophobia patients (de Quervain et al., 2011). Cumulative evidence from preclinical and clinical studies therefore provides promising initial support for the suggestion that both acute and repeated doses of cortisol may reduce anxiety symptoms. Further, more recent evidence suggests that cortisol may enhance consolidation of newly learned associations after successful exposure therapy, implying that an augmentative approach involving combination with exposure-based therapy may provide the strongest clinical effects.

YOHIMBINE HYDROCHLORIDE

Yohimbine, an African plant derivative, is a dietary supplement often used to treat sexual dysfunction and to metabolize fat. A selective competitive α_2 adrenergic autoreceptor antagonist, yohimbine acts on the noradrenergic system to modulate the formation and maintenance of emotional and fear memories (Myers and Davis, 2007). In particular, yohimbine increases norepinephrine levels in the hippocampus, amygdala, and prefrontal cortex, areas known to mediate fear extinction (reviewed in Holmes and Quirk, 2010).

Initial preclinical findings indicated that mice treated with yohimbine prior to extinction retained cued and contextual extinction memories, even when tested drug-free the next day (Cain et al., 2004). Paradoxically, yohimbine seems to increase arousal and anxiety in both animals and humans. This finding sparked interest into the ways in which the compound could be used as an adjunct for behavioral exposure-based therapies,

especially in relation to treatment-resistant anxiety disorders. That is, Cain et al. (2004) argued that yohimbine may be able to enhance the acute effects of exposure-based treatments where other treatments have failed. However, studies have shown that rats administered yohimbine significantly reduce freezing behavior after extinction but fail to eliminate this fear memory, as return of freezing is evident when tested out of the original context (Morris and Bouton, 2007). This suggests that gains may be context specific and return of fear may occur upon leaving the therapeutic context.

In terms of clinical utility in humans, a study in participants with claustrophobia demonstrated that although acutely administered yohimbine did not initially improve the efficacy of *in vivo* exposure sessions, at a one-week follow-up yohimbine participants exhibited significantly reduced fear (Powers et al., 2009). This is consistent with animal findings suggestive of stronger effects of yohimbine on memory consolidation after extinction than on initial extinction learning. In a recent study, individuals with a fear of flying were given yohimbine or placebo prior to five virtual reality exposure sessions (Meyerbroeker et al., 2012). Results indicated that while noradrenaline activity was increased by yohimbine as expected, no additional effect of the active drug was found on measures of anxiety or treatment outcome. However, an important caveat is that no follow-up assessment was conducted. Given the findings from the previous study by Powers et al., time of assessment seems to be a critical factor in determining the success of facilitatory effects of yohimbine on exposure therapy. Thus, preliminary evidence suggests that although yohimbine may enhance the outcomes of exposure-based therapies for anxiety disorders, this seems to be only evident after a period of consolidation or in specific contexts, which may limit potential clinical applications.

D-CYCLOSERINE (DCS)

DCS is a partial agonist of the glycine binding site in the NMDA receptor complex, which acts to cofacilitate glutamatergic activation of the receptor (Hofmann et al., 2006). In contrast with the drugs combined with psychotherapy in previous augmentation studies, DCS does not appear to have a direct anxiolytic or anxiogenic effect. Rather, acute doses of DCS appear to augment learning during extinction and thus facilitate exposure therapy (Norberg et al., 2008). It appears that DCS has two facilitatory effects on neuroplasticity in extinction training: first, it facilitates NMDA-dependent potentiation of GABA neurons within the BLA to enhance the learning that normally takes place during extinction, and second, it facilitates NMDA-dependent depotentiation of glutamate neurons in the amygdala (Krystal, 2012). It has been suggested that this second “depression-like” action may reduce the risk of reinstatement of the fear response as well as enhance extinction (Krystal, 2012).

EMPIRICAL EVIDENCE

DCS administered systemically or into the amygdala prior to conditioned fear extinction facilitates memory consolidation in

rats, with antagonists to the NMDA glycine binding site blocking these effects (as reviewed in Davis et al., 2006; Hofmann, 2007). Rodent studies indicate that DCS is most effective when given immediately before or after extinction training, which suggests that it works to moderate memory consolidation (Myers and Davis, 2007; Norberg et al., 2008). Research also suggests that DCS may not only enhance fear extinction for target CSs, but also reduce fear responses to other stimuli that have been previously paired with the aversive US but are not specifically targeted in extinction training (Richardson et al., 2004). That is, DCS may promote generalized fear extinction. One way in which these results have been interpreted is that DCS works to devalue the mental representation of the feared US (Ledgerwood et al., 2005). It suggests that DCS may work not only to speed up fear extinction (see Norberg et al., 2008) but also to enhance the strength of the effect. DCS may also reduce the risk of relapse after exposure-based therapy, as it has been shown to reduce reinstatement of fear responses following extinction training in rodents (Hofmann, 2007; Richardson et al., 2004). In conjunction with observed effects of DCS on protein expression and synaptic activity in the amygdala from rodent studies, it has been suggested that this indicates DCS promotes erasure of the fear memory (Myers and Davis, 2007).

Based on the parallels between extinction training and exposure therapy, it was hypothesized that DCS could be utilized as a novel adjunctive treatment to enhance learning in exposure-based psychotherapy (Davis et al., 2006; Myers and Davis, 2007). A number of RCTs to date investigating the use of DCS as an adjunct to exposure therapy in clinical anxiety populations have demonstrated promising initial findings (reviewed in Guastella and Alvares, 2012). Of note, the use of DCS has been examined in social anxiety disorder, specific phobias, PTSD, panic disorder, and obsessive-compulsive disorder (OCD). A recent meta-analysis by Norberg et al. (2008) found a moderate to large effect size favoring use of DCS over placebo when added to extinction or exposure therapy across both animal and clinical human studies. Examining the studies separately, the effect for animal studies was larger, more significant, and more robust. The clinical human studies exhibited a moderate yet significant effect size.

The most consistent positive results for DCS-facilitated exposure therapy have been observed in RCTs for social anxiety disorder and specific phobia, which are reviewed in Hofmann et al. (2006) and Guastella and Alvares (2012). The first adjunctive DCS study with exposure-based treatment, conducted by Ressler and colleagues (2004), demonstrated that DCS facilitated reductions in subjective fear after virtual reality treatment for fear of heights. This immediate effect generalized to improved outcomes at one-week and three-month follow-up assessments, with greater numbers of self-exposures to real-world heights among those receiving DCS, indicative of greater clinical efficacy outside of a therapeutic context. Two RCTs for social anxiety disorder have demonstrated similar results. In the first, Hofmann and colleagues demonstrated that DCS administered prior to four exposure sessions significantly reduced self-reported social anxiety symptoms compared with placebo, with the greatest

difference observed at a one-month follow-up assessment. We replicated these findings in what is currently the largest study of DCS in combination with exposure therapy to treat an anxiety disorder. Fifty-six social anxiety patients received either DCS or placebo prior to four exposure-based therapy sessions. DCS-administered patients reported fewer social fear and avoidance symptoms, fewer dysfunctional cognitions, and greater overall improved functioning in everyday life posttreatment. Moderate effect sizes were found on most measures, and near-significant effects suggested that fewer DCS-treated patients may have dropped out of treatment in comparison with placebo. Further, treatment effects emerged early, with differences between drug groups emerging at the third exposure session. These studies demonstrated a positive relationship between DCS enhancement of therapy outcomes and the amount of learning achieved between exposure therapy sessions. Notably, indirect evidence suggests that the greater the amount of learning achieved within exposure therapy sessions, the greater the effectiveness of DCS in combination with exposure therapy (Guastella and Alvares, 2012).

Despite the success from social anxiety and specific phobia clinical trials, more mixed results have been reported for OCD and panic disorder, with several studies reporting beneficial effects of DCS only in more symptomatic patients or at midtreatment, but not posttreatment or follow-up (Guastella and Alvares, 2012). Two studies administered DCS adjunctively to an exposure-based protocol for OCD, finding that while some moderate gains emerged midtreatment, these disappeared by the end of the 10 sessions (Kushner et al., 2007; Wilhelm et al., 2008). This suggests that DCS may be useful in speeding up or enhancing the effectiveness of the initial phase of exposure-based treatment (Guastella and Alvares, 2012), and is in agreement with mixed findings from panic disorder clinical trials. It further indicates that DCS may be sensitive to the number of administrations. Indeed, multiple DCS administrations prior to extinction training appears to reduce its potential efficacy (Parnas et al., 2005), implying a potential tolerance of NMDA-R sites associated with chronic administration. Such a tolerability effect may, in part, explain some of the inconclusive findings from OCD clinical trials. It may also be that, for some patients, ceiling effects emerge in terms of treatment efficacy. For example, in a recent study examining the combination

of DCS with exposure-based therapy in PTSD patients (de Kleine et al., 2012), no significant effect of DCS was found on symptom reduction across the total sample. However, subgroup analyses suggested beneficial effects of DCS for regular, as opposed to early, completers of exposure-based therapy. As suggested by the authors, this may imply that only more severe patients are likely to benefit from DCS augmentation, while others recover relatively quickly from exposure-based therapy alone.

DIRECTIONS FOR FUTURE RESEARCH

Although RCTs of DCS in anxiety disorders have shown promising findings, conclusions about the outcomes of DCS-facilitated exposure therapy from these studies are limited by a number of factors such as study design heterogeneity, dosage, timing of administration, and number of adjunctive therapy sessions (Guastella and Alvares, 2012). These factors have been summarized in Table 46.1.

Given that the drug absorbs relatively slowly and takes approximately two to four hours to reach peak plasma levels, it has been suggested that null effects in some studies could reflect administration too soon before therapy to facilitate learning (Krystal, 2012). Studies are therefore needed that directly compare the effectiveness of DCS administered at different times relative to exposure, and administration before versus after therapy. Rodent studies indicate significant effects of DCS even when administered a relatively long time after extinction training. One advantage of administration after therapy is that DCS could be given only in sessions where within-session extinction has actually occurred, and thus where there is learning to consolidate, in order to minimize the risk of tolerance effects following chronic administration (Norberg et al., 2008). Administration only after successful exposure therapy sessions may therefore further enhance potential efficacy and treatment acceptability in the clinic.

An additional factor is that of dose; systematic dose-response studies with DCS are needed to determine the optimal dose for each administration. Most previous human studies have used 50 mg, and few have directly compared the effects of administering doses of varying levels (Guastella and Alvares, 2012; Norberg et al., 2008). It has also been suggested that prior exposure to antidepressants may limit DCS efficacy

TABLE 46.1. Administration and dosage factors that may influence the effects of DCS administration on learning in exposure therapy

FACTOR	RELATIONSHIP WITH EFFECTS OF DCS
Time of administration relative to therapy	Has been used successfully with administration both before and after exposure therapy. Greater time interval between administration and therapy appears to reduce efficacy, although window yet to be clearly defined (Myers and Davis, 2007; Norberg et al., 2008).
Chronic versus isolated administration	Evidence indicates that repeated chronic administration reduces or eliminates beneficial effects of DCS on extinction learning (Hofmann, 2007). Optimal number of doses and interval between doses yet to be established.
Dose	Unclear, yet to be systematically investigated (Guastella and Alvares, 2012; Hofmann, 2007; Norberg et al., 2008).
Previous use of other medications	Rodent studies suggest that previous use of antidepressants may reduce efficacy of DCS (Hoffmann, 2007; Norberg et al., 2008).

on NMDA receptor functioning. For example, rodents previously administered with the antidepressant imipramine exhibit reduced DCS facilitation of extinction training (Norberg et al., 2008). Further research is needed to investigate whether this also occurs with other drugs commonly coadministered in clinical practice, such as benzodiazepines or SSRIs, and to investigate whether these effects are short- or long-term in nature (Hofmann, 2007).

Further, it appears that DCS is best used in isolated doses; both preclinical rodent and clinical human studies indicate that any beneficial effects become less pronounced or disappear across repeated or chronic administration (Davis et al., 2006; Hofmann, 2007). This may reflect tolerance effects or a modification of the structure and function of the NMDA receptor complex through repeated activation (Davis et al., 2006; Richardson et al., 2004). Although available evidence indicates that acute administration is most effective and efficacy declines with repeated administration, the optimal number of doses and interval between repeated administration of DCS still needs to be defined (Hofmann, 2007).

NOVELTY AND CLINICAL POTENTIAL

Bearing in mind a number of factors that may limit initial conclusions about its efficacy in clinical practice, the findings of these RCTs provide the strongest evidence to suggest that DCS enhances exposure-based therapy for disorders that respond strongly to CBT, such as specific phobias and social anxiety. Novel augmentative approaches to anxiety treatment have a number of clinical benefits over traditional approaches. Speeding treatment response allows for efficient treatment delivery, benefitting both the patient and therapist. Augmentation of exposure therapy with DCS may also enhance the therapeutic response in treatment non-responders, especially for those who demonstrate insufficient learning of the required safety associations for successful fear extinction (Norberg et al., 2008). This may result in more cost-effective outcomes and decrease attrition rates across services. An additional perspective comes from stepped care models, in which treatments that are less intensive in terms of cost or therapist time are used as first-line treatments and more intensive treatments are reserved for either nonresponders to first-line treatment or patients initially identified as potential nonresponders (Bower and Gilbody, 2005). Such a model offers the potential to tailor treatment level to patient characteristics and severity in order to reduce costs and enhance efficacy. Considered within this framework, DCS could be utilized as a second-line treatment for individuals who do not initially respond to exposure-based protocols. The real potential for DCS is that, for a limited cost, it may substantially improve a simple evidence-based treatment, thus making an already relatively effective intervention more accessible and efficient.

NOVEL COGNITIVE APPROACHES

Cognitive models of anxiety emphasize that biased or irrational cognitive processes (thoughts, attitudes, beliefs, and

information processes) and consequent maladaptive emotions and behaviors are crucial etiological and maintenance factors in anxiety (Clark and Beck, 2010). Many contemporary learning theories go beyond purely behavioral accounts to acknowledge additional cognitive factors in anxiety, such as social and observational learning, CS-US contingencies and expectancies, and perceived control and predictability (Barlow, 2002). However, cognitive models differ in that cognitive processes are seen as a cause rather than merely a consequence of pathological anxiety (Clark and Beck, 2010). As reviewed by Clark and Beck (2010), the strength of cognitive models is bolstered by neurobiological evidence concerning the extensive connections between the amygdala and the hippocampal and higher order cortical structures (prefrontal, anterior cingulate, and orbital cortical regions) involved in conscious cognitive processes as well as the role of these structures in moderating fear responses and contextual fear conditioning.

Cognitive processes have formed a key target in the treatment of anxiety for quite some time, particularly in the form of cognitive-behavioral therapy, which, as mentioned earlier, is currently the “gold standard” in terms of psychological treatments for anxiety. As reviewed by Porto et al. (2009), neuroimaging studies suggest that treatment with CBT is associated with changes in the activity of neural areas identified as playing a critical role in the fear response (including the insula, anterior cingulate cortex, prefrontal cortex, amygdala, and hippocampal regions).

More recently, the cognitive anxiety literature has focused on the potential role of biases in information processes (including attention, interpretation, memory, imagery, and appraisal) in the etiology and maintenance of anxiety (see recent reviews in Beard, 2011; Macleod and Mathews, 2012). Attentional and interpretive biases toward threatening information among clinically anxious individuals are well supported by empirical evidence. A substantial body of evidence (see Bar-Haim et al., 2007; Ouimet, Gawronski, and Dozois, 2009) indicates that, relative to healthy controls, clinically anxious populations tend to preferentially attend to threatening (as opposed to nonthreatening) stimuli (i.e., display an *attentional bias*), and to interpret ambiguous information as threatening rather than positive (i.e., display an *interpretive bias*). For instance, a socially anxious individual might be more likely to attend to others’ negative facial expressions and also more likely to interpret ambiguous body language in a negative manner (e.g., as a sign of distaste for themselves rather than unrelated situational factors; see Beard, 2011). Based on the hypothesis that these biases may play a role in the etiology and/or maintenance of the anxiety disorders, they have been proposed as a potential target mechanism for novel anxiety treatment approaches (Beard, 2011). As the majority of research thus far has focused on the modification of attentional and interpretive biases, these will form the focus of the present section.

According to biased competition models, attention is mediated by both automatic deployment through a “bottom-up,” amygdala-based threat evaluation system that directs attention toward salient stimuli, and a more flexible “top-down,”

prefrontal cortical attentional control signal that is evoked when there are conflicting demands placed on attention (see reviews in Bishop, 2007; Browning et al., 2010a). These signals direct processing resources in the sensory and association cortices toward the preferred stimulus. It has been argued that the biased competition model used to account for attentional processes can also be applied to the interpretation of ambiguous stimuli, such that competition between alternate interpretations is resolved through the interaction of an amygdala-based threat evaluation system and a top-down prefrontal control system (Bishop, 2007). It appears that both automatic and controlled cognitive processes are involved in attention and interpretation (Bar-Haim et al., 2007; Mathews, 2012; Ouimet et al., 2009).

In a meta-analytic study, Bar-Haim et al. (2007) found that attentional bias toward threat is robust across anxiety disorders for both consciously perceived stimuli and stimuli presented outside of awareness. Attention consists of three primary stages: orientation and engagement, disengagement, and avoidance (Ouimet et al., 2009), with biases toward threat observed among clinically anxious individuals at all three stages. That is, during earlier stages of processing anxious individuals are likely to preferentially allocate attention to threat (facilitated attention). Once engaged they are also likely to experience trouble disengaging from threatening stimuli to focus on other stimuli (difficulty disengaging). Finally, at later, more strategic stages of processing they may be seen to divert attention away from threatening stimuli (attentional avoidance), which is hypothesized to maintain anxiety by preventing elaborative processing that reduces the threatening value of the stimulus (Bar-Haim et al., 2007).

As Bishop (2007) notes, the literature concerning the neurocircuitry of attentional and interpretive processes in anxiety is less developed than that of fear conditioning and extinction learning. However neurobiological evidence from animal models and neuroimaging studies in humans implicate perturbations in both the amygdala-based and prefrontal fear systems when explaining biased information processing (see reviews in Bishop, 2007; Hofmann et al., 2012). More specifically, pathological anxiety is hypothesized to involve both hyperactivation of the amygdala-based threat evaluation system and insufficient downregulation of the fear response by prefrontal control mechanisms. This neurobiological perturbation results in heightened activation of threat-related representations and failure to activate nonthreatening representations, and has been used to account for both interpretive and attentional biases in the literature (Bishop, 2007; Cisler and Koster, 2010). Cisler and Koster (2010) have proposed that hyperactivity of the amygdala-based system is likely to account for automatic vigilance and facilitated attention to threat, while failure of the higher order prefrontal system to downregulate amygdala activity and direct attention to task-relevant stimuli may explain difficulty disengaging from threat. The attentional avoidance component of attentional biases also appears to reflect activity in the prefrontal region, through its role in strategic emotion regulation. Similarly, in their cognitive-neurobiological information-processing model, Hofmann et al. (2012) also emphasize the role of

subcortical networks in hypervigilance and facilitated attention to threat and prefrontal cortical structures in higher order regulation of anxiety responses.

COGNITIVE BIAS MODIFICATION—CBM

Recognition of the association between information processing biases and pathological anxiety led to the development of cognitive bias modification treatments for anxiety disorders. These treatments aim to modify these biases to subsequently alleviate anxiety symptoms.

ATTENTION BIAS MODIFICATION (CBM-A)

Attention bias modification focuses specifically on retraining attentional biases toward threat (see Bar-Haim, 2010, for an overview). Typically, this is done using a “dot-probe task” (depicted in Fig. 46.1), where participants are asked to discriminate between two variants of a probe (e.g., “.” and “..”) and respond by pressing the corresponding one of two keyboard keys. These probes are presented behind two stimuli (e.g., words or pictures), one threatening and one neutral. In the original task, developed to assess attentional biases, the target probe is presented behind the threatening stimulus 50% of the time. A threat bias is indicated when participants are faster to identify probes presented behind a threatening stimulus relative to those presented behind a neutral stimulus.

An extension of the dot-probe task manipulates or retrains this attentional bias toward threat. In the modified paradigm, the target probe is presented consistently behind either the threatening (attend-threat training) or neutral (avoid-threat

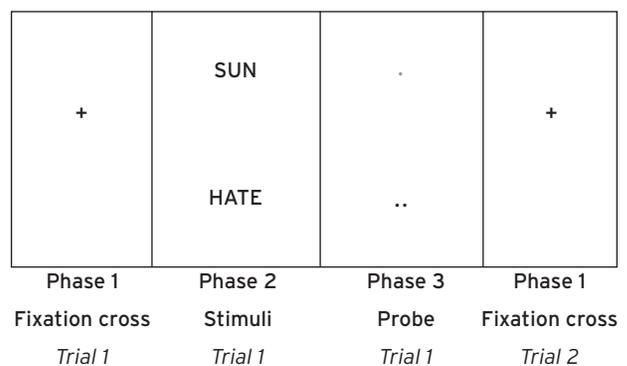

Figure 46.1 A typical protocol for attentional bias assessment or training using the dot-probe paradigm. A typical dot-probe attention bias task, where the target probe is the single dot (denoted in gray). The participant is instructed to fixate on the cross, then press the keyboard key that corresponds to the location of the target probe, and finally refixate on the cross for the start of the next trial. Between the presentation of the cross and the probe, two emotionally valenced stimuli are presented in the locations where the probes will appear. In attentional bias assessment (or control training with no contingency), the target probe appears behind the threatening and neutral stimuli with equal probability (i.e., 50% of the time for each). In avoid-threat attentional bias training, the target probe is always presented behind the nonthreatening stimulus. In attend-threat training, the target probe is always presented behind the threatening stimulus.

training) stimulus. Since attending to the relevant stimulus results in the correct identification of the target probe, repeated trials should implicitly train the individual to preferentially allocate attention either toward or away from threat, depending on the training contingency.

INTERPRETIVE BIAS MODIFICATION (CBM-I)

Interpretive biases can be assessed in two broad ways (as reviewed in Mathews and MacLeod, 2005). Online measures assess interpretations at the time of encountering ambiguous information, usually by assessing latency to read targets that either confirm or disconfirm possible threatening interpretations of ambiguous primes. Targets that confirm the participant's interpretation of the ambiguous prime are read or identified more quickly than those that disconfirm their interpretation. Offline measures assess interpretations either before or after encountering ambiguous information, usually through self-report. Studies using offline measures have consistently shown a negative interpretive bias in clinically anxious populations, while those using online measures have found mixed results but generally support either the presence of a negative interpretive bias or the absence of the emotionally positive bias often present in nonanxious controls (Mathews and MacLeod, 2005).

A common means of CBM-I involves the presentation of a series of ambiguous homographs or situations, followed by a word fragment target that must be completed after reading the stimulus (Beard, 2011). The emotional valence of the ambiguous stimulus can only be interpreted by using the subsequent target. The individual can be compelled to interpret these ambiguous stimuli in either a negative or positive manner through the consistent presentation of word fragment targets that relate to either the negative or positive interpretation. Thus, over repeated trials, the participant develops a positive or negative interpretive bias.

EMPIRICAL EVIDENCE

Many CBM studies have been conducted under a diathesis-stress model of anxiety, which suggests that CBM may reduce what is known as stress reactivity or vulnerability (i.e., the level of anxiety in response to a stressor) but not necessarily anxiety symptoms per se. Hence, the beneficial effects of CBM on anxiety should only be apparent once patients are exposed to a stressor (Hallion and Ruscio, 2011). Empirical studies have therefore investigated the impact of CBM on anxiety symptoms either immediately posttraining or in reaction to a stressor (laboratory-induced or naturalistic). A number of recent reviews have been conducted to consolidate findings from previous CBM-A studies (Bar-Haim, 2010; Hakamata et al., 2010) and CBM studies more generally (Beard, 2011; Macleod and Mathews, 2012).

CBM-A

The majority of CBM-A studies conducted thus far have employed a modified dot-probe paradigm (Macleod and

Mathews, 2012). Studies in nonclinical populations compare avoid-threat training to either an attend-threat or a no-training placebo control (no training contingency) condition. While these studies have consistently demonstrated that it is possible to induce an attentional bias toward or away from threat, the impact of CBM-A on anxiety scores posttraining and in response to a stressor have been mixed (Beard, 2011). More specifically, there is stronger evidence in support of reduced stress reactivity (i.e., anxiety in response to a stressor) following avoid-threat training than there is for reductions in posttraining state and trait anxiety. In clinical populations, CBM-A studies have thus far been conducted in generalized anxiety disorder (GAD) and social anxiety disorder (SAD) patients, typically allocated to either avoid-threat or a no-training placebo control. As reviewed in Bar-Haim (2010) and Macleod and Mathews (2012), these studies have consistently demonstrated that CBM-A can be used to retrain attentional biases away from threat toward neutral information. Furthermore, significant reductions in both anxiety symptoms and stress reactivity have been found for those participants allocated to avoid-threat training. These outcomes have been found following both single- and multisession attention training, and shown to persist over time to follow-up assessment up to 4 months later (Macleod and Mathews, 2012). Hakamata et al. (2010) recently conducted a meta-analysis of 12 CBM-A studies employing the dot-probe paradigm (among nonclinical populations, GAD, and SAD patients), including only studies where the control group was a no-training placebo rather than attend-threat training. This analysis demonstrated a large and significant effect size of avoid-threat training on attention bias. It also found a medium and significant effect on anxiety symptoms (relative to control training placebo). It is important to note, however, that the effect on anxiety symptoms included both posttraining measures of anxiety symptoms and measures of anxiety symptoms following exposure to a stressor (i.e., stress reactivity). Effect sizes for the impact of CBM-A on anxiety symptoms did not differ significantly between patients and nonclinical samples. Interestingly, the effect of CBM-A on magnitude of attention bias change (but not on magnitude of anxiety symptom change) was significantly moderated by the number of sessions involved. For attention bias change, a greater number of sessions was associated with a greater amount of change. However, these findings are tentative given the small number of studies concerned.

CBM-I

As reviewed in Beard (2011) and Macleod and Mathews (2012), single- and multiple-session versions of CBM-I have been used in nonclinical populations to successfully induce positive and negative interpretive biases. In these studies, interpret-positive and interpret-negative training have been compared with each other or to a no-training placebo control. Although a few studies have reported null findings, others have found significant reductions in outcome measures (state and trait anxiety and/or stress reactivity) for those allocated to the interpret-positive condition. Studies in GAD patients and populations with high trait or state

anxiety (including worry, social anxiety, spider fear, and trait anxiety) have compared the impact of single- or multiple-session interpret-positive training versus a no-training placebo control on stress reactivity and anxiety symptoms. In both clinical and nonclinical populations, interpretive bias modification from single-session training has been shown to persist over time up to 24 hours later, the longest time period investigated thus far (Macleod and Mathews, 2012). In terms of clinical outcomes, several studies have found that interpret-positive training induces a positive interpretive bias and reduces state and trait anxiety, anxiety symptoms, and/or stress reactivity. However, results have been mixed depending on the specific anxiety disorder and outcome measure concerned. First, CBM-I has not yet been shown to significantly reduce spider fear (Macleod and Mathews, 2012). Further, its effect on posttraining anxiety versus stress reactivity is still unclear. Some studies have shown significant reductions in state and trait anxiety from CBM-I but no effect on specific anxiety symptoms (e.g., social anxiety scales) or stress reactivity, while others have found the opposite (Beard, 2011).

Hallion and Ruscio (2011) recently conducted a meta-analysis to examine the effect of CBM (both CBM-I and CBM-A) on cognitive biases and anxiety symptoms posttraining and poststressor across both anxiety and depression. Their review included both clinical and nonclinical populations and, unlike Hakamata et al., did not exclude CBM-A studies using an alternative to the dot-probe paradigm or those comparing avoid-threat training to attend-threat training rather than a no-training placebo. Across anxiety and depression, this comprehensive review found a significantly larger effect of CBM on interpretive biases (medium effect size) than on attention biases (small effect size). After correcting for publication bias, the effect of CBM on anxiety and depression symptoms was significant following exposure to a stressor (with a small effect size), but not immediately posttraining. This echoes the mixed findings of narrative reviews outlined previously in relation to the effect of CBM on posttraining anxiety versus stress reactivity, although again it is important to bear in mind the inclusion of studies concerning both anxious and depressive symptoms. When anxiety studies were examined separately, there was a small but significant effect of CBM on symptoms both posttraining and after exposure to a stressor.

HYPOTHESIZED MECHANISM OF ACTION

A key assumption of CBM and associated models of anxiety is that information processing biases are a causal factor in the etiology and maintenance of anxiety disorders rather than merely a consequence of anxiety (Hallion and Ruscio, 2011). That is, CBM assumes that information processing biases precipitate negative thoughts and subsequent maladaptive behavioral and emotional patterns. This assumption about the causal role of information processing biases in anxiety disorders requires further empirical validation. Prospective studies have provided preliminary support, demonstrating that information processing biases are capable of predicting the presence and severity of anxiety disorders, as well as stress reactivity (as reviewed in Beard, 2011; Mathews and MacLeod, 2005). These associations

could, however, be a product of a third stable personality variable that predicts both cognitive biases and anxiety outcome measures (Mathews and MacLeod, 2005). Further support comes from the results of intervention studies outlined earlier, which have shown that CBM can be used both to modify cognitive biases (toward and away from threat) and accordingly increase or reduce anxiety levels. Further, in their CBM-A review Hakamata et al. (2010) reported a strong correlation between the degree of attention bias change and the degree of change in anxiety scores that approached significance. Again, however, it is possible that change in anxiety symptoms is not mediated by change in cognitive biases but by some other associated factor. In their meta-analysis of CBM for anxiety and depression, Hallion and Ruscio (2011) found that change in cognitive biases did not significantly moderate the effect of CBM on symptoms, although the effect did approach significance. They note that this finding should be interpreted cautiously given the diverse array of trials included in their analysis, and indeed a substantial number of individual trials have demonstrated that change in cognitive biases mediated change in anxiety symptoms (Beard, 2011). Together, existing evidence provides partial support for a causal role of biased information processing in anxiety and a mediational role of cognitive bias change in clinical outcomes of CBM interventions.

Preliminary research has been conducted to explore the neurobiological mechanisms underlying change following CBM-A. It has been suggested that CBM-A may serve to modify attentional control processes, as opposed to the more “bottom-up” threat evaluation processes (Bar-Haim, 2010; Beard, 2011). As reviewed in Beard (2011), Derryberry and Reed (2002) have shown that anxious individuals with strong attentional control do not show an attentional bias, which suggests that attentional control moderates the relationship between attention bias and anxiety. Further, neurobiological evidence suggests that CBM-A may serve to modify attention through effects on prefrontal attentional control processes (Browning et al., 2010a). A first CBM-A neuroimaging study (Browning et al., 2010b) among healthy individuals found significant differences in the activity of prefrontal cortical, but not amygdala-based, structures between those who had completed attend- versus avoid-threat training in a subsequent task. Further, Koster et al. (2010) found that avoid-threat CBM-A influenced late but not early stages of threat processing, hypothesizing that the procedure influences later stage attentional avoidance rather than earlier hypervigilance and facilitated attention processes.

Little is known at present about the specific mechanism of action by which CBM-I modifies interpretive processes. Some research has been conducted to explore whether artifacts are responsible for the changes in interpretive bias that occur. Evidence suggests that they do not simply reflect a response bias or demand effects induced by repeated trials, they are not fully accounted for by semantic priming effects alone, nor are they entirely dependent on changes in mood and state anxiety that may occur as a result of exposure to emotionally salient stimuli during training (Beard, 2011; Macleod and Mathews, 2012). It appears that active generation of interpretations rather than mere passive processing is necessary for CBM-I

to have a significant impact on anxiety levels (Beard, 2011). Mathews (2012) has suggested that this highlights a potential mechanism of action for CBM-I, specifically the acquisition of a particular processing style for emotionally salient information. That is, through interpretive training the individual may learn a new style of seeking and selecting specific types of emotional meanings, which is then unintentionally elicited and implemented when encountering subsequent ambiguous events in real life.

NOVELTY AND CLINICAL POTENTIAL

The critical finding from CBM-A trials has been evidence that these procedures produce treatment effect sizes comparable to traditional psychological and pharmacological interventions for anxiety, while requiring relatively minimal time and clinician input (MacLeod et al., 2009). In the future, computerized bias modification therapy could be made accessible on a range of technological platforms such as personal computers and mobile phones, and even over the Internet, for patients who are unable or unwilling to attend in-person therapy sessions. In this way, it offers the potential to address many practical barriers to participation in therapy. Furthermore, its convenience, accessibility, and low operating costs may be particularly beneficial in terms of facilitating ongoing practice and engagement in treatment and so potentially reducing the risk of attrition and relapse and promoting maintenance of treatment gains (Bar-Haim, 2010). The outcomes from CBM trials imply that it may also be useful as an adjunct to CBT, with the potential to be used as a preparatory step to exposure-based CBT in more severe patients, to reduce anxiety to a point where they can participate in behavioral experiments (MacLeod et al., 2009). CBM-A may also be a useful adjunctive treatment to psychotropic medications for anxiety (Browning et al., 2010a), or integrated into stepped-care models as a preliminary step for patients who are seen to require less intensive intervention. However, as cautioned by Macleod and Mathews (2012), there is not yet sufficient evidence to suggest that CBM can be used as a stand-alone treatment for anxiety disorders. Further, a first study of Internet-delivered CBM-A (Carlbring et al., 2012) published this year found it had no significant effect on social anxiety symptoms and general anxiety levels among individuals with social anxiety disorder. Thus, further investigation into the impact of delivery mode on treatment outcome for CBM is needed before implementation of Internet-based CBM treatment programs.

DIRECTIONS FOR FUTURE RESEARCH

Many potential avenues for improving both efficacy and utility of CBM remain. Further exploration into the role of other information processing biases aside from interpretation and attention (such as memory, imagery, and appraisal) in anxiety, and the development of relevant bias modification therapies, should be undertaken (Macleod and Mathews, 2012). It may well be that the type of CBM offered to patients could be customized to their particular information processing

biases (MacLeod et al., 2009). It has also been proposed that the impact of CBM could be boosted by using training packages targeted at modifying multiple cognitive biases (Hallion and Ruscio, 2011). Although a recent pilot study (Beard et al., 2011) found that a combined interpretive and attentional CBM training package significantly improved anxiety symptoms and speech performance among SAD patients, it remains to be seen whether this combination approach results in significantly greater symptom reduction than programs targeting one type of cognitive bias.

Future studies should also focus on using cognitive theory and knowledge of the cognitive mechanisms underpinning anxiety to enhance the efficacy of CBM. At present, technology is being used to enhance CBM through the development of programs delivered through the Internet or smartphones, meaning that patients can be exposed to treatment over extended periods of time and across multiple settings (Macleod and Mathews, 2012). The possibility of using novel pharmacological compounds, such as DCS, to enhance the potency of bias modification interventions is also being investigated (Behar et al., 2010). Another possible means of enhancing efficacy involves the modification of specific components of CBM. This could include the tailoring of stimuli to the specific informational domains related to each anxiety disorder (such as faces or other socially relevant stimuli in CBM-A for social anxiety; see Hakamata et al., 2010; MacLeod et al., 2009), based on findings that patients' information processing biases are most evident when assessed on stimuli related to their particular disorder.

Finally, in CBM, participants are generally not explicitly informed of the training contingency but instead implicitly learn it through the completion of repeated trials. Hence, although some CBT packages also include attentional training or interpretive restructuring exercises, a crucial distinction between CBM and these CBT exercises is that CBM aims to implicitly retrain information processing biases rather than to consciously challenge and modify thoughts and behaviors (Beard, 2011). An area for further investigation is the impact of adding explicit instructions to CBM training, which may either facilitate or impair learning of the training contingency (Bar-Haim, 2010; MacLeod et al., 2009). As outlined in Macleod and Mathews (2012), only two CBM-A studies to date have compared explicit and implicit instruction conditions, reporting contradictory findings such that explicit instruction either enhanced or eliminated the therapeutic effects of CBM-A on anxiety.

Therefore, the grounding of CBM in cognitive theory means that it has immense potential to be developed and enhanced as a treatment for anxiety. The strength of this approach will be further bolstered by integration with neuroimaging techniques and circuitry models of both cognitive processes and the etiology and maintenance of anxiety disorders. As the neurocircuitry of these cognitive processes (attention and interpretation) and the ways in which they are altered among individuals suffering from pathological levels of anxiety are better understood, CBM interventions can be developed that specifically aim to rectify these perturbations (such as enhancing prefrontal control of attention).

NOVEL DELIVERY APPROACHES— INTERNET THERAPY

One of the key barriers to treatment response outlined in the introduction to this chapter is the failure to successfully engage some individuals. The use of technology (particularly the Internet or computers) to deliver psychotherapy is a practical means of addressing this issue. Internet- and computer-based psychotherapy (ICT) programs involve the delivery of structured psychotherapy modules through a computer located at a clinic (computer-based), or remotely via the Internet on the patient's personal computer or smartphone (Internet-based). The anonymity and potential accessibility of ICT may overcome common practical barriers to seeking and participating in therapy such as unwillingness, fear of stigma, lack of time, mobility or transport, or isolated geographical location (Andrews et al., 2010; Schmidt, 2012). In this way, approaches such as ICT are a means of engaging patients in the therapeutic learning required to successfully modify fear circuitry and overcome their anxiety. ICT programs also offer the potential to provide a consistent standard of treatment (Reger and Gahm, 2009) that is independent of the success of a therapeutic alliance or the expertise of an individual therapist and may therefore maximize the potential for positive outcomes. Furthermore, ICT can be flexibly integrated into a patient's lifestyle and offers the potential for constant review of the treatment program in order to consolidate the learning taking place during treatment (Spek et al., 2007), which may also enhance efficacy and reduce risk of relapse. From a practical perspective, Internet-based treatments also offer the potential to reduce the economic burden placed on the health care system (Spek et al., 2007).

Clinician involvement in ICT ranges from entirely self-directed programs, with or without reminders and technical help from a therapist or nonclinical technician (*minimal assistance*), to clinician-directed programs with feedback and/or advice as patients progress through the program (Andrews et al., 2010; Spek et al., 2007). Minimal assistance does not involve clinical feedback or the establishment of a therapeutic relationship but mere facilitation of the patient's independent progress through the program (Spek et al., 2007). Contact from a therapist or technician may be in person or via phone, post, or e-mail. The majority of ICT programs that have been tested thus far have been based on a cognitive-behavioral therapeutic framework (Andersson et al., 2007). Accumulating evidence from RCTs of cognitive-behavioral ICT programs for anxiety disorders is promising. Spek et al. (2007) conducted a meta-analysis of seven treatment trials comparing Internet-based CBT with nontreatment control groups (waiting list, self-monitoring, or information control) for adults with panic disorder and social anxiety disorder, finding a large reduction in anxiety symptoms. There is also evidence from several studies that gains from ICT are maintained over time to follow-up assessment (Andrews et al., 2010). More recently, Reger and Gahm (2009) separately examined the effect sizes for ICT compared with wait list, placebo, and therapist-delivered treatment-as-usual (TAU) conditions. In their analyses ICT programs were significantly more effective than both

placebo (ES = 0.88) and wait list control (ES = 0.77) conditions, and there was no significant difference between ICT and therapist-delivered TAU. However, as reviewed in (Reger and Gahm, 2009), the conclusions of these studies are limited by both their heterogeneity and key methodological limitations such as small sample sizes, high dropout rates, and failure to use wait list control conditions.

ICT may prove especially useful as an initial treatment step in stepped-care models or as an adjunct to in-person CBT or pharmacological treatments. One key priority in future ICT research should be to establish the relationship between extent of clinician assistance and treatment outcome, with a view to balancing the potential cost savings associated with more self-directed programs with issues of risk management, motivation, and compliance according to the needs of the individual. The nature of this relationship is yet to be established. Andersson et al. (2007) found a strong and significant correlation between clinician contact and treatment outcome for ICT programs, and Spek et al. (2007) suggested programs with assistance had lower heterogeneity and greater effect sizes than those without. Meanwhile, Reger and Gahm (2009) found no significant effect of clinician assistance on the outcome of ICT programs, although this was based on a categorical comparison of programs with and without clinician assistance. Future studies should include a continuous measure of level of clinician assistance as a matter of course to address this issue.

Moreover, the ICT interventions that have been developed to date have largely been an extension of existing models of psychotherapy (CBT in particular), simply delivered in a new modality. While this has value in terms of determining whether traditional CBT can be successfully administered over the Internet or in other formats, it does not focus more broadly on what treatment strategies can be delivered via technology to produce the best clinical outcomes. Future interventions should capitalize on the practical advantages of self-delivered ICT, while targeting different cognitive and neurobiological mechanisms underlying anxiety disorders, rather than merely trying to replicate what takes place in the therapy room.

COST EFFECTIVENESS AND ACCEPTABILITY OF NOVEL INTERVENTIONS

Following on from further empirical and theoretical validation, effectiveness trials will now need to be undertaken with these novel treatment approaches in order to investigate their potential translation into clinical practice. Compared with patients enrolled in many RCTs, patient populations are less homogenous and exhibit significant comorbidity with other psychiatric disorders, which may play a role in treatment non-response. Outside the laboratory, it may also be difficult to regulate specific aspects of treatment regimes, such as timing of administration and the nature of exposure therapy, in the case of DCS (Guastella and Alvares, 2012). Similarly, cost effectiveness and acceptability to key stakeholders are important factors to consider when evaluating new treatment approaches and are reviewed in the next section.

DCS

As larger scale RCTs of DCS are only now beginning to emerge, there is limited evidence surrounding its acceptability and cost effectiveness. If, as empirical results suggest, DCS can be used to enhance clinical efficacy and/or the speed and efficiency of treatment, it may improve patient satisfaction and treatment outcomes and reduce attrition to enhance both the cost effectiveness and acceptability of exposure-based therapy (Norberg et al., 2008). No studies have examined the cost effectiveness of DCS-augmented CBT or compared it with nonaugmented CBT. In relation to acceptability, it appears that DCS is well tolerated with minimal side effects (Hofmann et al., 2006). Furthermore, one study (Kushner et al., 2007) that compared attrition rates for exposure therapy with and without DCS found that dropout rates were six times greater among those who did not receive DCS, hypothesized to be attributable to greater symptom reduction among the DCS group.

CBM

Although the cost effectiveness of CBM has not yet been studied specifically, it has the potential to be an effective treatment for anxiety that requires minimal therapist input and time and has relatively low operating costs. In a recent review of CBM (Beard, 2011), the authors note that the relatively low attrition rates in previous studies (0–8%) may not be an indication of the acceptability of CBM in the “real world” due to the incentive of participant reimbursement. In their own pilot study assessing multisession CBM (combined CBM-A and CBM-I) in real treatment settings without remuneration, Beard et al. (2011) reported a substantially greater attrition rate (33%), although those patients who completed the program reported high levels of satisfaction on a standardized questionnaire. Qualitative results of CBM studies indicate that treatment credibility is an issue (see review in Beard, 2011); as CBM involves implicit retraining using repeated practice on a cognitive task, it may be viewed by some patients as monotonous, obscure, or pointless. These concerns are particularly relevant to CBM-A, which appears to have lower perceived face validity than CBM-I (Beard et al., 2011). Unfortunately, negative attitudes are likely to influence not only the likelihood of uptake but also the success of treatment, given that perceived treatment credibility and treatment preferences are known to play a key role in adherence (Taylor et al., 2012) and treatment outcome (Collins et al., 2004).

One important final consideration relates to the generalizability, longevity, and real-world applicability of laboratory treatment effects for CBM. Consideration of context-specific learning effects has led to the development of home-based training programs to promote transfer of learning to naturalistic environments (Macleod and Mathews, 2012). However, more work needs to be done to assess the generalizability of treatment gains across a variety of stimuli, particularly given that many studies have assessed bias change using the same cognitive task on which participants were trained (MacLeod et al., 2009). Those studies that have included independent measures of cognitive biases to assess generalizability have reported mixed results (Beard, 2011). Future studies should also focus on

incorporating longer term assessment of cognitive biases, and the development of bias modification programs designed to maximize the duration of bias change (e.g., using spaced learning and booster sessions) (Macleod and Mathews, 2012).

ICT

Although at face value ICT would seem to reduce costs by minimizing the amount of therapist time required, the use of minimal therapies such as ICT may in fact result in cost shifting to other sectors and encourage patients to seek supplementary interventions (Bower and Gilbody, 2005). Interestingly, the sole cost effectiveness analysis that has been conducted thus far suggested that ICT is competitively cost effective (McCrone et al., 2004). Of particular concern in terms of acceptability of ICT is the issue that should ICT programs be implemented as a preliminary stage to in-person therapy in a stepped-care approach, patients may view ICT as an inferior and less “personal” treatment option (Andersson et al., 2007). Results thus far have been mixed, with concerningly low uptake rates and substantial variation in attrition rates across the various ICT trials that have been conducted. Overall, self-reported patient satisfaction tends to be relatively high among those who have used the treatment (see review in Waller and Gilbody, 2009). However, individuals who have chosen to participate in ICT trials may be more computer literate or amenable to computer-delivered treatments than the general population, and thus satisfaction from such self-selecting samples should be considered with caution. Clearly, treatment acceptability among broader samples should be a focus of future research.

CONCLUSION

As summarized in Table 46.2, the novel treatment approaches explored here differ greatly in terms of their nature and the specific mechanisms of anxiety they target. However, they share a common goal of harnessing knowledge of the cognitive, behavioral, and neurobiological mechanisms underlying anxiety to enhance treatment outcomes.

Future research should continue to assess and further improve the clinical efficacy, cost effectiveness, and acceptability of these interventions. In particular, their efficacy across different anxiety disorders needs to be established to inform evidence-based treatment guidelines. As outlined in Table 46.3, most evidence for the efficacy of these interventions is either still forthcoming or has exhibited mixed results.

Aside from further refining and extending these existing novel approaches, future research should continue within this translational framework to capitalize on our growing understanding of the anxiety disorders and extend our reach with further novel augmentative approaches. A particular emphasis should be placed on understanding the effects of interventions on underlying fear neurocircuitry, the ways in which this circuitry may be different among individuals with anxiety disorders, and which aspects may be modified to produce therapeutic outcomes. Furthermore, there is now a growing and substantial

TABLE 46.2. Proposed therapeutic mechanism of action and neural target site for each of the novel pharmacological, cognitive, and technological interventions reviewed in this chapter

INTERVENTION	(POTENTIAL) THERAPEUTIC EFFECT	PROPOSED TARGET SITE/ NEURAL MECHANISM OF ACTION
Cortisol	Impairs retrieval of fear memories, enhances consolidation of fear extinction training/exposure therapy (Wolf, 2008)	Acts on glucocorticoid receptors; impaired retrieval relates to medial temporal lobe activity (Wolf, 2008); fear extinction mediated by the basolateral amygdala (Myers and Davis, 2007)
Yohimbine	Enhances learning in fear extinction training/exposure therapy (Holmes and Quirk, 2010)	α 2-adrenoreceptor antagonist in the hippocampus, amygdala, and prefrontal cortex; increases extracellular norepinephrine (Holmes and Quirk, 2010)
DCS	Enhances learning in fear extinction training/exposure therapy (Davis et al., 2006)	Cofacilitates glutamatergic activation of NMDA receptors in the amygdala at glycine binding site (Davis et al., 2006)
CBM-A	Reduces threat-related attention bias (Bar-Haim, 2010)	Not yet well established; may modify prefrontal activity (Beard, 2011)
CBM-I	Reduces threat-related interpretive bias (Mathews, 2012)	Not yet established
ICT	Depends on therapeutic framework. For CBT-based interventions, aims to modify distorted cognitions and maladaptive behavior patterns.	Not yet established

TABLE 46.3. State of current evidence for the effectiveness of each novel intervention in the reduction of anxiety symptoms across the various anxiety disorders

	GAD	SAD	SPECIFIC PHOBIA	PTSD	OCD	PANIC DISORDER
Cortisol	—	✓	✓	✓	—	—
Yohimbine	—	—	?	—	—	—

ICT	✓	✓	✓	?	?	✓

✓ indicates that trials to date have supported effectiveness of this intervention; ? indicates insufficient or mixed evidence from trials to date; — indicates that this intervention has not been studied in relation to this disorder.

body of evidence concerning the role of genetic and environmental factors in the etiology and maintenance of anxiety (as reviewed in Hamilton and Fyer, 2009). As research in this area expands, a better understanding of the interactions between genetic and environmental risk factors in the neuroplastic changes that underpin pathological anxiety will facilitate the delivery of preventative and early-stage interventions targeted toward at-risk groups. Such early-stage interventions are a critical step in improving the outcomes of anxiety treatment. For both existing and future treatment approaches, these interindividual genetic and neurobiological differences are likely to be a key predictor of treatment response, providing a potential means to target efficacious interventions to the right individuals.

DISCLOSURES

The chapter authors have no conflicts of interest to declare.

47 | PHARMACOTHERAPY OF ANXIETY DISORDERS

JAMES W. MURROUGH, DAN V. IOSIFESCU, AND
DENNIS S. CHARNEY

INTRODUCTION

Anxiety disorders are among the most prevalent mental disorders in the United States and are associated with a high degree of morbidity and public health costs (Kessler et al., 2005a). Approximately one in four adults will suffer from an anxiety disorder at some point in their lives. Anxiety disorders often have an age of onset in young adulthood or before and are frequently comorbid with general medical disorders and other psychiatric disorders. General risk factors for the development of an anxiety disorder include a temperamental trait described as behavioral inhibition—increased physiological reactivity and anxious behaviors observed in some children in response to unfamiliar surroundings—female gender, family history, and exposure to certain types of environmental stress in childhood or adulthood. Chapter 40 of this volume provides a thorough discussion of the genetics of anxiety disorders.

There are seven primary anxiety disorders defined in the Diagnostic and Statistical Manual of Mental Disorder—Fourth Edition, Text Revision (DSM-IV-TR): panic disorder, specific phobia, social phobia, obsessive-compulsive disorder (OCD), posttraumatic stress disorder (PTSD), acute stress disorder, and generalized anxiety disorder (GAD) (American Psychiatric Association, Task Force on DSM-IV, 2000). The current chapter will focus on the pharmacotherapeutic treatment of panic disorder, PTSD, GAD, and social phobia. The treatment of OCD is discussed by Dr. H. Blair Simpson in Chapter 48 and will not be reviewed here. Acute stress disorder is characterized by symptoms similar to those of PTSD that occur immediately following a traumatic event and will not be discussed separately from PTSD. Finally, specific phobia will not be discussed since there is a minimal role for pharmacotherapy for this disorder.

Other anxiety disorders defined in the DSM-IV-TR are considered to be secondary to either the direct physiological result of another medical condition (anxiety disorder due to a general medical condition: e.g., hyperthyroidism) or the direct physiological consequence of a substance (substance-induced anxiety disorder: e.g., withdrawal from alcohol or a sedative/hypnotic medication). These important secondary causes of anxiety disorders will not be discussed in depth; however, it is critical that these disorders be considered in the diagnostic assessment of the patient who presents with anxiety. The residual category termed “anxiety disorder not otherwise specified”

is included in the DSM to enable patients who present with prominent anxiety symptoms and functional impairment but who do not meet the criteria for a specific anxiety disorder to be diagnosed. Chapter 39 of this volume provides a complete discussion of the diagnosis of anxiety disorders.

A general approach to the evaluation and treatment of anxiety disorders is presented in Table 47.1. A complete diagnostic assessment—including medical and psychiatric history, vital signs, physical exam, and laboratory or other tests if indicated—should precede initiation of a treatment intervention. As mentioned earlier, particularly important to consider in the differential diagnosis of a patient who presents with anxiety symptoms are general medical disorders and substance use disorders. Other important principles relevant to the diagnosis and treatment of anxiety disorders include the establishment of a therapeutic alliance, provision of psychoeducation and counseling, and ongoing assessment of treatment adherence (Table 47.1). For most patients, first-line treatment will consist of an evidence-based trial of a medication, a psychotherapeutic modality (e.g., cognitive-behavioral therapy ([CBT]), or a combination of the two. If the treatment is effective, it should generally be continued for at least 6–12 months in the case of pharmacotherapy while some prescribed forms of CBT are considerably shorter. If the initial treatment modality is either partially effective or ineffective, then the treating clinician must determine the next best treatment step for the particular patient. Pharmacotherapeutic next-step options typically consist of augmentation—the addition of another agent to increase the effectiveness of the primary agent, or combination—the addition of a second antianxiety agent, or switching agents (Table 47.1).

An overview of U.S. Food and Drug Administration (FDA)-approved pharmacotherapeutic agents available to the clinician for the treatment of anxiety disorders is presented in Table 47.2. As will be reviewed in detail in the following text for specific anxiety disorders, serotonin-selective reuptake inhibitors (SSRIs) and serotonin-norepinephrine reuptake inhibitors (SNRIs) are usually considered first-line medication treatment. Older monoaminergic agents—including the tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs)—are often efficacious but are usually reserved for second-line treatment due to safety and tolerability issues. The benzodiazepines (BZDs) play an important role in the treatment of some anxiety disorders; however, these agents, too, are usually reserved for second-line or adjunctive use due

TABLE 47.1. Approach to the treatment of anxiety disorders

1. Diagnostic Assessment
Complete medical and psychiatric history.
Assess for general medical or substance-related causes of anxiety symptoms.
Obtain laboratory (e.g., TSH) or other diagnostic tests if indicated by history.
Establish working diagnosis of a primary anxiety disorder after ruling out secondary causes.
Establish presence or absence of comorbid psychiatric, medical, or substance use disorders.
2. Develop therapeutic alliance with patient to facilitate adherence to treatment.
3. Provide initial and ongoing psychoeducation to facilitate adherence to treatment.
4. Initiate first-line pharmacotherapeutic or psychotherapeutic treatment.
5. If initial treatment is effective, continue treatment for a minimum of 6 to 12 months, depending on clinical situation.
6. If initial treatment is ineffective:
Assess adherence to treatment, provide psychoeducation, address potential barriers to treatment adherence, optimize therapeutic alliance.
Reassess primary diagnosis and presence of comorbid psychiatric, medical, or substance use disorders.
Consider switch to alternative first-line treatment option or augment current treatment with another evidence-based treatment option.
7. If first-line treatment options are ineffective:
Identify potential specific psychosocial stressors that may respond to nonmedical intervention.
Recommend evidence-based psychotherapy if not already tried.
Consider second-line treatment options based on clinical circumstances and patient preference.
Pursue ongoing diagnostic reevaluation and adherence monitoring

to tolerability and abuse liability issues. Benzodiazepines act by binding to a specific site on the gamma-aminobutyric acid (GABA)-A receptor and increasing the inhibitory effect associated with GABA binding. Other pharmacological agents, including anticonvulsants and atypical antipsychotics, have been investigated in different anxiety disorders, and the evidence to date generally does not support their use as first-line treatments; however, they may represent appropriate options in refractory patients.

While there has been an increasing recognition of the public health burden of anxiety disorders, historically there has been relatively little research focus on the development of new treatments. Most of the treatments for anxiety disorders are based

on medications developed for the treatment of major depressive disorder (MDD). New research focusing on targets outside of the monoamine system—e.g., amino acid, neurohormonal, and neuropeptide systems—may yield novel and much needed treatment interventions for these common disorders.

PANIC DISORDER

OVERVIEW

Panic disorder (PD) is characterized by recurrent, unexpected panic attacks with attendant adverse behavioral effects between attacks (American Psychiatric Association, Task Force on DSM-IV, 2000). Panic attacks are periods of intense fear that peak within 10 minutes but can continue on for much longer. The intense fear is typically accompanied by physical symptoms such as heart palpitations, sweating, shortness of breath, chest pain or tightness, nausea, and dizziness. Sensations of choking or smothering and/or derealization during a panic attack are also common. By definition, the panic attacks are not due to the direct physiological effects of a substance or a general medical condition—both of which are important for the clinician to consider in the differential diagnosis of panic disorder. Ongoing worry about the implications of the panic attacks and/or anxiety about experiencing another unprovoked attack characterizes the disorder, and a duration of at least one month of persistent concern is required for the diagnosis. Individuals diagnosed with panic disorder may or may not also have agoraphobia—anxiety about and avoidance of situations where escape may be difficult.

Panic disorder affects between 1% and 3% of the U.S. population and is associated with significant morbidity and public health costs (Kessler et al., 2005b). Increased health care utilization is common in patients with panic disorder, and the presence of the illness places individuals at elevated risk for suicide (Perna et al., 2011). Overall there is good evidence for the efficacy of both pharmacotherapeutic and psychotherapeutic treatments for panic disorder, although there is still significant room for improvement to current treatment options. While evidence supports both approaches as first-line treatment, this chapter will focus on pharmacotherapeutic approaches.

FIRST-LINE PHARMACOTHERAPY

There is good evidence for the efficacy of SSRIs, SNRIs, TCAs, and BZDs in the treatment of panic disorder (American Psychiatric Association, 2009; McHugh et al., 2009). The 2009 American Psychiatric Association practice guideline on the treatment of panic disorder found that there was insufficient evidence to recommend one of these therapeutic options over the others (American Psychiatric Association, 2009). Given their relative tolerability, safety, and efficacy, a trial of an SSRI or SNRI for the patient with panic disorder is a pragmatic first treatment step. As always, factors specific to a particular case will guide treatment selection, including patient preference and the presence of comorbid medical or psychiatric conditions.

TABLE 47.2. Overview of pharmacotherapy for anxiety disorders

PHARMACOLOGIC CLASS	EXAMPLES	MOLECULAR TARGET(S)	FDA-APPROVED INDICATIONS	DOSE RANGE	HALF-LIFE	COMMON ADVERSE EFFECTS	SERIOUS ADVERSE EFFECTS	PREGNANCY CATEGORY
SSRI	Escitalopram	SERT	GAD	10–20 mg daily	27–32 hours	Nausea, diarrhea, headache, insomnia, somnolence, sexual dysfunction (class effects)	Bleeding, seizure, serotonin syndrome, worsening depression or anxiety, suicidal thoughts (class effects)	C
	Fluoxetine	SERT	OCD, PD	20–60 mg daily	4–6 days	Class effects	Class effects	C
	Fluvoxamine	SERT	OCD, SP	100–300 mg daily	16 hours	Class effects	Class effects	C
	Paroxetine	SERT	GAD, OCD, PD, PTSD, SP	20–50 mg daily	33 hours	Class effects	Class effects	D
	Sertraline	SERT	OCD, PD, PTSD, SP	50–200 mg daily	26 hours	Class effects	Class effects	C
SNRI	Duloxetine	SERT, NET	GAD	60–120 mg daily	12 hours	SSRI class effects, hypertension	SSRI class effects, hypertensive crisis, hepatitis	C
	Venlafaxine	SERT, NET	GAD, PD, SP	75–225 mg daily	5 hours	SSRI class effects, hypertension	SSRI class effects, hypertensive crisis, hepatitis	C
BZD	Alprazolam	GABA-AR	Anxiety (nonspecific), PD	1–4 mg daily	11–16 hours	Somnolence, cognitive problems, appetite change, fatigue (class effects)	Stevens-Johnson syndrome, hepatic dysfunction, withdrawal seizure (class effects)	D
	Chlordiazepoxide	GABA-AR	Anxiety (nonspecific)	15–40 mg daily	24–48 hours	Class effects	Class effects, hepatitis, agranulocytosis	?
	Clonazepam	GABA-AR	PD	1–4 mg daily	30–40 hours	Class effects	Class effects	D
	Diazepam	GABA-AR	Anxiety (nonspecific)	2–10 mg daily	15–20 hours	Class effects	Class effects, neutropenia	D
	Lorazepam	GABA-AR	Anxiety (nonspecific)	1–6 mg daily	12–14 hours	Class effects	Class effects	D
	Oxazepam	GABA-AR	Anxiety (nonspecific)	30–120 mg daily	6–11 hours	Class effects	Class effects	?

(continued)

TABLE 47.2. (Continued)

PHARMACOLOGIC CLASS	EXAMPLES	MOLECULAR TARGET(S)	FDA-APPROVED INDICATIONS	DOSE RANGE	HALF-LIFE	COMMON ADVERSE EFFECTS	SERIOUS ADVERSE EFFECTS	PREGNANCY CATEGORY
TCA	Clomipramine	SERT, NET, mACh, alpha1, H1	OCD, PD	25–250 mg daily	32 hours	Dry mouth, constipation, urinary retention, somnolence, dizziness, weight gain, sexual dysfunction, orthostasis (class effects)	Can be lethal in overdose, cardiac arrhythmia, hematological abnormalities, suicidal thoughts (class effects)	C
	Doxepine	SERT, NET, mAChR, A1R, H1R	Anxiety (nonspecific)	75–300 mg daily	15 hours	TCA class effects	TCA class effects	C
	Imipramine	SERT, NET, mAChR, A1R, H1R	PD	100–200 mg daily	6–18 hours	TCA class effects	TCA class effects	C
MAOI	Phenelzine	MAO	PD	45–90 mg daily	12 hours	Dry mouth, constipation, orthostasis, weight gain, sexual dysfunction, somnolence, dizziness, headache (class effects)	Can be lethal in overdose, cardiac arrhythmia, hypertensive crisis, myocardial infarction	?
Antihistamine	Hydroxyzine	H1R	Anxiety (nonspecific)	200–400 mg daily	20 hours	Sedation, dry mouth, dizziness, headache	Hypotension, cardiac arrhythmia, respiratory depression	C
Other	Buspirone	5-HT1AR	Anxiety (nonspecific)	20–60 mg daily	2–3 hours	Nausea, dizziness, headache	Myocardial infarction (rare), stroke (rare)	B

A1R, alpha-adrenergic type 1 receptor; BZD, benzodiazepines; GABA, gamma-aminobutyric acid; GABA-AR, GABA type A receptor; GAD, generalized anxiety disorder; H1R, histamine type 1 receptor; MAO, monoamine oxidase; MAOI, MAO inhibitor; mAChR, muscarinic acetylcholine receptor; NET, norepinephrine transporter; OCD, obsessive-compulsive disorder; PD, panic disorder; SERT, serotonin transporter; SP, social phobia; SNRI, serotonin norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant; 5-HT, 5-hydroxy-tryptamine; 5HT1AR, 5-HT type 1A receptor.

The SSRIs fluoxetine, paroxetine, and sertraline are FDA approved for the treatment of panic disorder, as is the SNRI venlafaxine. Three meta-analytic reviews of SSRIs in panic disorder support the efficacy of these interventions (Bakker et al., 2002; Mitte, 2005; Otto et al., 2001). In one example, an analysis of 12 placebo-controlled trials found a mean effect size for acute treatment outcome for SSRIs relative to placebo of 0.55 (Otto et al., 2001). A study including 664 patients with panic disorder randomized to venlafaxine extended-release (ER) 75 mg or 150 mg daily, paroxetine 40 mg daily, or placebo for up to 12 weeks found response rates of 77–80% for the venlafaxine and paroxetine groups compared with 56% for the placebo group (Pollack et al., 2007). Studies comparing different agents in the SSRI class to each other or to venlafaxine have generally not found support for the efficacy of one agent over another (see Freire et al., 2011 for review).

SSRIs and SNRIs are generally safe and well tolerated in this and other anxiety disorder populations. The most commonly reported side effects include sleep changes, nausea, headache, sleep problems, and sexual dysfunction (see Table 47.2). Importantly, patients with panic disorder may be particularly sensitive to transient increases in anxiety that are sometimes observed at the initiation of treatment or upon a dosage increase with an SSRI or SNRI agent. Psychoeducation represents an important component of the treatment in this regard. Adjunctive treatment with BZD at the outset of treatment with an SSRI or SNRI to mitigate this increase in anxiety may also be indicated, as discussed in more detail next.

SECOND-LINE/OTHER APPROACHES

The BZDs alprazolam and clonazepam are FDA approved for the treatment of panic disorder. BZDs are potent anxiolytic medications that can result in substantial symptom relief for patients with panic and other anxiety disorders when used appropriately (American Psychiatric Association, 2009; Ballenger et al., 1988). BZDs have the advantage of a more rapid onset of action compared with SSRIs or other monoaminergic agents, although data supporting their longer term efficacy is more limited. Alprazolam has a short half-life and a rapid onset of action, particularly desirable when rapid relief from a developing panic attack is the treatment goal. Clonazepam has a longer half-life and is more suited to standing dosing as opposed to as-needed (e.g., “prn”) use. See Table 47.1 for a description of commonly prescribed BZD medications. Principal disadvantages associated with the use of BZDs in panic or other anxiety disorders include their well-known abuse liability and the predictable development of tolerance, the need for dose escalation, and prominent withdrawal effects. Somnolence and cognitive problems are additional adverse effects characteristic of this drug class.

As mentioned in the preceding section, patients may experience a temporary increase in anxiety following initiation of treatment with an SSRI or SNRI agent. Another limitation commonly observed with monoaminergic treatments is a delay in onset of therapeutic effect of several weeks. BZDs can, therefore, have an important therapeutic role as adjunctive treatment to a first-line agent. Goddard et al.

showed that coadministration of low-dose clonazepam with sertraline in the treatment of panic disorder resulted in a significantly greater proportion of responders in the sertraline/clonazepam compared with the sertraline/placebo group at the end of one week (41% compared with 4%) (Goddard et al., 2001). Notably, the groups did not differ in response rate by the end of the study. These data support the common clinical practice of initiating a BZD agent concurrently with an SSRI or SNRI at the outset of the treatment and then tapering the BZD after three to four weeks and continuing the first-line agent.

The TCAs clomipramine and imipramine are FDA approved for the treatment of panic disorder, and several early studies have established the efficacy of these agents in reducing the frequency and intensity of panic attacks (Bakker et al., 2002; Perna et al., 2011). The TCAs are considered second-line agents for the treatment of panic disorder—as well as other anxiety disorders—primarily due to their side effect burden. For example, a meta-analysis including 2,367 patients compared SSRIs with TCAs and found that the proportion of patients free of panic attacks did not differ while the number of dropouts was significantly lower in the group of patients treated with SSRIs compared with TCAs (18% vs. 31%, respectively) (Bakker et al., 2002). Commonly observed adverse effects for this drug class are attributable to blockade of the muscarinic acetylcholine receptor (e.g., dry mouth, constipation, urinary retention) or the alpha-adrenergic or histamine receptors (e.g., somnolence, orthostasis, weight gain). Serious adverse reactions such as cardiac arrhythmia can occur and TCAs can be fatal in overdose. Despite the potential for side effects, a trial of a TCA is warranted in patients who fail to demonstrate an adequate response to first-line therapy.

The MAOI phenelzine is approved for the treatment of panic disorder and represents an important third- or fourth-line agent for refractory patients. MAOIs irreversibly inhibit the enzyme monoamine oxidase and result in a net increase in monoamine availability in the synapse. The use of MAOIs is restricted by the need to maintain a low-tyramine diet and the risk of (potentially fatal) hypertensive crisis and drug-drug interactions. Moclobemide—a reversible MAOI (RIMA [reversible inhibitors of monoamine oxidase A]) not currently available in the United States—has some efficacy data in panic disorder and does not have the same strict dietary restrictions and safety liability as the irreversible MAOIs.

There is currently no controlled evidence supporting the use of anticonvulsant medications in panic disorder. RCTs examining the efficacy of the anticonvulsants gabapentin and tiagabine in panic disorder have been conducted, and these studies did not find support for the use of these agents.

There is a paucity of evidence available to the clinician to help determine the next treatment step in the management of panic disorder in the event that first-line pharmacotherapy fails. Given the evidence supporting the efficacy of specific psychotherapeutic interventions for panic disorder, this option should be considered at the top of the treatment algorithm. If a partial response is gained with an SSRI or SNRI, upward dose titration and/or augmentation with psychotherapy or a BZD may represent a pragmatic therapeutic step. If no response

is achieved with a first-line agent after appropriate treatment duration (at least four to six weeks) and dose escalation, then a switch to a second first-line agent is an appropriate step. TCAs, MAOIs, or other agents (e.g., anticonvulsants) may be reserved for more refractory cases.

POSTTRAUMATIC STRESS DISORDER

OVERVIEW

Posttraumatic stress disorder is a disabling condition that develops in a subset of individuals exposed to extreme psychological stress. The disorder is characterized by intrusive reexperiencing of traumatic memories along with symptoms of increased arousal and avoidance of stimuli associated with the trauma (American Psychiatric Association, Task Force on DSM-IV, 2000). By definition, the symptoms must be present for more than one month and be associated with significant distress and functional impairment. PTSD is increasingly being recognized as a major public health problem, and the alarming rates of PTSD and associated sequelae—including suicide attempts and completed suicide—observed in U.S. soldiers returning from combat portend the urgent need to identify effective treatments.

The estimated lifetime prevalence of PTSD in the United States is 7.8% according to the National Comorbidity Survey, with women being approximately twice as likely to suffer from PTSD compared with men (10.4% vs. 5.0%, respectively) (Kessler et al., 1995). The estimated lifetime prevalence of trauma exposure is 60.7% for men and 51.2% for women. Therefore, while trauma exposure is very common, development of PTSD is relatively less so. It is estimated that 79% of women and 88% of men with PTSD have also been diagnosed with at least one other psychiatric disorder—most frequently MDD, other anxiety disorders, and substance use disorders (Pratchett et al., 2011).

FIRST-LINE PHARMACOTHERAPY

Two SSRIs—sertraline and paroxetine—are approved by the FDA for the treatment of PTSD, and SSRIs are generally recommended by practice guidelines as first-line pharmacotherapy for the disorder (American Psychiatric Association, 2004). In an early positive, 12-week RCT (randomized controlled trial) comparing sertraline with placebo, the response rate was 53% for drug compared with 32% for placebo (Brady et al., 2000) and similar data are available for paroxetine (Marshall et al., 2001). Sertraline was found to be more effective than placebo at preventing relapse in a 28-week relapse prevention study (Davidson et al., 2001). In contrast, a more recent acute-phase RCT comparing sertraline to placebo conducted in a Veterans Affairs (VA) setting was negative (Friedman et al., 2007). Some data are also available in support of the SNRI venlafaxine in the treatment of PTSD. Importantly, a report from the Institute of Medicine (IOM) found that the existent evidence was inadequate to support the efficacy of SSRIs or other pharmacotherapy in PTSD (Institute of Medicine, 2008). A *Cochrane Review* of pharmacotherapy for PTSD including

35 RCTs and 4,597 participants did support the use of SSRIs as first-line medication treatment; however, it also acknowledged that there exist significant gaps in the evidence base (Stein et al., 2006). Responder status from 13 trials included in the *Cochrane Review* demonstrated overall superiority of medication compared with placebo: relative risk 1.49 (95% CI: 1.28, 1.73).

The data just reviewed paints a sobering picture of the current state of pharmacotherapy for PTSD, and new, more effective treatments are clearly needed for this disability disorder. Although not the focus of the current review, it is important to note that specific psychotherapeutic interventions—most notably, exposure therapy—have relatively strong evidence for efficacy in PTSD and may be considered a first-line treatment for PTSD. For example, in contrast to its conclusions regarding pharmacotherapy, the IOM report described earlier found sufficient evidence to conclude that exposure therapy is effective for PTSD (Institute of Medicine, 2008).

SECOND-LINE/OTHER APPROACHES

As noted preceding, exposure therapy or related CBT approaches should be considered for patients with PTSD early in the treatment algorithm, particularly if a patient does not respond adequately to a trial of an SSRI. Regarding second-line pharmacotherapeutic options, some evidence exists supporting the use of MAOIs, TCAs, BZDs, atypical antipsychotics, or anticonvulsants in the treatment of PTSD (see Baker et al., 2009 for review). The TCA amitriptyline has weak evidence for efficacy while desipramine was not found to be effective. One trial comparing the MAOI phenelzine with the TCA, imipramine, or placebo found support for both drugs, although another study investigating phenelzine in PTSD was negative.

BZDs can be used to target specific anxiety symptoms, hyperarousal, or insomnia associated with PTSD. Well-controlled data supporting the overall efficacy of BZD in the treatment of PTSD, however, is lacking, and tolerance and abuse potential issues limit the role of these medications. Studies investigating the use of BZDs immediately following trauma were not favorable. A small amount of research investigating alpha-adrenergic antagonists—prazosin, in particular—provides some support for their use in treating nightmares and sleep disturbance associated with PTSD (Raskind et al., 2003).

Atypical antipsychotic medication is frequently used as an adjunctive treatment in PTSD when first-line agents fail to yield a complete response. Risperidone has been the focus of the majority of research in PTSD with several smaller studies suggesting a beneficial effect of the addition of risperidone to an SSRI or SNRI. A recent, large, six-month RCT of adjunctive risperidone in PTSD conducted in a VA setting, however, did not find a significant advantage of risperidone over placebo (Krystal et al., 2011). In the same study, risperidone was associated with significantly greater adverse events compared with placebo, including weight gain, fatigue, and somnolence. The data reviewed in the preceding, along with consideration of potentially serious longer term adverse effects associated with atypical antipsychotic agents, including tardive dyskinesias and metabolic syndrome, must be weighed against potentially

therapeutic gains when considering risperidone or other antipsychotic agents as a treatment option for refractory PTSD.

Several studies investigating the use of anticonvulsants in PTSD have been conducted with generally discouraging results. Topiramate, tiagabine, and valproate have failed to demonstrate clear efficacy in PTSD in controlled study designs. Several case series and open studies of anticonvulsants have yielded favorable results, suggesting that these agents may help in select cases.

In summary, the evidence base for effective treatments in PTSD is unfortunately limited, and new treatments for this disabling condition are urgently needed. SSRIs and exposure therapy have the best efficacy evidence, but a significant proportion of patients will remain symptomatic with currently available treatments. The evidence supporting the use of TCAs, MAOIs, BZDs, anticonvulsants, atypical antipsychotics, or other agents is quite limited.

GENERALIZED ANXIETY DISORDER

OVERVIEW

Generalized anxiety disorder (GAD) is characterized by excessive anxiety and worry occurring more days than not for at least six months (American Psychiatric Association, Task Force on DSM-IV, 2000). By definition, the worry is difficult to control, is out of proportion to real or perceived external factors, and is associated with three or more of the following six symptoms: restlessness, fatigue, difficulty concentrating, irritability, muscle tension, or sleep disturbance. To meet criteria for the disorder, the symptoms must cause clinically significant distress or impairment in social, occupational, or other important areas of functioning, and the disturbance must not be due to the direct physiological effects of a general medical condition or substance.

GAD is a common disorder, with a lifetime prevalence of 5–6% in the general population, and is more common in women than in men (approximately 2:1). Notably, GAD is one of the most common psychiatric disorders in primary care settings and is associated with increased utilization of health services. The disorder has a high rate of comorbidity with mood and other anxiety disorders, as well as with substance use and general medical conditions. It is estimated that nearly 50% of patients with GAD also meet criteria for MDD. The high rate of comorbidity between GAD and MDD and symptomatic overlap have led to the idea that these syndromes may be different manifestations of the same disorder, although there continues to be debate regarding this issue.

FIRST-LINE PHARMACOTHERAPY

More than a dozen RCTs of drugs in the SSRI class support the use of SSRIs as first-line pharmacotherapy for GAD (Baldwin et al., 2011; Kapczinski et al., 2003). Escitalopram and paroxetine have an FDA indication for the treatment of GAD and good controlled data also exist for sertraline. Response rates for SSRIs of between 60% and 75% are generally reported in RCTs, compared with response rates of between 40% and 60%

for placebo (Baldwin et al., 2011). In a study by Rickels et al. where outpatients with GAD ($N = 566$) were randomized to eight weeks of paroxetine at 20 or 40 mg/day or placebo, response rates were 62%, 68%, and 46% for patients receiving 20 mg, 40 mg, or placebo, respectively (Rickels et al., 2003). Data also support the longer term efficacy of SSRIs in sustaining treatment effects over a period of six months (Stocchi et al., 2003).

In addition to that of SSRIs, good controlled data also support the use of SNRIs as a first-line treatment option in GAD. The SNRIs venlafaxine ER and duloxetine both carry FDA indications for the treatment of GAD and observed response rates and drug–placebo differences in RCTs generally similar to what is observed in trials of SSRIs (Baldwin et al., 2011). In one study, patients with GAD ($n = 377$) were randomized to venlafaxine ER 75, 150, or 225 mg/day or placebo for eight weeks, and resulting analysis indicated that patients had significant reductions in illness severity under venlafaxine ER compared with placebo conditions (Rickels et al., 2000). A second RCT including 251 patients with GAD assessed longer term efficacy of venlafaxine ER over six months and found response rates of 69% or higher in the active drug group compared with 42–46% in the placebo group (Gelenberg et al., 2000). Duloxetine has demonstrated efficacy comparable to venlafaxine for GAD (Hartford et al., 2007), although longer term maintenance studies of duloxetine in GAD have not been conducted to date.

As reviewed in previous sections, SSRI and SNRI medications have favorable tolerability profiles. Alerting patients to the common, usually transient, adverse effects of these medication classes—including nausea, headache, changes in sleep, and nervousness—is an important component of psychoeducation and will facilitate treatment adherence. Transient nervousness, jitteriness, or worsening of anxiety at the onset of treatment with an SSRI or SNRI may be a particular concern for this patient population. In addition to psychoeducation, short-term treatment with low-dose BZD at the outset of treatment, as described next, may be a fruitful pharmacotherapeutic strategy.

Considering the safety, efficacy, and tolerability of SSRIs and SNRIs, these drugs represent first-line treatment for GAD.

SECOND-LINE/OTHER APPROACHES

There is limited data available to guide clinicians regarding next best steps for treatment in patients with GAD who manifest an inadequate response to first-line therapy. There is fair evidence for BZDs, the azapirone buspirone, TCAs, and the anticonvulsant agent pregabalin in the treatment of GAD. Weak evidence also exists for other anticonvulsants (e.g., valproic acid), antihistamines (e.g., hydroxyzine), and atypical antipsychotics (e.g., quetiapine). CBT is an important therapeutic consideration for patients with GAD, especially if they have not responded to a prior first-line medication trial.

The rapid and robust anxiolytic effects of BZDs make this class of drugs an important component of the treatment armamentarium for GAD. A key early RCT comparing diazepam

with trazodone and imipramine found that diazepam was associated with the most improvement in anxiety during the first two weeks of treatment (Rickels et al., 1993). In contrast, during weeks three through eight, imipramine was superior to diazepam in the proportion of patients achieving moderate or marked symptom improvement (73% vs. 66%). Given the limitation of BZD therapy discussed in the preceding sections, including sedation, cognitive disturbance, and abuse or dependence liability, these agents should be used judiciously in the treatment of GAD. Specific circumstances that may be particularly suited to the use of BZDs include short-term use as an adjunct to antidepressant medication or in patients who are refractory to first-line treatments after consideration of the risk:benefit ratio for the individual patient. Patients with a history of substance use disorder may be particularly vulnerable to the abuse or dependence liability of BZDs, and additional caution should be used in this patient population.

The azapirone buspirone is a unique partial agonist at the 5-HT_{1A} receptor and is FDA approved for the treatment of GAD. Buspirone and other azapirones have demonstrated superiority to placebo in the treatment of GAD in a number of large RCTs (Chessick et al., 2006). Despite reasonable controlled evidence for its efficacy, buspirone is not generally considered a first-line treatment for GAD, in part due to its relatively slow onset of action, tolerability issues at higher doses, and some data suggesting inferiority to antidepressant or BZD treatment options (Davidson et al., 1999).

As referenced earlier, there is some data for the effectiveness of TCAs, imipramine in particular, in the treatment of GAD (Rickels et al., 1993). Potential advantages of TCAs over BZDs include their ability to treat symptoms of both anxiety and depression and the absence of potential for abuse and physiological dependence. As a class, TCAs are generally reserved for patients who have failed other treatment strategies, owing to safety and tolerability issues related to this class of medications. As discussed in previous sections, pharmacological blockade of muscarinic, histamine, and alpha-adrenergic receptors limit their use. The utility of TCAs is also limited by their cardiotoxic potential and lethality in overdose.

Pregabalin, a voltage-dependent calcium channel modulator approved for the adjunctive treatment of seizure disorder, has fair efficacy data for the treatment of GAD from several RCTs (Montgomery et al., 2006; Rickels et al., 2005). In one study, patients were randomized to four weeks of treatment with pregabalin, 300 mg, 450 mg, or 600 mg per day, alprazolam, 1.5 mg per day, or placebo, and results indicated that both pregabalin and alprazolam produced significant reductions in anxiety compared with placebo (Rickels et al., 2005). A second study randomized patients with GAD ($n = 421$) to six weeks of double-blind treatment with pregabalin 400 mg or 600 mg per day, venlafaxine 75 mg per day, or placebo and found both pregabalin and venlafaxine to be more effective than placebo in decreasing anxiety symptoms (Montgomery et al., 2006).

A recent effect size analysis of treatments for GAD—including SSRIs, SNRIs, BZDs, buspirone, hydroxyzine, and pregabalin—yielded an overall effect size of 0.39 for all drugs versus placebo (Hidalgo et al., 2007). Drug-specific effect sizes,

listed from largest to smallest effect, were as follows: pregabalin: 0.50, hydroxyzine: 0.45, SNRI: 0.42, BZD: 0.38, SSRI: 0.36, buspirone: 0.17. While this analysis provides some interesting insights and suggests that overall our current treatments for GAD vary from modestly to poorly effective, methodological limitations inherent in effect size analysis limit specific conclusions that can be drawn.

In summary, first-line pharmacotherapy for GAD—including SSRIs and SNRIs—provides substantial symptomatic relief in many but not all patients with GAD. Second-line treatment options include BZDs, buspirone, TCAs, pregabalin, and hydroxyzine, among other agents. Future research is required to establish the optimal treatment approach for patients who do not respond to a first-line treatment trial.

SOCIAL PHOBIA

OVERVIEW

Social phobia—also known as social anxiety disorder—is a common and potentially disabling anxiety disorder with a lifetime estimated prevalence of approximately 12% (Kessler et al., 2005b). The disorder is characterized by marked anxiety in reaction to social or performance situations, often leading to avoidance behavior (American Psychiatric Association, Task Force on DSM-IV, 2000). By definition, exposure to the feared social situation nearly always provokes anxiety, and the resulting avoidance, anxious anticipation, or distress interferes significantly with the person's social or occupational functioning. Comorbidity is common, and social phobia often precedes the onset of other disorders, in particular MDD and substance use disorders. (Stein and Stein, 2008). The disorder often begins in childhood or early adolescence and has been associated with the heritable temperament trait behavior inhibition.

FIRST-LINE PHARMACOTHERAPY

More than two dozen RCTs of SSRIs or SNRIs support the use of these medications as first-line pharmacotherapy in social phobia (de Menezes et al., 2011; Stein et al., 2004; Stein and Stein, 2008). Fluvoxamine, paroxetine, sertraline, and venlafaxine have FDA approval for the treatment of social phobia. In the case of paroxetine trials, reported response rates for active drug vary from 55% to 72% compared with response rates for placebo between 8% and 50% (Stein and Stein, 2008a). Reported response rates are similar for other SSRIs and venlafaxine. A *Cochrane Review* including 36 RCTs and 4,268 patients with social phobia demonstrated short-term superiority of medication over placebo with a relative risk of nonresponse of 0.63 (95% CI: 0.55, 0.72) (Stein et al., 2004). For SSRIs in particular, the relative risk of nonresponse was 0.67 (95% CI: 0.59, 0.76). A recent quantitative meta-analysis including 27 RCTs aimed to compare efficacy between members of the SSRI, SNRI, and atypical antidepressant classes and found paroxetine, sertraline, fluvoxamine, escitalopram, and venlafaxine to be consistently more effective than placebo (de Menezes et al., 2011). The superiority of drug over placebo was less convincing for other agents, including citalopram, mirtazapine, and nefazodone.

Fewer data exist concerning the effectiveness of longer-term treatment in social phobia. The *Cochrane Review* just described included three maintenance studies and five relapse prevention studies and found some support for longer term treatment (relative risk of nonresponse was 0.58 [95% CI: 0.39, 0.85] and 0.33 [95% CI: 0.22, 0.49], respectively). Considering the safety, efficacy, and tolerability of SSRIs, these drugs—along with the SNRI venlafaxine—represent first-line treatment for social phobia.

SECOND-LINE/OTHER APPROACHES

A series of early studies established the efficacy of the MAOI phenelzine in the treatment of social phobia (Blanco et al., 2002). For example, an RCT including 85 patients with social phobia found a 64% response rate in the phenelzine group compared with 23% in the placebo group (Liebowitz et al., 1992). Despite safety and tolerability issues related to irreversible MAOIs, a trial of phenelzine or other MAOI should be considered in cases where patients fail to achieve response to first-line treatment. The RIMA moclobemide has some efficacy evidence from RCTs in social phobia conducted in Europe. To date there have been no RCTs published of TCAs in social phobia.

There is limited data to support the use of BZDs in the treatment of social phobia. An early 10-week RCT found support for clonazepam (mean dose 2.4 mg/day) with a 78% response rate in the active arm compared with a 20% response rate in the placebo arm while evidence for the efficacy of alprazolam or other BZDs was less favorable (Blanco et al., 2002). Given the predictable disadvantages of chronic BZD therapy, this class of medication should be used judiciously and reserved for treatment-refractory cases.

Several studies have investigated the role of anticonvulsants in social phobia and have yielded generally negative results. RCTs of levetiracetam, gabapentin, and pregabalin have failed to demonstrate superiority of these agents over placebo. A small amount of evidence exists for the atypical antipsychotic quetiapine in social phobia.

As with other anxiety disorders, CBT has been shown to be effective for patients with social phobia and should be considered as part of the treatment plan, particularly if first-line pharmacotherapy has been ineffective. An interesting and potentially important line of research focuses on using glutamate-based pharmacotherapy to enhance the effectiveness of CBT. An initial RCT conducted in 27 patients with social phobia investigated the efficacy of combining the glutamatergic *N*-methyl-*D*-aspartate (NMDA) receptor agonist *D*-cycloserine with exposure therapy and found that patients receiving *D*-cycloserine in addition to exposure therapy reported significantly less social anxiety compared with patients receiving exposure therapy plus placebo (Hofmann et al., 2006). While these results are preliminary and await replication, the strategy of leveraging pharmacotherapy to enhance learning-based treatments represents a novel and potentially powerful treatment approach to anxiety disorders in the future.

CONCLUSIONS AND FUTURE DIRECTIONS

Substantial progress has been made over the past several decades in the treatment of anxiety disorders. Large RCTs support the efficacy of SSRIs and in some cases SNRIs in the treatment of many of the anxiety disorders, including panic disorder, GAD, and social phobia. Second-, third-, or fourth-line agents for the different anxiety disorders include TCAs, MAOIs, BZDs, buspirone, anticonvulsants, or atypical antipsychotics wherein the evidence base is less than optimal. Despite their superiority compared with placebo, the effect sizes for first-line agents in most anxiety disorders are only modest, and a substantial number of patients suffering from anxiety disorders do not gain full relief from their symptoms with currently available treatments. In the case of PTSD, the situation is particularly concerning, and there is current uncertainty regarding the effectiveness of any medication in the treatment of this potentially disabling disorder. Taken together, improved treatments for anxiety disorders represent a critical unmet public health need.

Significant progress in neuroscience is illuminating potential new avenues of treatment discovery and novel targets from rational drug development. The rapidly developing neuroscience related to fear and anxiety is described in several chapters in the current volume, including Chapters 41, 42, 43, 44, 45, 48 and 49. Compounds with novel mechanisms of action currently in development for anxiety disorders include corticotropin releasing factor antagonists, neurokinin receptor antagonists, a variety of glutamate modulators, and glucocorticoid modulators. The endocannabinoid system has recently emerged as an interesting target in PTSD and other anxiety disorders. Continued progress in basic and translational neuroscience is expected to meet the need for new, more effective treatments for patients suffering from these disorders.

DISCLOSURES

Dr. Iosifescu has consulted for CNS Response, Inc. and has received grant/research support through Mount Sinai School of Medicine from Brainsway, Euthymics Bioscience Inc., Neosync, and Shire.

Dr. Murrough is supported by a Career Development Award from the National Institute of Mental Health (K23MH094707) and by the Brain and Behavior Research Foundation (NARSAD Young Investigator Award) and the American Foundation for Suicide Prevention.

Dr. Charney has been named as an inventor on a pending use-patent of ketamine for the treatment of depression. If ketamine were shown to be effective in the treatment of depression and received approval from the Food and Drug Administration for this indication, Dr. Charney and Mount Sinai School of Medicine could benefit financially.

SUSANNE E. AHMARI AND H. BLAIR SIMPSON

INTRODUCTION

OCD IS A DISABLING ILLNESS

Obsessive-compulsive disorder (OCD) is characterized by recurrent intrusive thoughts, images, or impulses (obsessions) that cause anxiety or distress, and repetitive mental or behavioral acts (compulsions). The obsessions and compulsions are time consuming (e.g., more than an hour a day), are distressing, and interfere with functioning. Compulsions are typically performed in response to an obsession (e.g., fears of contamination leading to washing rituals), with the aim of reducing the distress triggered by obsessions or to prevent a feared event (e.g., becoming ill). However, these compulsions are either not connected in a realistic way or are clearly excessive (e.g., showering many hours each day). Of note, compulsions are not performed with a primary purpose of deriving pleasure, although some individuals experience the relief from anxiety that accompanies the compulsive behavior as pleasurable.

With a lifetime prevalence of up to 2–3% (i.e., two to three times more common than schizophrenia), the World Health Organization has identified OCD as one of the world's 10 leading causes of illness-related disability. This is largely due to the fact that OCD typically starts in childhood or adolescence, persists throughout a person's life, and produces substantial impairment in functioning due to the severe and chronic nature of the illness (Koran, 2000). In addition, OCD has a significant financial impact, with the most recent report indicating that treatment and management of OCD costs several billions of dollars a year in the United States alone.

KEY CLINICAL FEATURES OF OCD

Onset of OCD usually occurs in adolescence or early adulthood; however, a subgroup of OCD patients, a majority of them male, have symptom onset in childhood. Some childhood-onset OCD may have a different clinical course and a different underlying neurobiology than adult-onset OCD.

Though all OCD patients have obsessions and/or compulsions, specific content of the obsessions and compulsions differs between individuals. However, certain themes are common, including forbidden or taboo thoughts (e.g., aggressive, sexual, and religious obsessions and related compulsions), cleaning (fears of contamination and related cleaning rituals), harm (fears of harm to oneself or others and checking compulsions), symmetry (symmetry obsessions and repeating, ordering, and counting compulsions), and hoarding (obsessive collecting and maintaining of worthless objects). These different themes,

also known as symptom dimensions, are similar across different cultures, are relatively consistent over time in adults with OCD, and may be associated with different neural substrates (Leckman et al., 2010). Importantly, individuals often have symptoms in more than one dimension, suggesting that the dimensions do not represent discrete subtypes.

Patients may also differ significantly in their level of insight into the irrationality of their obsessions and compulsions. Level of insight can be classified as good/fair (the patient recognizes that the beliefs are definitely or probably not true, e.g., that compulsions are not effective at warding off feared consequences), poor (the patient thinks the beliefs are probably true), or absent (the patient is completely convinced the beliefs are true, thus bordering on a delusional belief in the reality of the obsessions). Notably, level of insight can fluctuate over the course of illness (Leckman et al., 2010).

OCD has significant comorbidity with other psychiatric illnesses, particularly major depressive disorder (MDD: 61% current; 85% lifetime), other anxiety disorders (range: 24.5–69.6%), and Tourette's disorder (range: 7–59%). Notably, there is evidence that OCD patients with comorbid tic disorder may be a biologically distinct entity, with earlier age of onset, greater prevalence in males, different neurochemical and neurobiological features, and distinct treatment response. In addition, OCD is very prevalent in individuals with anorexia/bulimia (37%) and schizophrenia (8–32%) (Leckman et al., 2010).

ETIOLOGY OF OCD

Though our understanding of the etiology underlying OCD is quite limited, it is an area of very active investigation. Current evidence implicates both genetic and environmental factors in development of OCD, though the importance of particular factors is still unclear. It is crucial to identify specific pathogenic insults and/or protective factors; we may then be able to intervene early in development to prevent onset of this severe and chronic illness.

GENETIC FACTORS

Twin and family studies suggest that there is genetic susceptibility to OCD. In addition, this genetic vulnerability may be greater in pediatric onset OCD, since there is greater heritability in this population (genetic influences in the range of 45–65% in pediatric OCD vs. 27–47% in adult-onset OCD [Pauls, 2008]). These findings have been followed up by candidate gene studies (over 60 studies from 1998 to 2008); many of these candidate

gene studies focused on genetic loci associated with serotonin, dopamine, and glutamate, based on their hypothesized roles in the etiology of OCD. In addition, genome-wide linkage and association studies have recently been performed. In the next section, we will review selected findings from candidate gene studies and genome-wide association studies that may have implications for the pathophysiology underlying OCD.

Glutamate

SLC1A1 To date, the only consistently replicated genetic finding in OCD is an association with the neuronal glutamate transporter *SLC1A1* (protein known as EAAT3 or EAAC1) (see Wu et al., 2012 for review). Findings cluster in the 3' gene region, with most evidence for association with the rs301430C allele. In cell models and brain tissue, this allele is associated with increased *SLC1A1* expression, suggesting that overexpression contributes to OCD susceptibility. Coding variants in *SLC1A1* are very rare (3/1400 subjects screened) and do not clearly segregate with OCD. Thus, noncoding polymorphisms most likely account for the association of *SLC1A1* with OCD.

GRIN2B Other genetic association studies have less consistently implicated *GRIN2B*, a gene that encodes the NR2B subunit of the NMDA glutamate receptor (see Wu et al., 2012, for review). The NR2B subunit is an important contributor to synaptic plasticity, since incorporation of the subunit renders NMDA receptors more permeable to calcium. In 2004, Arnold et al. found that both a *GRIN2B* polymorphism and one additional haplotype were associated with OCD. Further support for a *GRIN2B* role in OCD comes from magnetic resonance spectroscopy studies in OCD patients that have demonstrated an association between *GRIN2B* polymorphisms and glutamatergic concentrations in the anterior cingulate cortex. Overall, the association of NR2B with OCD is consistent with the theory that glutamatergic dysfunction underlies OCD pathophysiology. However, NR2B deficits throughout the brain would be expected to lead to significant abnormalities in global functioning, since NMDA receptors are essential for basic neurobiological functions necessary for learning and memory, including long-term potentiation. It is therefore more likely that NR2B functional abnormalities in specific brain regions account for the genetic association with OCD.

Grik2 Another glutamatergic gene that has been implicated in OCD is the ionotropic glutamate receptor gene, *Grik2* (see Wu et al., 2012, for review). In an initial association study, a secondary analysis indicated that a *Grik2* polymorphism was undertransmitted in OCD patients. A follow-up candidate gene study found that a particular haplotype at this same locus was significantly associated with OCD. Further investigation is required to determine if this association is robust and biologically significant.

Serotonin

Serotonin-1b Receptor (5-HT1B) Several lines of evidence suggest that abnormalities in 5-HT1B receptor function (known as the 5-HT1D receptor in the human literature) play a role in

OCD (reviewed in Hemmings and Stein 2006). Pharmacological challenge studies found that acute activation of 5-HT1B receptors with the specific agonist sumatriptan can cause a transient worsening of OCD symptoms. In contrast, case reports suggest that chronic administration of 5-HT1B agonists can lead to a reduction in OCD symptoms possibly through receptor desensitization. Finally, some studies show a genetic association between a variant of the *5-HT1B* receptor gene and OCD. While a role of *5-HT1B* gene variants in susceptibility to OCD is not consistently supported, there is tentative support for the idea that such variants could be related to OCD severity. It is not clear whether the inconsistencies in the literature are due to small sample size, methodological problems inherent in challenge paradigms, dose of challenge agents, or differences between OCD patient samples. Nevertheless, in aggregate, the data point to 5-HT1B abnormalities in some OCD patients.

Serotonin-2A Receptor (5-HT2A) A positive association has been inconsistently reported between the A allele of the 5-HT2A receptor and OCD. However, though preliminary PET studies supported a link between 5-HT2A receptors and OCD, a more recent study did not find differences in 5-HT2A binding between OCD patients and controls (Simpson et al., 2011). There is still the possibility that 5-HT2A receptor polymorphisms may be linked to OCD symptomatology or treatment response, but the evidence is weaker than for other polymorphisms.

Serotonin Transporter There have been many studies examining the potential association between the serotonin transporter polymorphism (5-HTTLPR) and OCD. Though some family-based association studies have reported an association between the 5-HTTLPR long allele and OCD, these findings have been inconsistently replicated—in fact, a 2007 meta-analysis found an association between the 5-HTTLPR short allele and OCD susceptibility. A more recent meta-analysis (Bloch et al., 2008) demonstrated an association between the long allele and OCD in specific subgroups, including childhood onset OCD; however, this was only found in the stratified meta-analysis and did not retain significance in the overall meta-analysis. The significance of 5-HTTLPR in OCD etiology remains unclear.

ENVIRONMENTAL FACTORS

Many studies have suggested a role for environmental factors in the etiology of both childhood- and adult onset OCD, but it has been difficult to establish direct links. In this section, we review environmental theories with the strongest evidence.

Infectious

Acute onset of OCD symptoms in children has been observed; this syndrome has been associated with environmental factors, including various infectious agents and a postinfectious autoimmune syndrome. There has been some support for a specific association between infection with group A β -hemolytic streptococcus and onset of an autoimmune disorder that triggers OCD; this is commonly known as PANDAS (Pediatric Autoimmune Neuropsychiatric Disorder Associated with

Streptococcal Infections). However, this association remains controversial, as other infectious agents may also trigger an acute neuropsychiatric syndrome. This is a topic of active research (Singer et al., 2012).

Hormonal

There have been multiple reports of premenstrual and postpartum exacerbation of OCD, suggesting that hormonal fluctuations may play a role in either the onset or the exacerbation of OCD symptoms. A majority of these studies were limited by the fact that they were retrospective analyses and did not directly assess hormone levels (McGuinness et al., 2011). However, they complement findings from the neurocognitive literature demonstrating that prepulse inhibition deficits, which are observed in OCD patients, are most pronounced during phases of elevated progesterone (i.e., late pregnancy and premenstrual).

Psychological Trauma

Though rare, there have been reports of acute OCD onset in adults following exposure to traumatic events. Until recently, these studies had consisted of case reports and case series in chronic OCD patients whose trauma had occurred a significant amount of time before initiation of the study, leading to uncertainty about the timing of symptom onset, and possible conflation of OCD and PTSD symptoms. A recent study addressed this problem by assessing five veterans with new onset OCD shortly after combat and found a suggestive link between the

traumatic events and the initiation of OCD symptoms (Fostick et al., 2012). Interestingly, these OCD symptoms continued to evolve independently of the initial environmental trigger, such that rituals were no longer related to thoughts associated with the trauma.

NEUROBIOLOGY OF OCD

Although the etiology of OCD is unknown, many studies have investigated the brain mechanisms underlying OCD symptoms. Development of modern neuroimaging technology has led to a dramatic increase in our understanding of the neurobiology of OCD over the past 20 years. In the next section, we will discuss findings from studies that have used this technology to examine neuroanatomy, circuit function, and neurochemistry in OCD. Together, these findings have converged to implicate cortico-striato-thalamo-cortical circuits in the pathophysiology of OCD.

OVERVIEW OF CORTICO-STRIATO-THALAMO-CORTICAL (CSTC) CIRCUITS

Cortico-striato-thalamo-cortical circuits (Fig. 48.1) have been implicated in many higher order cognitive functions, including allocation of attention, executive functioning (e.g., inhibition of impulsive behavior), and modulation of motor activity. Anatomical studies in both humans and nonhuman primates

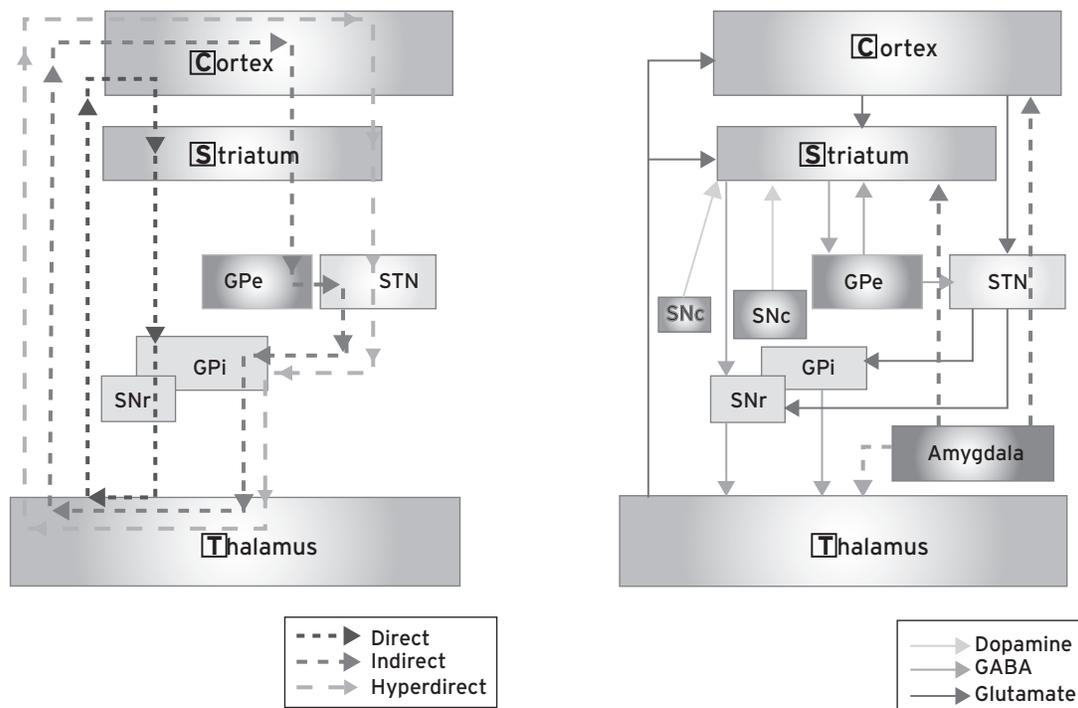

Figure 48.1 Cortico-striato-thalamo-cortical (CSTC) loops. Circuit diagrams of CSTC loops. (left) It is hypothesized that multiple parallel CSTC circuits connecting the cortex and basal ganglia subserve different neural functions. Three examples of parallel loops are the direct pathway, hyperdirect pathway, and indirect pathway. SNr substantia nigra, pars reticulata; GPe globus pallidus externa; GPi globus pallidus interna, STN subthalamic nucleus. (right) Glutamate and GABA serve as the main neurotransmitter systems underlying communication within CSTC loops. However, other brain regions/neurotransmitter systems play significant modulatory roles (dashed lines), including ventral tegmental area (VTA) (dopamine), substantia nigra pars compacta (SNc) (dopamine), and amygdala (glutamate and GABA).

have demonstrated that CSTC circuits are composed of multiple parallel and interconnected loops that connect frontocortical and subcortical brain areas (Parent and Hazrati, 1995). These loops are comprised of (1) glutamatergic corticostriatal projections synapsing onto striatal medium spiny neurons, (2) GABAergic medium spiny neurons projecting to the output structures of the basal ganglia (globus pallidus pars internalis [GPi] and substantia nigra pars reticulata [SNr]), (3) GABAergic output neurons from GPi and SNr projecting to thalamus, and (4) glutamatergic neurons from thalamus connecting back to cortical areas. Within the striatum, medium spiny neurons can connect to GPi/SNr through either the direct (striatonigral) or indirect (striatopallidal) pathways. In a simplified framework, these anatomically distinct pathways are thought to oppose each other, resulting in inhibition of thalamus through activation of the indirect pathway, or disinhibition by activation of the direct pathway.

It is thought that different sets of CSTC loops may be responsible for dictating particular motor and cognitive functions, and it has been suggested that this selectivity is determined by the particular frontocortical area included in the loop (Pennartz et al., 2009). Functional imaging studies support this hypothesis, indicating that different cognitive functions are subserved by distinct CSTC circuits, and that disruption of these circuits occurs in multiple psychiatric disorders. Multiple models have been proposed suggesting that the interplay between frontocortical areas and basal ganglia determines which behaviors are performed, and which are screened out as being “undesirable.” In particular, it is hypothesized that changing the balance of activity between direct and indirect pathways can either promote or inhibit the selection of appropriate behavior sequences. Dysfunction in screening out “undesirable” behavior sequences would potentially lead to symptomatology. An accumulation of evidence specifically implicates CSTC dysfunction in OCD pathophysiology.

NEUROANATOMY

Anatomical findings suggest that abnormalities in the orbitofrontal cortex (OFC), anterior cingulate cortex (ACC), and striatum contribute to pathogenesis of OCD, as reviewed in Pittenger et al. (2011). The largest structural MRI study to date reported reduced gray matter in the OFC and increased gray matter in the ventral striatum, a structure intimately connected with the OFC. A recent meta-analysis including 14 structural studies of both pediatric and adult patients with OCD reported reduced volumes of the left ACC and bilateral OFC, and increased thalamic volumes bilaterally, but no differences in basal ganglia volumes relative to control samples. Thus, structural abnormalities in a CSTC circuit involving the OFC, ACC, and striatum have been repeatedly demonstrated in OCD, although exact findings have varied across studies. This is supported by neurosurgical studies that demonstrate symptom reduction after surgical interventions disrupting connections between frontocortical and subcortical areas. In addition, successful deep brain stimulation (DBS) for treatment-refractory OCD typically targets connections between prefrontal cortex and striatum, and is often accompanied by reduced OFC activity as measured by PET.

FUNCTIONAL NEUROIMAGING (RESTING STATE, SYMPTOM PROVOCATION, AND PRE-/POSTTREATMENT STUDIES)

Functional PET and fMRI neuroimaging studies in OCD have implicated the OFC, ACC, caudate nucleus (specifically the head), and thalamus in OCD, brain regions linked by well-described neuroanatomical connections as described in the previous section (reviewed in Pittenger et al., 2011). In resting studies, OCD subjects have hyperactivity in OFC, and, to a lesser extent, caudate, ACC, and thalamus. When their symptoms are provoked, OCD subjects have increased activity relative to baseline in the OFC, caudate, ACC, and, to a lesser extent, thalamus. In studies that examined OCD patients before and after treatment, most found that successful SRI or cognitive behavioral therapy treatment was associated with reduced activity in the OFC or caudate, and to a lesser extent the ACC.

COGNITIVE ACTIVATION STUDIES

In recent years, there has been a shift toward performing imaging studies in OCD patients using cognitive activation paradigms; studies of executive functions have been particularly emphasized. Many neurocognitive tasks have been used (for a comprehensive list, see Maia et al., 2008). Some of the evidence for differences between OCD patients and controls comes from three studies that found that OCD subjects aberrantly recruited the hippocampus during an implicit sequence-learning task, while healthy participants recruited the striatum; behavioral performance was the same across groups. These findings suggest that OCD patients have dysfunction in the striatal portions of CSTC circuits known to mediate normal implicit sequence learning. However, the link between this deficit in implicit sequence learning and OCD pathogenesis and/or symptomatology remains unclear, since hippocampal activation was not correlated with the severity of global OCD symptoms or specific symptom dimensions. In addition, several studies have demonstrated hyperactivity of the dorsal anterior cingulate cortex (dACC) in OCD patients during performance of tasks that probe brain activity during error monitoring and/ or conflict resolution, suggesting that this region might function differently in OCD (Milad and Rauch, 2012). Other studies have used go/no-go tasks to assess inhibitory control processes in OCD, with some finding greater OFC activation compared with controls (Elliott et al., 2010) and others reporting less activation compared with controls in inferior frontal regions (Roth et al., 2007). Greater frontostriatal activation has recently been demonstrated in unmedicated OCD compared with control participants during the engagement of control and conflict resolution on the Simon task (Marsh et al., 2009). The findings from these studies are inconsistent, likely due to differences in the tasks used and neural processes that they measure, in addition to differences in the patient samples.

NEUROCHEMISTRY

Based on the specific efficacy of SRIs for the treatment for OCD (see “Treatment of OCD” section for further details), it has

been hypothesized for over 20 years that serotonergic dysfunction plays a central role in the pathophysiology of OCD (Insel et al., 1985). As a result, many neurochemical studies in OCD have focused on the serotonergic system (reviewed in Goddard et al., 2008; Koo et al., 2010). Studies of peripheral markers of serotonin (5-HT) function (e.g., receptor binding in the blood) or of concentrations of 5-HT metabolites in cerebral spinal fluid have produced inconsistent results. Furthermore, it is not clear that these markers accurately reflect brain 5-HT function. Pharmacological challenge studies in OCD have used a variety of challenge agents (e.g., mCPP, MK-212, fenfluramine, metergoline, ipsapirone, buspirone, tryptophan, and sumatriptan/ zolmitriptan). Findings suggest that there is altered 5-HT function in OCD. However, these challenge studies have been unable to pinpoint the exact 5-HT abnormality, and many findings have not been consistently replicated.

Finally, neuroimaging studies have examined the distribution of serotonin transporters (5-HTT) and 5-HT_{2A} receptors in the brains of OCD patients. With regard to 5-HTT binding, three SPECT studies found three disparate results (increased, decreased, and no differences in midbrain 5-HTT binding). Using PET, we found no differences in 5-HTT binding between OCD patients and controls in striatal, limbic, or midbrain regions, which are the brain areas that could be reliably assessed with the PET ligand used (Simpson et al., 2003). In addition, we found that there are no differences in 5-HT_{2A} binding between OCD patients and controls (Simpson et al., 2011).

Abnormalities in regulation of dopamine signaling have also been implicated in OCD (see Koo et al., 2010 for review). Specifically, it has been hypothesized that dopaminergic abnormalities exist in some OCD patients based on findings that antipsychotic medications augment SRI response in up to 50% of OCD patients. However, SPECT studies investigating the dopaminergic system have led to inconsistent or unrepliated findings in small samples.

A current leading model also proposes that OCD symptoms result either directly or indirectly from increased glutamatergic signaling in corticostriatal pathways (reviewed in Pittenger et al., 2011). Both clinical and preclinical evidence supports this “hyperglutamatergic” hypothesis of OCD symptomatology. Rosenberg et al. (2000) initially found that glutamatergic compounds measured by magnetic resonance spectroscopy (MRS) were increased in the caudate nucleus of SRI-naïve children with OCD. This led to speculation that OCD patients have abnormalities in glutamatergic-serotonergic neurotransmission and to the initial development of hyperglutamatergic models of OCD. Additional MRS studies in OCD patients have demonstrated increased GLX (a combination of glutamate and glutamine) concentrations in the OFC and caudate; levels correlate with symptom severity and are decreased after effective treatment with paroxetine. In addition, as described in the preceding, genetic studies have found associations between the glutamate transporter SLC1A1 and OCD. An association was also found between a polymorphism in the NMDA receptor (NR2B) and decreased ACC glutamate in pediatric OCD. Finally, case studies and open label trials demonstrate efficacy of glutamatergic agents in reducing OCD symptoms—namely,

NMDA antagonists including memantine and riluzole (though unexpectedly there is also evidence for symptom relief following treatment with an NMDA agonist, glycine).

In summary, it is likely that abnormalities in multiple different neurotransmitter systems are related to the generation and resolution of OCD symptoms. There is good evidence that abnormalities in serotonin, dopamine, and glutamate signaling are associated with OCD. However, the following issues remain unclear: (1) the precise circuit localization of neurochemical abnormalities, (2) their role in either the generation or resolution of OCD symptoms, and (3) when they have their effects during development.

WORKING MODEL OF OCD PATHOPHYSIOLOGY

Based on the findings previously reviewed, several brain models of OCD have been proposed (reviewed in Saxena et al., 2001; Ting and Feng, 2011). While the models differ in specific details, they share the idea that obsessions and compulsions result from a malfunctioning neural circuit that includes the orbitofrontal (and sometimes the cingulate) cortex, caudate nucleus, and thalamus. The models differ in how this circuit malfunctions and/or is affected by SRIs. Some models try to account for different potential subtypes of OCD. For example, Baxter et al. (2001) proposed that tic-related and non-tic-related OCD have different patterns of striatal pathophysiology. More recently, because different OCD symptom dimensions (e.g., symmetry and ordering vs. washing and cleaning) have been associated with different patterns of neural activity in OFC, ACC, and caudate on PET scans, some have proposed that different symptom dimensions have different underlying neural substrates.

A leading model proposes that different populations of striatal medium spiny neuron projections differentially regulate the direct and indirect basal ganglia pathways, ultimately leading to alterations in motor behavior and stereotypies. Given the known functions of the direct pathway (including the striatum, globus pallidus interna, and substantia nigra) and indirect pathway (including the striatum, globus pallidus externa, and subthalamic nucleus) in modulating thalamic input to the cortex and in generating motor patterns, this has led to the hypothesis that OCD is due to excess activity in the direct versus indirect orbitofrontal-subcortical pathways. This increased direct pathway activity leads to decreased inhibition of the thalamus, and decreased filtering of intrusive thoughts and images to the cortex. Ritualistic compulsions are then triggered.

Another model that could be consistent with direct versus indirect pathway imbalance proposes that OCD symptoms result from increased glutamatergic signaling in corticostriatal pathways (see Pittenger et al., 2011). There is both clinical and preclinical evidence supporting this “hyperglutamatergic” hypothesis of OCD symptomatology, as discussed in detail in the preceding. The accumulation of evidence that increased cortical glutamatergic activity is linked to OCD symptoms has led to the suggestion that increased glutamatergic activity in specific cortical areas (OFC and ACC) may lead to generation of intrusive thoughts and images in the cortex that override other sensorimotor input; this, in turn, could trigger ritualistic

compulsions driven by the striatum through persistent activation of the direct pathway.

Though models of OCD have typically focused on abnormalities in CSTC circuitry, there has recently been a call for investigation of the role of other brain regions in OCD pathophysiology (Milad and Rauch, 2012). Specifically, CSTC models do not generally provide an explanation for the increased anxiety observed in OCD. However, exaggerated responses in the amygdala, a structure classically associated with anxiety and fear, have typically been observed after the presentation of OCD-specific stimuli. In addition, although the dACC has been classically associated with conflict monitoring (and therefore linked to obsessions in OCD), there is also recent evidence that it plays a role in the expression of fear responses. Hyperactivation of the dACC could therefore lead to increased anxiety and fear responses observed in OCD patients. It may therefore be necessary to integrate other brain structures, such as the amygdala or the dACC, to provide a satisfying explanatory model of OCD.

CHALLENGES IN STUDYING OCD CIRCUITRY

The field of OCD research has faced significant difficulties with study replication. This has been particularly evident in studies of neurophysiologic task performance. One of the most reliable abnormalities in OCD is prepulse inhibition (PPI) deficits, which have now been found in three studies from independent groups (although another group failed to find the deficit). However, this level of consistency has not been demonstrated with other neurophysiologic tasks. For example, there are significant discrepancies in the field on tests of executive function, motor speed, visual memory, and response inhibition using tasks such as Spatial Working Memory, Stockings of Cambridge, and Stop-Signal Reaction Time (Simpson et al., 2006). Many different factors may contribute to the difficulties with replication. For example, a recent study found that up to 25% of OCD patients reported significant OCD-related anxieties and motivational difficulties during neurophysiologic task performance. The self-reported symptoms and decreased motivation were significantly associated with objective performance deficits on the tasks (Moritz et al., 2012). Thus, cognitive deficits may not necessarily reflect a uniform neurobiological abnormality (as would be expected in an endophenotype) but, instead, may be state dependent. It is therefore possible that a single patient may have vastly different performance depending on his or her level of acute symptomatology at the time of testing. Though this could be related to disease-specific deficits, it could also be due to a more general difficulty with allocation of attentional resources during symptom flares.

Another possible complicating factor is heterogeneity of clinical phenotype that may reflect heterogeneity in the underlying neural substrate (Mataix-Cols et al., 2005). For example, OCD patients differ in the content of their symptoms (also known as symptom dimensions—e.g., washers versus checkers), their comorbidity (e.g., tic versus non-tic-related OCD), and the course of illness (e.g., early versus late onset). Attempts to identify homogeneous subgroups in OCD based on a single clinical feature have had limited success. To address this issue, a dimensional model of OCD has been proposed. In this model,

OCD is composed of several different and potentially overlapping symptom dimensions, each with its own associated clinical features and with possible differences in neurobiology. This model has been supported by some imaging studies, indicating that different patterns of brain activity are associated with different symptom dimensions. Thus, different OCD subtypes could have different core neurobiologic deficits leading to differences in imaging findings and neurophysiologic task performance.

PRECLINICAL STUDIES OF OCD

There have been numerous attempts to establish rodent models of OCD, since valid animal models will assist in the dissection of the molecular and cellular pathophysiology of the illness (see Wang et al., 2009 for review). Though it is now generally accepted that no one animal model will be able to recreate all aspects of a complex neuropsychiatric disorder such as OCD, it is possible to create powerful models that mimic particular aspects of a disorder (e.g., symptoms, medication responses, imaging findings, genetic abnormalities). However, it is important for these models to be carefully assessed to determine their relevance to the human disorder.

One method for judging clinical relevance is to determine the extent of face, predictive, and construct validity of a particular animal model. Face validity refers to the phenomenologic similarity between the phenotype measured in the mouse and human symptomatology. It is generally considered to be the least rigorous method for validating an animal model, since the assessment is relatively subjective, and identical phenotypes can be produced by different underlying biological processes. Predictive validity is the ability of a model to make accurate predictions about the human phenomenon of interest. Though typically understood as the ability of a model to replicate effects of medications, it also refers to its ability to make accurate predictions about the impact of environmental variables on the disorder being studied. Construct validity refers to how well an animal model mimics pathophysiological constructs that are thought to underlie the disorder in question. These constructs can include things such as genetic abnormalities or circuit dysfunction. Though construct validity is inherently limited in OCD due to our nascent understanding of the disorder, rodent models based on construct validity are valuable tools for testing and generating new hypotheses about underlying pathology. In the next section, we will provide a brief overview of established OCD animal models and discuss the validity associated with each.

MODELING SYMPTOMS

Many OCD animal models have emphasized face validity based on stereotypy and compulsivity. These include marble burying, barbering (repetitive hair biting and pulling), acral paw-lick (repetitive paw-licking in dogs), zoo-related stereotypies (e.g., pacing around cages), and pharmacologically induced compulsive checking. In addition, behavioral paradigms have been established in rodents that generate (1) perseverative lever pressing in the absence of reward, and (2) persistent revisiting of unrewarded arms in a T-maze (i.e., impaired reversal learning). Furthermore, pharmacologic studies in wild-type rats have

demonstrated that striatal injections of an NMDA-antagonist led to increased perseveration on a T-maze delayed alternation task. Finally, a recently developed model capitalizes on the fact that injection of 5-HT1B agonists in mice leads to both PPI deficits (also observed in OCD patients) and perseverative behavior; unlike other models discussed here, this model exhibits strong predictive validity for the chronic time course and high SRI dose necessary for human OCD treatment response. Finally, the deer mouse, an ethological model of OCD, also has strong face validity. At baseline, deer mice demonstrate repetitive running, jumping, and flipping behaviors. *In vivo* microdialysis in corticostriatal projections was performed to investigate the molecular correlates of these repetitive behaviors. These studies found that increased glutamate directly preceded stereotypic behaviors in these mice, supporting the idea that glutamatergic abnormalities may lead to OCD symptomatology.

MODELING GENETIC ABNORMALITIES

Transgenic technology has enabled the generation of animal models of OCD based on alteration of specific genes (see Ting and Feng, 2011 for comprehensive review). This increasingly advanced technology allows investigators to upregulate or downregulate genes of interest in specific regions of the brain that have been implicated in OCD. Thus, the function of candidate genes identified in human studies can be directly tested in mice. This allows for dissection of molecular and cellular mechanisms that may underlie OCD pathophysiology.

As discussed earlier, the identification of candidate genes in OCD has been difficult, since the field has been hampered by a lack of replication in genetic studies. However, there is increasing interest in the role of glutamate system genes in OCD pathophysiology. This is due in large part to the fact that the only consistently replicated genetic finding in OCD is an association with the neuronal glutamate transporter *SLC1A1* (see Wu et al., 2012 for review). Based on findings that *SLC1A1* overexpression contributes to OCD susceptibility, we are in the process of making a transgenic mouse that yields tissue-specific *SLC1A1* overexpression. This will allow us to directly address the molecular, cellular, and behavioral impact of changes in expression of this OCD candidate gene.

OCD animal models have also been unexpectedly generated following disruption of genes not previously implicated in OCD. For example, knockout of the developmentally expressed *Hoxb8^{lox}* gene leads to perseverative grooming, while disruption of the serotonin 2C receptor leads to perseverative chewing. However, the link between disruption of these genes and the human OCD phenotype remains unclear. There is somewhat stronger evidence that two other knockout mouse models may have relevance to OCD. In a recent elegant study, Welch et al. (2007) used a transgenic approach to knock out SAPAP3, a corticostriatal postsynaptic density protein. Knockouts had excessive grooming leading to facial lesions, similar to some OCD subgroups (contamination fears/washing rituals). In addition, these mice demonstrated abnormal glutamatergic signaling at corticostriatal synapses (increased NMDA-dependent fEPSPs (excitatory post-synaptic potentials) and decreased AMPA-dependent fEPSPs) that correlated with the OCD-related behaviors. Overgrooming and the electrophysiologic changes

were eliminated after either lentiviral-mediated SAPAP3 rescue in corticostriatal synapses or acute treatment with low-dose fluoxetine. In another study, Shmelkov et al. (2010) performed targeted inactivation of the *Slitrk5* gene, a postsynaptic density transmembrane protein that is one of a family of genes implicated in Tourette's and obsessive-compulsive spectrum disorders. *Slitrk5* knockout mice demonstrate several OCD-relevant behaviors that are reversed by chronic treatment with the serotonin-reuptake inhibitor fluoxetine, including increased anxiety and perseverative grooming behaviors; this lends predictive validity to the model. Notably, knockout of *Slitrk5* also led to selective overactivation of orbitofrontal cortex; this parallels findings in human OCD patients.

For both SAPAP3 and *Slitrk5* knockouts, the challenge of linking these findings back to the human disorder remains. For example, the SAPAP3 knockout phenotype may be more consistent with pathological skin picking than OCD: a recent human genetics study found no association of SAPAP3 SNPs with OCD in a clinical sample but did find associations with grooming disorders such as pathologic skin picking, nail biting, and/ or trichotillomania. Preliminary evidence from *Slitrk5* genetic studies is promising, indicating the presence of rare *Slitrk5* genetic variants in OCD patients; however, these findings still need to be validated (F. Lee, personal communication). Regardless, both of these studies clearly demonstrated a link between molecular changes at corticostriatal synapses and repetitive pathological behaviors. These studies therefore yield new insights into possible molecular and cellular mechanisms underlying OCD.

MODELING CIRCUIT ABNORMALITIES

New technology development now facilitates the generation of OCD animal models based on manipulation of specific neural circuits. These technologies allow direct translation of human neuroimaging findings into mice. This approach was first elegantly demonstrated through the generation of D1CT-7 transgenic mice. In this transgenic line, the active subunit of cholera toxin was placed under the regulation of the D1 receptor promoter (D1CT-7 transgenic mice). Thus, the stimulatory subunit of cholera toxin was expressed in a subset of D1-positive neurons, leading to constitutive hyperactivation of these neurons. This mouse model therefore had strong overactivation in prefrontal-cortex and striatal neurons, similar to observations from OCD imaging studies. These mice demonstrated baseline perseverative climbing, leaping, and biting behaviors that were exacerbated by increased NMDA-dependent glutamatergic transmission, yielding a model with strong construct validity.

Other new technologies can also be used to mimic circuit abnormalities seen in human imaging studies (reviewed in Rogan and Roth, 2011). For example, there have been recent significant advances in precise modulation of activity of neural circuits using light-activated microbial ion channel proteins. The development of this optogenetic technology has focused on channelrhodopsin-2, an excitatory sodium channel gated by 470 nm blue light; and halorhodopsin, an inhibitory chloride pump gated by 580 nm yellow light. By specifically expressing and stimulating these light-activated proteins, distinct neural populations can be rapidly activated or inhibited without

affecting neighboring cells. We are currently using this technology to directly translate imaging findings from OCD patients into rodents. In addition, technology has been recently developed that allows for cell type-specific expression of mutant G-protein coupled receptors (GPCRs) that can be activated by administration of inert small molecules. These mutant GPCRs are known as DREADDs (Designer Receptors Exclusively Activated by Designer Drugs). Whereas optogenetic technology allows for rapid and specific activation and inhibition, DREADD technology yields more sustained but specific activation and inhibition that may better mirror pathophysiologic processes.

FUTURE DIRECTIONS

The examples discussed in the preceding demonstrate the power of using animal model systems to explore the molecular and cellular pathology underlying OCD. In addition, by capitalizing on new technologies, we may be able to develop more refined disease models through precise control of neural activity. However, these examples also highlight the importance of critically evaluating mouse models to determine if they are truly relevant to the disorder of interest—in this case, OCD. Ongoing studies in our group are identifying translatable probes of neural circuits that are reliably abnormal in OCD patients. Using these neural circuit probes, we can better determine clinical relevance of our animal models. These types of studies will help ensure that dissection of molecular and

cellular abnormalities in animal models will ultimately yield information relevant for the development of new treatments.

TREATMENT OF OCD

Although the etiology and pathophysiology of OCD are still under study, evidence-based treatments for OCD have been developed in the absence of unclear mechanisms of action. These treatments can lead to remission of symptoms in up to 50% of patients. First-line treatments recommended by the American Psychiatric Association (American Psychiatric Association, 2007) include pharmacotherapy with serotonin reuptake inhibitors (SRIs), and cognitive-behavioral therapy (CBT) consisting of exposure and response prevention (Fig. 48.2). These two treatments are described next along with other strategies that are used when these first-line treatments do not suffice.

PHARMACOTHERAPY FOR OCD

SEROTONIN REUPTAKE INHIBITORS

OVERVIEW

The only medications proven effective as monotherapy for OCD in multisite randomized controlled trials are serotonin reuptake inhibitors (SRIs). SRIs include clomipramine, a tricyclic antidepressant, and the selective serotonin reuptake

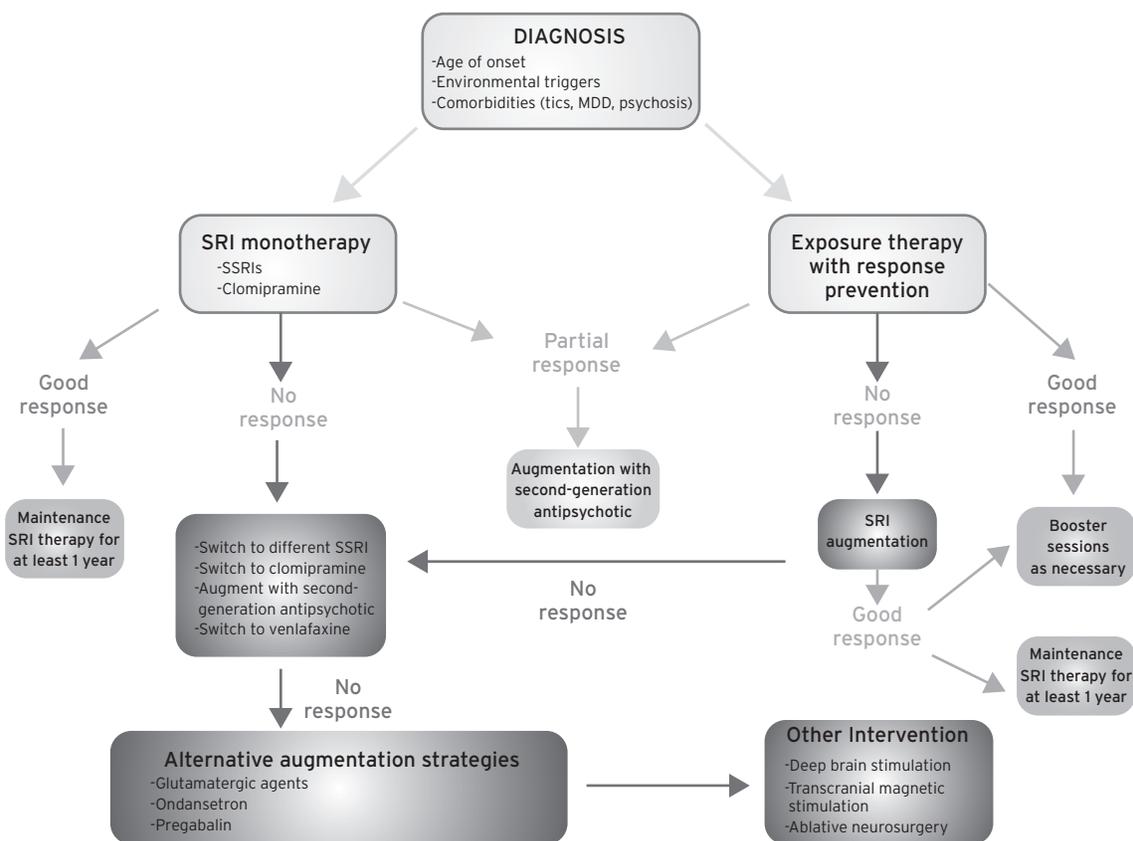

Figure 48.2 OCD treatment guidelines. OCD treatment guidelines are based on APA recommendations. After diagnosis, flowchart outlines treatment algorithms for individual and combined pharmacotherapy and exposure therapy. Alternative interventions for treatment-refractory OCD are also indicated.

inhibitors (i.e., fluoxetine, fluvoxamine, sertraline, paroxetine, citalopram, and escitalopram). All but citalopram and escitalopram are currently approved by the Food and Drug Administration for the treatment of OCD. Though the mechanism of action of SRIs in OCD is unknown, it was initially thought that their efficacy was linked to the direct modulation of serotonin levels. However, more recent hypotheses propose that SRIs modulate CSTC circuit function through action on serotonergic heteroreceptors, which in turn control levels of glutamate, GABA, and dopamine.

In general, serotonin reuptake inhibitors lead to improvement in 40–60% of people with OCD, and OCD patients who receive an adequate trial will achieve on average a 20–40% reduction in their OCD symptoms (reviewed in Simpson, 2010). Thus, serotonin reuptake inhibitors typically lead to amelioration rather than elimination of symptoms. Various issues arise when treating OCD with serotonin reuptake inhibitors that are discussed in the following sections: which one to try first, what dose to use, the time to response, how to manage potential side effects, and the recommended duration of treatment.

COMPARATIVE EFFICACY

Serotonin reuptake inhibitors are not thought to differ from each other in efficacy for OCD, with the possible exception of clomipramine. Clomipramine, a tricyclic antidepressant, is both a serotonin reuptake inhibitor and a norepinephrine reuptake inhibitor. In meta-analyses, clomipramine has greater effects than the other serotonin reuptake inhibitors. However, the clomipramine studies were done earlier in time than the studies using the selective serotonin reuptake inhibitors and thus likely included more treatment-naïve samples. In head-to-head comparisons, clomipramine has not been found to be superior to fluoxetine, fluvoxamine, or paroxetine.

Practice guidelines (American Psychiatric Association, 2007) recommend that patients first be started on a selective serotonin reuptake inhibitor because they have a better side effect profile than clomipramine (as described in the next section). If there is no response, they should be switched to another selective serotonin reuptake inhibitor and, if satisfactory symptom reduction is not achieved, eventually tried on clomipramine. To determine which selective serotonin reuptake inhibitor to try first, the clinician should consider prior treatment response, safety and acceptability of particular side effects for the individual patient (see the next section), and the potential for drug–drug interactions.

DOSE

Clinical trials of fluoxetine, paroxetine, and citalopram that randomized patients to different doses of the same medication (i.e., fixed-dose studies) found that higher doses produced a higher response rate and/or greater degree of improvement than lower doses; one fixed-dose study of sertraline did not find significant differences between the effects of 50 and 200 mg/day. Based on these data, the American Psychiatric Association’s Practice Guidelines (2007) recommend the following usual target doses for adults with OCD: fluoxetine, 40–60 mg/day; fluvoxamine, 200 mg/day; paroxetine, 40–60 mg/day; sertraline, 200 mg/day; citalopram, 40–60 mg/day (note: the FDA no longer recommends citalopram above 40 mg/day because of dose-dependent QT prolongation); escitalopram, 20 mg/day; clomipramine, 100–250 mg/day (see Table 48.1). These therapeutic doses of SRIs for OCD tend to be higher than the doses used for treatment of other anxiety disorders and depression. It is advised that patients start at a low dose for tolerability (e.g., fluoxetine 10 or 20 mg/day) and that the dose be increased every week or every other week (as tolerated) to doses at least as high as listed in the preceding (with

TABLE 48.1. Dosage guidelines for OCD pharmacotherapy in adult patients. Starting dose, FDA-approved dose, and usual maximum dose for OCD are based on the American Psychiatric Association’s Practice Guidelines (2007). If patients do not respond to the usual maximum dose, OCD specialists will often try higher doses.

DRUG CLASS	MEDICATION	STARTING DOSE (in mg)	FDA-APPROVED DOSE (in mg)	USUAL MAXIMUM DOSE (in mg) FOR OCD PATIENTS	MAXIMUM DOSE (in mg) USED IN CLINICAL PRACTICE (NORMALLY INITIATED BY SPECIALISTS)
Selective serotonin reuptake inhibitors (SSRIs)	Fluoxetine	40	60	80	120
	Paroxetine	20	40	60	100
	Sertraline	50	200	300	400
	Citalopram***	20	20–40	60–80***	120
	Escitalopram	10	30	40	60
	Fluvoxamine	50	100–200	300	450
Tricyclic antidepressants	Clomipramine	25	250	250	<500 ng/mL by blood levels

***Note that the FDA no longer recommends citalopram above 40 mg/day because of dose-dependent QT prolongation and Torsades de Pointes. Patients with pre-existing congestive cardiac failure, brady-arrhythmias or predisposition to hypokalemia or hypomagnesemia are at increased risk of developing these cardiac abnormalities, and should therefore be monitored closely, ideally in conjunction with a cardiologist. Recommended medication dosage for treatment of OCD in adults (18–65).

the exception now of citalopram) before deciding that a patient is resistant to any particular serotonin reuptake inhibitor.

When patients do not respond to the doses outlined, doses even higher have been tried in clinical practice (e.g., fluoxetine, 120 mg/day; paroxetine, 100 mg/day). For example, Ninan et al. (2006) randomized patients who had not responded to 16 weeks of sertraline (titrated from 50 mg/day to 200 mg/day) to continued sertraline (200 mg/day) or to increased sertraline (250–400 mg/day). Although the high-dose group had significantly more improvement than the lower dose group, the difference in additional improvement was clinically modest, and both groups were still left with clinically significant symptoms. Thus, increasing selective serotonin reuptake inhibitors to higher than recommended doses may be effective for certain OCD patients, but this strategy is not useful for all.

TIME TO RESPONSE

Many of the randomized controlled trials of serotonin reuptake inhibitors for OCD did not show a significant difference between placebo and active medication before six weeks. Thus, an adequate trial has been defined as the maximum dose tolerated for a minimum of six weeks (American Psychiatric Association, 2007). This usually amounts to an 8–12 week trial overall given usual titration schedules. Preclinical studies have found that therapeutic response to serotonin reuptake inhibitors corresponds to the time course of desensitization of inhibitory serotonin receptors. It has thus been suggested that delayed receptor desensitization in the OFC accounts for the delay in treatment response seen in OCD patients (Moritz et al., 2012). It is important to explain this delayed response to treatment to patients so that they don't prematurely stop their serotonin reuptake inhibitor.

SIDE EFFECTS

Selective serotonin reuptake inhibitors are generally well tolerated. Potential side effects include gastrointestinal problems (e.g., nausea or diarrhea), agitation, sleep disturbances (e.g., insomnia, vivid dreams), increased tendency to sweat, and sexual side effects (e.g., decrease in libido, trouble ejaculating, delayed orgasm). In addition, weight gain or fatigue can occur (reviewed in Simpson, 2010). There are also clinical reports of specific side effects with certain agents that are presumed due to their unique pharmacological characteristics (e.g., more sedation and constipation due to the mild anticholinergic effects of paroxetine, more anorexia and activation due to the 5HT_{2C} antagonism of fluoxetine). Thus, it is possible for a patient to tolerate one serotonin reuptake inhibitor, but not another.

As mentioned, the FDA has recently issued a safety warning for citalopram because of data that it causes dose-dependent QT interval prolongation, which can cause Torsades de Pointes, ventricular tachycardia, and sudden death. Thus, citalopram is no longer recommended for use in patients with congenital long QT syndrome, bradycardia, hypokalemia, hypomagnesemia, recent acute myocardial infarction, or uncompensated heart failure. Citalopram is also not recommended for use in patients who are taking other drugs that prolong the QT interval. QT interval prolongation was not observed with escitalopram (the S-isomer of citalopram).

The other serotonin reuptake inhibitor with known effects on the heart is clomipramine. In addition to being a serotonin and norepinephrine reuptake inhibitor, clomipramine blocks muscarinic cholinergic receptors, H₁ histamine receptors, alpha₁ adrenergic receptors, and sodium channels in the heart and brain. Thus, in addition to the side effects described for selective serotonin reuptake inhibitors, clomipramine can cause anticholinergic effects (e.g., dry mouth, constipation, delayed urination), antihistamine effects (e.g., sedation, weight gain), antiadrenergic effects (e.g., orthostatic hypotension), and cardiac conduction abnormalities or seizures.

DURATION OF TREATMENT

Clinical trials that treat with medications for a certain period of time and then randomly assign responders to either continue on that medication or be switched to pill placebo (i.e., double-blind drug discontinuation studies) help determine the risk of relapse if medication is stopped. Several double-blind discontinuation studies in adults with OCD (reviewed in Fineberg et al., 2012; Simpson, 2010) examined different serotonin reuptake inhibitors, used different designs (e.g., length of follow-up, procedure for placebo substitution) and had different relapse definitions. The studies came to different conclusions about the risk of relapse if medication is stopped. For example, relapse rates (or discontinuation due to insufficient clinical response) after double-blind switch to placebo ranged from a high of 89% within 7 weeks for clomipramine, to a low of 24% within 28 weeks for sertraline. Given the limited number of studies and the methodological differences, the risk of relapse remains unclear. Practice guidelines (American Psychiatric Association, 2007) recommend that an OCD patient who has improved during an adequate trial of a serotonin reuptake inhibitor should stay on that medication for one to two years and that if the medication is discontinued, it should be slowly tapered (e.g., 10–25% every one to two months).

If stopped abruptly, serotonin reuptake inhibitors can lead to a drug discontinuation syndrome. This can include flulike symptoms (e.g., dizziness, nausea/vomiting, headache, and lethargy) as well as agitation, insomnia, myoclonic jerks, and paresthesias (Tamam and Ozpoyraz, 2002; Zajecka et al., 1997). Drugs with a shorter half-life (e.g., paroxetine) are more likely to cause this than those with a longer half-life and an active metabolite (e.g., fluoxetine).

ROLE OF VENLAFAXINE AND DULOXETINE IN THE TREATMENT OF OCD

Like clomipramine, venlafaxine and duloxetine are both serotonin and norepinephrine reuptake inhibitors. Because they inhibit serotonin reuptake, both are presumed effective for the treatment of OCD. Other than two case reports, the only published study of duloxetine in OCD to date is a case series of four patients with OCD who had either a partial or no response to an SRI; after being switched to duloxetine up to 120 mg/day, three responded to duloxetine (Dell'osso et al., 2008). Larger controlled studies are needed to confirm this preliminary observation.

SRI AUGMENTATION STRATEGIES

Randomized controlled trials support the addition of antipsychotics or the addition of CBT consisting of exposure and response prevention. Many other augmenting agents have also been tried, as reviewed next (see Simpson, 2010 for review).

ANTIPSYCHOTIC AUGMENTATION

Haloperidol, risperidone, quetiapine, olanzapine, and aripiprazole have all been shown in randomized controlled trials to augment the effects of serotonin reuptake inhibitors. There are also negative findings from studies of these agents, although this may be due to methodological issues (reviewed in Fineberg et al., 2012). A systematic review of antipsychotic augmentation (Bloch et al., 2006), which combined nine double-blind, randomized controlled clinical trials involving 278 subjects, concluded that about one-third of OCD patients will be helped by antipsychotic augmentation. The strongest evidence supports the use of haloperidol or risperidone. Some data suggest that the patients most likely to respond to antipsychotic augmentation may be those with a minimal response to an SRI and/or those with comorbid tic disorders.

Given the delayed onset of action of serotonin reuptake inhibitors in OCD, it is recommended that antipsychotic augmentation only be implemented after an OCD patient has failed to respond to a maximal dose of a serotonin reuptake inhibitor for at least 12 weeks (American Psychiatric Association, 2007). Low antipsychotic doses appear effective (e.g., <3 mg for risperidone or the equivalent), and the time to response is about two to four weeks. Given that only some OCD patients will respond to antipsychotic augmentation, the antipsychotic should be terminated after one month of intervention in those who do not clearly benefit. This minimizes the known risks of antipsychotic exposure, which can include metabolic syndrome, tardive dyskinesia, and neuroleptic malignant syndrome.

Questions remain about the use of antipsychotics in OCD, including whether some agents are more effective than others, their long-term efficacy, and the risk of relapse upon discontinuation. One small retrospective study suggested that 13 of 15 patients had a resurgence of OCD symptoms when their antipsychotic was discontinued.

CBT AUGMENTATION

Two randomized controlled trials have demonstrated the benefit of adding CBT consisting of exposure and response prevention to OCD patients with clinically significant symptoms despite an adequate SRI trial. The specific components of this treatment are described in detail in the following. In the first study, Tenneij et al., (2005) compared the effects of continuing medication (paroxetine or venlafaxine) versus adding exposure and response prevention in patients who had mild OCD symptoms. Adding exposure and response prevention (eighteen 45-minute sessions over 6 months) was superior to medication alone, but the effects were modest. In the second study, Simpson et al. (2008) recruited patients on an adequate dose for at least 12 weeks of any serotonin reuptake inhibitor who still had clinically significant OCD symptoms. Patients

Venlafaxine has been studied more extensively, but the findings from different studies are conflicting (reviewed in Simpson, 2010). The only randomized controlled trial of venlafaxine in OCD found no significant difference between venlafaxine and placebo. However, the sample was small ($n = 30$), the maximum dose was 225 mg/day, and the trial was only eight weeks long. Other randomized controlled trials have compared venlafaxine (or venlafaxine XR) with either paroxetine or clomipramine. These trials were limited by the lack of a placebo group, but each was 12 weeks in length and used higher doses of venlafaxine (e.g., 225–300 mg/day). In both studies, venlafaxine was as efficacious as the serotonin reuptake inhibitor with which it was compared. Finally, in a crossover study of nonresponders, when paroxetine nonresponders were switched to venlafaxine, only 3 of 16 (19%) responded, whereas when venlafaxine nonresponders were switched to paroxetine, 15 of 27 (56%) responded. These findings suggest that paroxetine is more efficacious than venlafaxine in patients with limited response to the other medication.

In sum, venlafaxine is often tried in clinical practice in OCD patients who have not responded to several selective serotonin reuptake inhibitors and cannot tolerate clomipramine. However, the evidence supporting the use of venlafaxine in OCD is not as strong as the evidence for the serotonin reuptake inhibitors, and there is little data supporting the use of duloxetine. Neither is approved by the Food and Drug Administration for the treatment of OCD.

LIMITATIONS OF SEROTONIN REUPTAKE INHIBITORS IN THE TREATMENT OF OCD

Although they are the only medications proven effective as monotherapy for OCD, serotonin reuptake inhibitors have important limitations: only up to 65% of people will respond to an adequate trial, the typical response is a 20–40% reduction in symptoms, and patients can relapse if the medication is discontinued. Because many OCD patients will have a clinically meaningful but modest reduction in symptoms and others will have no response (e.g., <25% reduction in symptoms), clinicians who treat OCD patients will commonly be faced with both problems.

One strategy is to switch to another SRI (e.g., if there is no response to the first) and to eventually switch to clomipramine. The American Psychiatric Association's Practice Guidelines suggest that up to 50% of patients might respond to a second SRI trial but that the rate of response diminishes as the number of failed trials increases (American Psychiatric Association, 2007). Switching to venlafaxine or duloxetine is another option; however, the data for both agents is limited (as reviewed earlier). Mirtazapine, shown in a small double-blind discontinuation study to reduce OCD symptoms, is another possibility (Koran et al., 2005). However, the efficacy of switching either to another SRI or to another agent as monotherapy has not been well studied, and there are limited data to support this strategy.

Another strategy with more data to support it is to include additional treatments in ongoing SRI treatment to augment SRI response. SRI augmentation strategies are discussed in the following.

were randomized to exposure and response prevention or to stress management therapy as a control therapy; both treatments included seventeen 90-minute sessions delivered over eight weeks. Patients who received exposure and response therapy had a significantly greater decrease in symptoms, and significantly more achieved minimal symptoms at the end of treatment (33% versus 4%). These effects were maintained in many at six-month follow-up.

Together, these findings support the use of exposure and response prevention in augmenting the effects of serotonin reuptake inhibitors in OCD. The addition of exposure and response prevention is clearly safer than the addition of antipsychotics, given the known risks of the latter (Marder et al., 2004). On the other hand, exposure and response prevention is not widely available, it is more time consuming, and some patients refuse it because it requires exposures to feared stimuli.

OTHER AGENTS

Many other medications have been tested as adjunctive agents to serotonin reuptake inhibitors in OCD (reviewed in Fineberg et al., 2012; Simpson, 2010). Although promising in case reports or open trials, several did not show clear efficacy in small placebo-controlled trials, including lithium, buspirone, clonazepam, L-triiodothyronine, pindolol, and desipramine (American Psychiatric Association, 2007). The initially promising effects of other augmentation agents await confirmation in large randomized controlled trials (as reviewed in Fineberg, 2012; Simpson, 2010), including clomipramine, morphine sulfate, pregabalin (Oulis et al., 2011), celecoxib (Sayyah et al., 2011), dextroamphetamine, and ondansetron. Medications that modulate the glutamatergic system or that might enhance learning from cognitive-behavioral therapy have been a recent area of study, as described in what follows.

NOVEL MEDICATIONS FOR OCD THAT TARGET BRAIN MECHANISMS

Because of the limitations of serotonin reuptake inhibitors, new medications continue to be tried in OCD. Because of data from human genetic studies, human imaging studies, and animal models of OCD that glutamatergic abnormalities in corticostriatal circuits might underlie OCD symptoms (as reviewed previously in this chapter), medications that modulate the glutamate system have been a recent focus of study. Various agents, each thought to modulate glutamate in different ways, have shown some promise in case reports, open-label studies, or small controlled trials either as monotherapy or as an adjunct to SRIs (reviewed in Pittenger et al., 2011). These include *N*-acetylcysteine (an amino acid derivative that reduces synaptic glutamate; Lafleur et al., 2006), memantine (a noncompetitive NMDA receptor antagonist), topiramate, riluzole (an antiglutamatergic agent that reduces glutamatergic neurotransmission in several ways), and minocycline. A case report demonstrated rapid resolution of obsessions in a treatment-resistant patient after IV ketamine infusion (Rodriguez et al., 2011). Though this initial finding must be explored in a larger controlled study, the possibility of a rapidly acting treatment for OCD is exciting.

Historically, medications have been used to target OCD symptoms directly. However, a novel approach is to use medication to enhance learning from psychotherapy. One of the best examples is the use of D-cycloserine (a partial agonist at the *N*-methyl-D-aspartate receptor), which is known to facilitate fear extinction in animal models. D-cycloserine is being paired with CBT that is focused on exposure techniques like exposure and response prevention, with the goal of enhancing extinction learning. This is described in more detail in the next section.

PSYCHOTHERAPY FOR OCD

COGNITIVE-BEHAVIORAL THERAPY

OVERVIEW

In addition to SRI pharmacotherapy, CBT is the other recommended first-line treatment for adults with OCD and the only first-line treatment recommended for pediatric OCD (see Rodriguez and Simpson, 2010, for review). Historically, CBT has evolved from two traditions: (1) CBT that relies primarily on behavioral techniques such as exposure and response prevention, known as exposure therapy, or ERP or EX/RP; and (2) CBT that relies primarily on cognitive techniques, such as identifying, challenging, and modifying faulty beliefs. Of these two, ERP-based CBT has the strongest evidence in OCD. However, it is important to note that ERP routinely includes some informal CT techniques (e.g., a discussion of fear-related thoughts and beliefs) and that CBT typically includes behavioral experiments, which are similar to exposure techniques. Thus, there is an overlap between these two forms of CBT. In clinical practice, cognitive and behavioral techniques are often combined.

EXPOSURE AND RESPONSE PREVENTION

CBT consisting of exposure and response prevention (called EX/RP or ERP in the literature and ERP in this chapter) involves *in vivo* (i.e., actual) exposures to feared situations, imaginal exposure to feared consequences, and ritual prevention, in which patients refrain from compulsive rituals (see Rodriguez and Simpson, 2010). For example, a patient with contamination obsessions and washing rituals is coached to confront feared contaminants (e.g., by touching objects in public restrooms), to imagine touching feared contaminants, and to refrain from washing rituals. For ERP to work, the therapist tailors the exposure exercises to the varied obsessive fears of patients with OCD (e.g., fear of contamination, fear of harm befalling themselves or others, fear of perverse sexual or religious thoughts, fear of not doing something just right). There are two main theories about the mechanisms underlying effective ERP. From a behavioral perspective, it is thought that repeated prolonged exposures to triggering situations while preventing conditioned rituals leads to extinction of conditioned fear responses (i.e., compulsions) through habituation. Over time, this leads to decreases in anxiety even in the face of obsessional thoughts. From a cognitive perspective, it is thought that ERP helps OCD patients eradicate dysfunctional beliefs (such as overestimation of threat in a particular situation), by providing information that leads to correction of faulty associations.

ERP therapy has been shown to be superior when compared with other treatments and control conditions in randomized controlled trials (as reviewed by Rodriguez and Simpson, 2010; Simpson, 2010) including pill placebo, anxiety management therapy, self-guided relaxation therapy, therapist-guided progressive muscle relaxation, and wait list control. ERP is also effective at augmenting response to SRI medications, as described previously. Up to 70% of patients who enter ERP treatment will respond to it, and up to 50% will achieve minimal symptoms after acute treatment. Importantly, not only does ERP lead to acute improvement in OCD symptoms, but many patients can also maintain their gains over time.

Several factors appear to affect ERP outcome (as reviewed by Rodriguez and Simpson, 2010), including the number and intensity of sessions, patient adherence with ERP procedures, comorbidities (e.g., severe depression, comorbid posttraumatic stress disorder), and degree of insight. Further study is required to determine if addressing these factors prior to or during ERP treatment leads to better outcomes. Data suggest that providing relapse prevention techniques helps patients to maintain the gains of ERP therapy. In addition, how patients adhere to acute treatment is a robust predictor of long-term outcome (Simpson et al., 2012).

In sum, after acute treatment with ERP (either with or without concomitant SRIs), up to half of patients will achieve minimal symptoms and many can maintain their gains after acute treatment ends. This is quite remarkable given the typically chronic and impairing nature of OCD.

COGNITIVE THERAPY FOR OCD

Cognitive therapy (CT), another form of cognitive-behavioral therapy, has also been used in OCD. In CT, patients and therapist work together to identify distorted patterns of thinking that lead to emotional reactions and then challenge and alter their ways of thinking in order to change their emotional response. Clinical trials have compared CT with ERP. However, separating these treatments can be procedurally difficult because many ERP protocols include informal cognitive techniques (e.g., relapse prevention, cognitive restructuring during exposures), and standard CT includes behavioral experiments that can resemble exposures. Clinical trials that have tried to separate these treatments suggest that CT that includes behavioral interventions is similar in efficacy to ERP when it is not optimally delivered (e.g., 45-minute weekly sessions, self-guided exposure) (reviewed in Rodriguez and Simpson, 2010). An open trial suggested that CT in the absence of behavioral experiments can help some OCD patients. However, given the limited data for CT alone, ERP remains the recommended first-line psychotherapy for OCD (APA Practice Guidelines).

LIMITATIONS OF CBT IN THE TREATMENT OF OCD

Even though CBT consisting of exposure and response prevention is a very effective treatment for OCD, it also has important limitations. The therapy requires a substantial time commitment on the part of the patient and is labor intensive. It requires full adherence with treatment procedures to achieve

full effects. To complete treatment, patients have to be willing to tolerate high levels of anxiety during the exposure procedures. In addition, certain types of OCD patients (e.g., those with prominent hoarding symptoms or with mental, unobservable compulsions that the therapist can't directly observe) may have a poorer response to standard ERP procedures. Finally, one of the biggest hurdles is that ERP is not widely available, and many patients therefore do not have access to it.

Because ERP is challenging for many patients, approaches such as motivational interviewing and modification of treatment-interfering cognitive beliefs are used to improve treatment adherence (Simpson et al., 2012). Another approach for maximizing ERP efficacy stems from animal research: using medications to enhance what patients learn during exposures. As previously mentioned, one of the best examples is the use of D-cycloserine (a partial agonist at the N-methyl-D-aspartate receptor), which is known to facilitate fear extinction in animal models. There are three published studies of the effects of D-cycloserine augmentation of ERP in OCD; these are reviewed in Simpson, 2010. In two, D-cycloserine reduced the time to response. A reanalysis of the data from one study confirmed that D-cycloserine does not change overall effectiveness of ERP but speeds up the time to response.

The problem of access to ERP is also being addressed. For example, Web-based platforms have recently been developed that deliver ERP over the Internet; minimal therapist support is provided by e-mail or phone. Andersson et al. (2012) found that this Web-based ERP therapy was significantly better than an attention control condition delivered by the Internet and led to clinically meaningful improvement in OCD symptoms.

In sum, CBT consisting of exposure and response prevention is a first-line treatment for OCD, and research is underway to make it not only more accessible but also more efficacious for different types of patients with OCD.

SURGICAL AND OTHER TREATMENTS FOR OCD

OVERVIEW

A subset of OCD patients do not respond to the pharmacologic and psychotherapy treatment strategies described in the previous sections. To be designated as treatment refractory according to current clinical trial guidelines, patients must have failed at least three adequate trials of SRIs for at least three months at the maximum tolerated dose; at least one augmentation trial with clomipramine, a neuroleptic, or clonazepam; and at least one ERP trial performed in combination with pharmacotherapy. These treatment-refractory patients are then potential candidates for neurosurgical intervention. Up to 10% of patients fit into this category. Most modern neurosurgical techniques take advantage of the fact that OCD symptoms are associated with abnormal neuronal activity in CSTC circuits. These techniques share the same general approach—i.e., attempting to decrease symptoms via disruption of CSTC circuits at circuit nodes. However, the exact targets for surgical interventions vary from study to study, since

target selection and side effect minimization are active areas of investigation. In this section, we will review currently available procedures, including ablation/radiosurgery, deep brain stimulation, electroconvulsive therapy (ECT), and transcranial magnetic stimulation (TMS). Some of these procedures have not only been used to treat OCD, but are also increasingly being used to study brain mechanisms underlying OCD (e.g., see Sheth et al., 2012).

SURGERY

MRI-guided stereotactic neurosurgical lesions in the anterior limb of the internal capsule, the anterior cingulate, and/or the subcaudate region appear to be beneficial in the treatment of highly refractory OCD. These lesions can be generated either using traditional MRI-guided stereotactic neurosurgery, or radiosurgery (i.e., gamma knife), which does not require a craniotomy. The fact that symptom relief can be generated through intervention at multiple points in the CSTC circuit provides further evidence that hyperactive CSTC circuits may lead to OCD symptomatology.

DEEP BRAIN STIMULATION

Deep brain stimulation (DBS) is being investigated as an experimental surgical therapy in treatment-resistant OCD (reviewed in Greenberg et al., 2010). DBS requires craniotomy to implant stimulating electrodes in specific brain targets and is therefore an invasive procedure. However, because it is nonablative, it permits flexible and largely reversible modulation of brain function. Conceptually, it may therefore permit normalization of abnormal activity patterns seen in OCD patients by “resynchronizing” circuit activity. Though DBS shows promise, optimal brain targets continue to be refined to avoid side effects, and the underlying mechanism of action remains unknown. Of note, all current targets are consistent with the theory that CSTC pathology underlies OCD symptoms. Though DBS is sometimes performed in the anterior limb of the internal capsule, target regions in the ventral capsule/ventral striatum (VC/Vs) are currently the primary location under investigation for treatment-refractory OCD. A recent meta-analysis examining the combined long-term results of DBS in 26 OCD patients demonstrated clinically significant symptom reductions and functional improvement in approximately two-thirds of the patients. At last follow-up, 73% of patients had at least a 25% Y-BOCS improvement. Based on these results, the FDA has approved the use of DBS in OCD patients as a humanitarian device exemption. However, general utility of DBS based on long-term efficacy in large, controlled clinical trials remains to be determined.

OTHER

TRANSCRANIAL MAGNETIC STIMULATION (TMS)

TMS is a neurophysiologic technique that permits noninvasive stimulation of cortical structures. Magnetic stimulation frequencies and strengths can be altered to generate either

stimulatory or inhibitory effects on neural transmission. There have been several treatment targets that have been investigated in OCD. To date, the main area of investigation has been the prefrontal cortex (PFC). Initial data from Greenberg et al. (1997) suggested that a single session of stimulation of the right PFC led to a decrease in compulsive urges that lasted for eight hours. However, a recent meta-analysis of the three studies of TMS in prefrontal regions in OCD did not demonstrate overall efficacy (see Slotema et al., 2010). These conclusions may be limited due to differences in the studies, including geometry of the TMS coil and frequency of stimulation. Though TMS is therefore not currently recommended as a standard treatment for OCD, it is still being investigated as an experimental treatment. For example, based on evidence for hyperactivity in the supplemental motor area (SMA) in OCD, an open label study was performed to investigate the use of low-frequency SMA TMS in OCD patients. In the follow-up randomized sham-controlled trial, response rate (i.e., >25% reduction in Y-BOCS scores) in treatment-refractory OCD patients was 67% compared with sham responses of 22% (see Mantovani et al., 2010). Ongoing studies continue to investigate SMA as a potential TMS treatment target.

ELECTROCONVULSIVE THERAPY (ECT)

Because there has been limited investigation into the efficacy of ECT in OCD, it is not currently recommended as a treatment by the APA practice guidelines unless there is a comorbid condition (e.g., severe major depression) for which ECT is effective.

CONCLUSIONS

In summary, OCD is a severe, chronic, and disabling illness that is highly prevalent. Though we still have a limited understanding of the etiology and pathophysiology of OCD, these are very active areas of research. Accumulated evidence from both clinical and preclinical studies suggests that there is dysregulation of activity in CSTC circuits, particularly in connections between prefrontal cortical regions and striatum. This evidence lends both experimental and theoretical support to the idea that multiple neurotransmitter systems and neuromodulators play a role in OCD pathophysiology, including GABA, dopamine, and glutamate (which has the strongest support from genetic studies). It is also necessary to investigate whether other circuits more specifically related to anxiety and fear extinction (e.g., cortico-amygdala connections) are dysfunctional in OCD. Though it is still unclear whether/how circuit abnormalities lead to symptomatology, new technologies such as optogenetics are allowing us to directly investigate these questions in animal models.

The only medications proven to be effective for monotherapy in OCD are the serotonin reuptake inhibitors. Although helpful for many patients, some patients do not respond, and many achieve only a partial response and are left with clinically meaningful residual symptoms. Proven augmentation strategies include the addition of antipsychotics and/or CBT consisting of exposure and response prevention; exposure and

response prevention is also a highly effective monotherapy for patients who are able to complete it. For patients who do not respond to serotonin reuptake inhibitors, cognitive-behavioral therapy, or the combination of an SRI and either CBT or an antipsychotic medication, alternative strategies can be tried; however, evidence supporting these alternatives is limited. Ongoing studies are investigating novel treatment strategies that target underlying brain mechanisms, and determining how currently accepted treatments should be sequenced for maximum efficacy.

DISCLOSURES

Dr. Ahmari has no conflicts of interest to disclose. She is funded by NIMH, the Irving Institute for Clinical and Translational Research, and the Louis V. Gerstner, Jr., Foundation. NIMH: K08MH087718-01A1; Irving Institute Pilot Award; Gerstner Scholar Grant.

In the past three years, Dr. Simpson has received medication at no cost from Janssen Pharmaceuticals for an NIMH-funded study, consulting fees from Pfizer Inc. for advice regarding the medication Lyrica, and research funds from Neuropharm Ltd. and from Transcept Pharmaceuticals to conduct clinical trials of novel medications for OCD. In addition, she receives grant support from the NIMH.

49 | NEUROBIOLOGY AND TREATMENT OF PTSD

KAREN E. MURRAY, ORION P. KEIFER JR., KERRY J. RESSLER,
SETH DAVIN NORRHOLM, AND TANJA JOVANOVIĆ

INTRODUCTION

Experiencing an extremely traumatic event, such as combat or violent assault, can lead to posttraumatic stress disorder (PTSD). PTSD is the fourth most common psychiatric diagnosis (Breslau et al., 1998) and is defined by three primary symptom clusters (Fig. 49.1) following an event that elicited fear, helplessness, or horror (Criterion A) (APA, 2000). The first cluster of symptoms (Criterion B) includes reexperiencing of the traumatic event through intrusive thoughts, nightmares, flashbacks, and related phenomena that are often produced by reminders of the traumatic event. The second cluster (Criterion C) is characterized by avoidance symptoms including loss of interest in social situations and emotional detachment. The third cluster (Criterion D) includes psychophysiological reactivity in response to trauma-related stimuli including exaggerated startle, hypervigilance, elevated perspiration, and shortness of breath. Finally, PTSD is defined by the mentioned symptoms lasting for more than 30 days after the trauma exposure, given that the initial response to trauma may resolve itself within one month's time. This chapter will explore vulnerability and resilience factors for developing PTSD, describing several theoretical frameworks for the disorder, as well as examining the animal model systems, differential pathways, and brain regions identified as involved in the disorder, and finally the available treatments for patients with PTSD.

MORBIDITY AND EPIDEMIOLOGY OF PTSD

Current estimates report that 37–92% of all people will be exposed to a severe traumatic event during their lifetime (Breslau et al., 1998). Given the high rates of trauma exposure, the prevalence of PTSD is relatively low, affecting approximately only 10% of the general population, with women being twice as likely to develop PTSD as men (Kessler et al., 1995). The rates of lifetime PTSD are closer to 40% in highly exposed trauma populations, such as low-income urban populations (Breslau et al., 1998). Recent studies have demonstrated a steep dose–response curve between trauma frequency and PTSD symptom severity such that the more traumatic events a person experiences, the greater the intensity of PTSD symptoms (Binder et al., 2008).

PTSD is a heterogeneous disorder, and some patients may present higher symptom severity in one domain compared

with another, and other patients may only exhibit lower intensity levels along the spectrum of PTSD symptoms. Recent papers highlighted the importance of treating patients who exhibit some but not all of the requisite PTSD symptoms across clusters for a full PTSD diagnosis (subsyndromal PTSD), suggesting that a “one-size-fits-all” treatment approach is often inadequate (Norrholm and Jovanovic, 2010). Furthermore, the neurobiological underpinnings of the different symptoms may not overlap (Hopper et al., 2007), suggesting that different “subtypes” of PTSD may have different treatment targets. Finally, PTSD is frequently comorbid with other disorders, such as depression, substance abuse, and other anxiety disorders (Kessler et al., 1995). Taken together, these issues result in a complex phenotype of PTSD, one that is difficult to model in animal research and does not easily lend itself to treatment outcome studies. However, several laboratory paradigms have shown promise in testing different elements of the PTSD syndrome—from aspects of risk and resilience, fear consolidation and expression, memory discrimination versus generalization, and differential symptom clusters. Although these cannot encompass the full complexity of the disorder, they provide useful tools to evaluate its different aspects. Next we outline theoretical frameworks for PTSD and describe several animal model systems and laboratory paradigms derived from these theoretical bases.

THEORETICAL FRAMEWORK FOR TRANSLATIONAL STUDIES OF PTSD

Several theorists have proposed that fear-conditioning processes are involved in the etiology and maintenance of PTSD. This model suggests that through Pavlovian conditioning, neutral cues (conditioned stimuli, CSs) present at the time of the trauma (the unconditioned stimulus, US) acquire the ability to elicit a conditioned fear reaction that can be triggered when the person subsequently encounters these or similar cues in his or her environment. Consistent with this hypothesis, emotional and physiological reactivity to stimuli resembling the original traumatic event (even years after the event's occurrence) is a prominent characteristic of PTSD and has been reliably replicated in the laboratory (Orr et al., 2002). Additionally, overgeneralization of trauma-related stimuli or situations, that is, an impaired ability to discriminate between danger and safety cues, can lead to hypervigilance and exaggerated startle

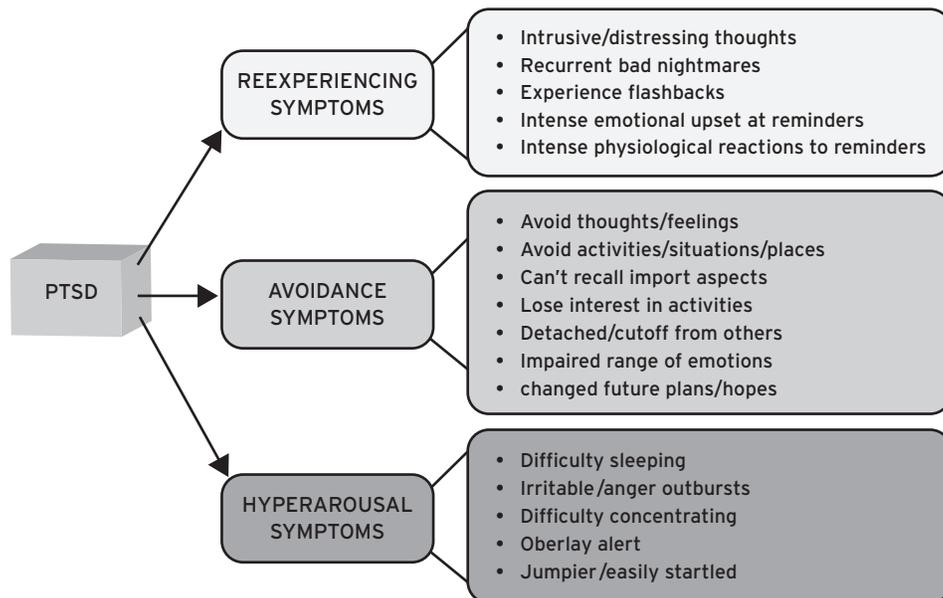

Figure 49.1 Symptom clusters in posttraumatic stress disorder (PTSD). The syndrome of PTSD includes the following clusters of symptoms following the experiencing of a traumatic event that elicits fear, helplessness, or horror (DSM-IV Criterion A). The clusters include reexperiencing symptoms (Criterion B), avoidance symptoms (Criterion C), and hyperarousal symptoms (Criterion D).

responses that are part of the hyperarousal symptom cluster (Mahan and Ressler, 2012), depicted in Figure 49.2.

Conceptualizing PTSD within the framework of fear conditioning affords the use laboratory paradigms, such as fear inhibition and fear extinction, to better understand altered fear processing and to develop better treatments for this dysregulation. As noted earlier, most trauma victims show fear-related

reactions immediately after the traumatic event, but these effects diminish over time in most traumatized individuals. The reduction in fear-related behavior over time is similar to extinction and may indicate that the development of chronic PTSD represents a failure of such fear extinction (Norrholm et al., 2011). Such an inability to extinguish conditioned fear may be due to a complex gene × environment interaction

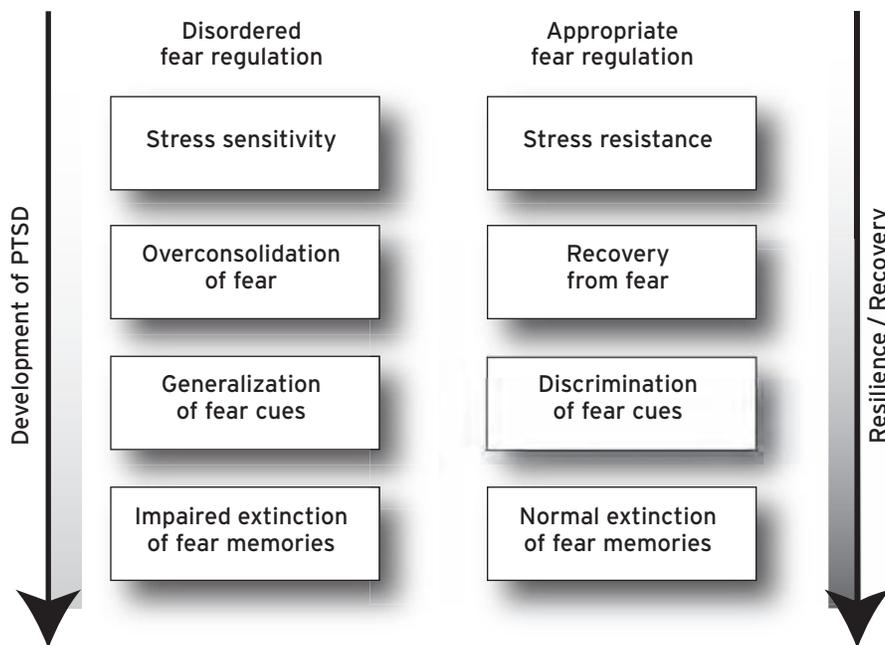

Figure 49.2 Disordered fear regulation in posttraumatic stress disorder (PTSD). Individuals with PTSD typically show increased sensitization to stress, overgeneralization of fear to irrelevant stimuli, and impaired extinction of fear memories. Individuals who demonstrate resilience to PTSD, and/or who recover from traumatic/stressful experiences, are able to better discriminate between fearful and nonfearful stimuli. Further, those with disordered fear regulation may also have impairment of extinction of fearful memories, further contributing to the lack of recovery as seen in PTSD. (Adapted from Mahan and Ressler, 2012.)

between one's individual predisposition(s) and environmental factors such as early life stress and the frequency, degree, and intensity of the traumatic event(s). Fear conditioning offers a unique framework for translational studies because it can be modeled in animal experiments. Given the richness of the animal literature, the neural underpinnings of fear conditioning are well understood, and PTSD research can capitalize on these findings (Jovanovic and Ressler, 2010).

ANIMAL MODEL SYSTEMS OF PTSD

Studies of PTSD in humans have several logistical and ethical limitations, such as the lack of control over the extent and level of trauma exposure, or the inability to match individuals based on past trauma history. Animal models provide the opportunity for increased experimental flexibility and control of trauma exposure in order to examine causal relationships in PTSD. While model systems of mental illness are discussed in other chapters, here we briefly describe animal models of relevance to PTSD.

FEAR CONDITIONING MODEL

As described in the preceding, PTSD patients have dysregulated fear responses including overgeneralization of the conditioned response, fear extinction deficits, and impaired safety signal learning (Mahan and Ressler, 2012). Fear conditioning and extinction are a widely used paradigm used in

many species, including humans (Mahan and Ressler, 2012). The deficits in fear extinction observed in several studies of PTSD patients are particularly important for animal models of PTSD treatment. As shown in Figure 49.3, fear extinction is a laboratory analogue of exposure therapy (Rothbaum and Davis, 2003). Manipulating rodent models using behavioral, pharmacological, lesion, or genetic techniques is useful in elucidating molecules and brain structures that are necessary for normal extinction. For example, brain-derived neurotrophic factor (BDNF) is one of the molecules that has been identified as having a role in fear conditioning and has been studied in rodent models (Andero et al., 2011). Therefore, compounds thought to act on BDNF can be administered during fear conditioning or extinction sessions to rodent models to assess their potential for PTSD treatment. Please see Chapter 41 in this volume for further details on understanding fear in animal model systems.

REPEATED CHRONIC STRESS MODEL

While the fear conditioning model can be used to examine extinction deficits in PTSD, other animal models can mimic the trauma exposure in order to examine the etiology of the human illness. Many PTSD patients experience repeated exposure to unpredictable traumatic events, particularly in combat-related PTSD. Therefore, a rodent model using chronic variable stress (CVS) provides a unique tool (McGuire et al., 2010). McGuire and colleagues described the CVS paradigm followed by a recovery period (CVS-R). The CVS model is characterized by

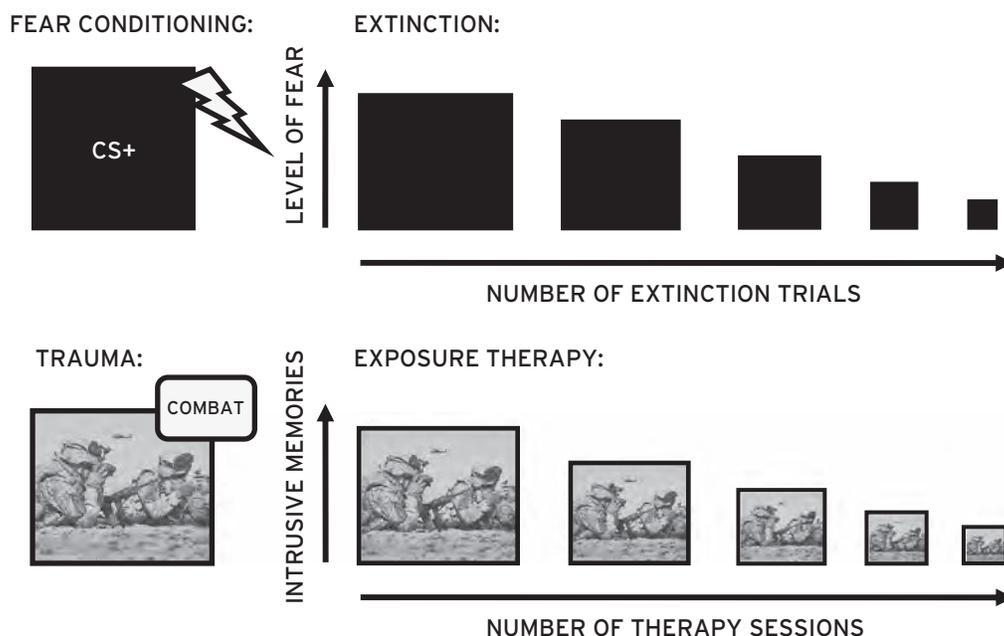

Figure 49.3 Parallels between fear conditioning and extinction in preclinical studies and trauma and exposure therapy in the treatment of PTSD. (Top) Fear conditioning, through the combination of a previously neutral conditioned stimulus (CS) combined with an aversive unconditioned stimulus (e.g., foot shock), leads to high levels of fear expression. However, with repeated reexposure to the CS in the absence of the aversive stimulus, a process known as extinction, the CS no longer elicits substantial levels of fear. (Bottom) Fear conditioning models of PTSD suggest that the cues that are associated with the aversive trauma experience, for example, the sights, sounds, and smells related to trauma exposure, come to elicit fearful intrusive memories, even if they are only somewhat related to the initial trauma (such as with fear generalization). Repeated exposure to these memories and trauma cues over time, through psychotherapy, leads to extinction and symptom reduction.

a week of various stressors, such as cold swim, warm swim, or hypoxia followed by an assessment of the rat's fear-conditioned responses, weight changes, or molecular changes in the tissue.

SINGLE PROLONGED STRESS MODEL

Although some PTSD patients experience chronic or repeated trauma exposure, such as prisoners of war, within-theater refugees, and military personnel, other PTSD patients experience a single trauma, such as people who develop PTSD after a natural disaster or terrorist attack. For the latter situation, the CVS model may not properly mimic the human experience. The single prolonged stress (SPS) model, developed by Liberzon and colleagues in the late 1990s (Liberzon et al., 1997) exposes the rodent to a single stressor followed by a period of rest before assessing the rodent's responses. SPS has been accepted as a valid model because it elicits neuroendocrine changes similar to those observed in PTSD patients (reviewed in Yamamoto et al., 2009). SPS consists of a quick succession of restraint, swim, and loss of consciousness stressors, followed by a week of rest period prior to further testing. This delay period is thought to function as the duration criterion for PTSD inasmuch as it allows for the separation of adaptive versus pathological responses to trauma (Yamamoto et al., 2009).

DIFFERENTIAL PATHWAYS TO PTSD

The discrepancy in prevalence rates of trauma exposure and PTSD suggests resiliency in the majority of individuals, indicating the presence of “risk factors” that increase vulnerability in those who develop PTSD in the aftermath of trauma (Fig. 49.4). These factors can be environmental, such as early life stress during development (Heim and Nemeroff, 2001), as well as genetic, as shown by several recent gene-by-environment interaction studies (Binder et al., 2008). It should be noted that there are also “resilience factors” that reduce the likelihood of PTSD, even after severe trauma exposure; these include environmental factors, such as social support (Charney, 2004) and genetic factors (Binder et al., 2008).

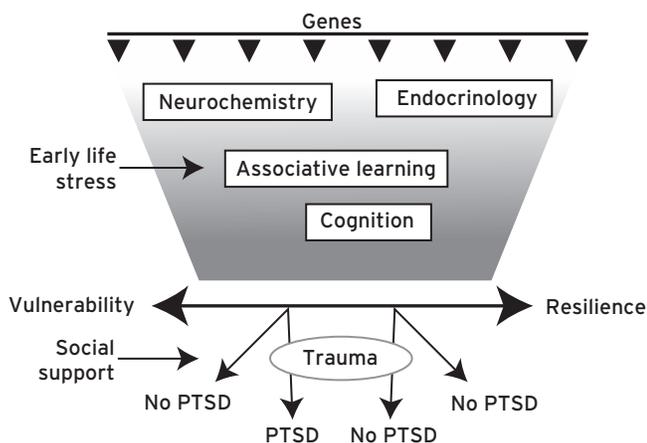

Figure 49.4 Interaction of genetics, biology, and environment in regulating vulnerability versus resilience following trauma.

DEVELOPMENTAL TRAUMA—CHILD ABUSE AND MALTREATMENT

The impact of early adverse events on mental health has been established for more than a decade: early-life stress (ELS) is a predictor of adult depression, while ELS and adult trauma are both predictors of PTSD (Nemeroff et al., 2006). A rodent model of ELS in which neonates were repeatedly separated from their mothers found long-term effects on the hypothalamic-pituitary-adrenal (HPA) axis (Plotsky and Meaney, 1993). Similarly, women who were abused in childhood show increased HPA reactivity to a psychosocial stressor (Heim and Nemeroff, 2001). The hormones of the HPA axis, including corticotrophin-releasing hormone (CRH), can have anxiogenic effects and are some of the most replicated neuroendocrine alterations found in PTSD.

Childhood abuse and maltreatment can have especially pervasive negative psychiatric outcomes. Chen and colleagues (2010) reviewed the prevalence of lifetime diagnosis of psychiatric disorders and sexual abuse and reported a significant association of childhood sexual abuse with later PTSD even after controlling for factors such as socioeconomic status, relationship to the abuser, and number of abuse episodes. Maltreatment before the age of 12, including physical abuse and neglect, produces significant increases in adulthood diagnosis of PTSD (Gilbert et al., 2009). With rates of child abuse ranging from 4–35% in high-income countries such as the United States and the United Kingdom, the persistent effects manifested in PTSD and other psychiatric illnesses create a long-lasting public health burden (Gilbert et al., 2009). Further, as discussed later in this chapter, childhood abuse interacts with genetic vulnerabilities to increase the severity of PTSD symptoms.

GENETIC VULNERABILITY

Although twin data support the importance of genetic inheritance in vulnerability to PTSD (Koenen et al., 2003), there are few studies that have found main effects of candidate gene(s) related to PTSD. This dearth of studies arises from the complexity of the phenotype, the difficulty of defining groups with comparable traumatic exposure, and the high comorbidity with other psychiatric disorders (Nemeroff et al., 2006). However, the fact that a majority of individuals experience a trauma in their lifetime but only a subset develop PTSD is suggestive of a strong genetic component. Identifying these genetic risk factors for PTSD may provide future avenues to personalize treatment in vulnerable individuals with recent exposure to trauma. Next we describe a number of candidate genes, identified to date, with the most robust effects on PTSD.

FKBP5

FKBP5 is a cochaperone protein that interacts with hsp90 and regulates glucocorticoid receptor (GR) sensitivity. Binder and colleagues (2008) identified several single-nucleotide polymorphisms (SNPs) within the *FKBP5* gene (rs9296158, rs3800373, rs1360780, rs9470080) that were linked to adult PTSD symptoms in patients with a history of child abuse. In the largest candidate gene study of PTSD at that time, this group has shown a gene \times environment (G \times E) effect of the polymorphisms in

FKBP5 with a history of childhood maltreatment to predict level of adult PTSD symptoms in a traumatized civilian sample (Binder et al., 2008). There have been several replications of this finding since its initial description. Notably, no main effects were found for the *FKBP5* genotype directly associating with PTSD symptoms, nor was there an effect of the gene interacting with adult trauma levels. These data suggest that the interaction of trauma, perhaps during a developmental critical period, with the HPA-stress related genes increases vulnerability for PTSD.

CRHR1

The corticotropin-releasing hormone receptor (CRHR1) is also a part of the GR system and involved in HPA axis regulation. A polymorphism in the *CRHR1* gene has been linked to PTSD associated with child abuse (Amstadter et al., 2011). CRHR1 polymorphisms have also been recognized as a risk factor for depressive symptoms in adults with a history of child abuse (Bradley et al., 2008). CRHR1 polymorphisms as a risk factor for both PTSD and depression symptoms suggest that the *CRHR1* gene plays a role in a PTSD depression phenotype.

5HTTLPR

The serotonin transporter gene's promoter region has a polymorphism that results in short and long alleles. In one of the greatest breakthroughs in psychiatry in the last decade that illustrates gene-environment interactions, Caspi and colleagues (2003) reported that 5HTTLPR is associated with symptoms of depression but only in stressed individuals. This early G × E discovery fueled investigations of the same polymorphism with PTSD. Kilpatrick and colleagues (2007) identified a G × E interaction predictive of PTSD in an analysis of individuals exposed to 2004 hurricanes in South Florida. As part of this same hurricane study, it was also reported that the short allele of the 5-HTTLPR polymorphism was associated with decreased risk of PTSD in low-risk environments but increased risk of PTSD in high-risk environments (Amstadter et al., 2009), suggesting that social environment modifies the effect of 5-HTTLPR genotype on PTSD risk. Several groups have now identified that individuals who are homozygous for the short allele are more likely to develop PTSD (Mercer et al., 2012) and are less likely to respond to PTSD treatment (Bryant et al., 2010). This gene also remains of interest because the serotonin transporter is the site of action for a class of compounds used to treat PTSD patients' symptoms, as discussed later in this chapter.

COMT

A functional polymorphism of the gene coding for catechol-*O*-methyltransferase (COMT), an enzyme that catalyzes the breakdown of norepinephrine and dopamine, in which valine (Val) has been substituted by methionine (Met) at codon 158, is associated with lower enzyme activity. *COMT* is primarily expressed in the prefrontal cortex and hippocampus (Matsumoto et al., 2003) and represents the principal synaptic dopamine-clearing mechanism in these brain regions. Recent work has implicated the *COMT* Val¹⁵⁸Met polymorphism in the development of PTSD following repeated traumatic exposure (Kolassa et al., 2010).

PACAP

Pituitary adenylate cyclase-activating polypeptide (PACAP) coordinates normal physiological stress reactions. PACAP and corticotrophin-releasing hormone work together in limbic brain areas to modulate anxiety-like behavior (Hammack et al., 2010). We have recently shown that blood levels of PACAP and a SNP within its PAC1 receptor (PAC1R) may be critical mediators of response to psychological trauma. The *PAC1R* gene has an SNP (rs2267735) in its putative estrogen response element that is predictive of PTSD (Ressler et al., 2011). Specifically this SNP appears to be a risk factor in females but not males. This sex effect is particularly interesting because females are more likely to develop PTSD (Kessler et al., 1995). So while the *PACAP receptor* is not the only gene identified to have a PTSD risk SNP, it may be an important factor in the development of the disorder in females.

NEUROBIOLOGY OF PTSD FROM HUMAN NEUROIMAGING STUDIES

The last two decades of neuroimaging work have pointed to a functional neurocircuitry of PTSD that highly overlaps with the neuroanatomical substrates of fear described in animal studies. The primary neuroimaging techniques used in humans have been magnetic resonance imaging (MRI) and positron emission tomography (PET). A number of areas have been implicated in PTSD; however, the sections that follow highlight the most replicated findings, focusing on the hippocampus, amygdala, medial prefrontal cortex, and insula. Although the early studies of brain structure and function were limited with regard to spatial resolution, recent advances in imaging methodology have allowed for more fine-grained analyses of subcomponents of these areas.

HIPPOCAMPUS

The hippocampus plays an integral role in memory formation and context conditioning (see Fig. 49.5). In one of the earliest neuroimaging studies in PTSD, Bremner and colleagues, taking advantage of both the clear anatomical boundaries of the hippocampus in MRI and the known deficits in memory associated with PTSD (reviewed in Bremner et al., 2008), compared hippocampal volume between the Vietnam combat veterans with PTSD and healthy controls. There was a significant reduction of 8% in the right hippocampus, a rather surprising finding in a functional psychiatric disease as opposed to an organic disease (e.g., neurodegenerative disease like Alzheimer's disease). To ensure the effect was not specific to combat-related PTSD, it was also shown that the effects were replicated in PTSD patients with a history of childhood sexual and physical abuse, who demonstrated a 12% reduction in the volume of the left hippocampus (Bremner et al., 2008). However, around the same time De Bellis and colleagues (1999) examined maltreated children with PTSD using MRI and found a reduction in overall cerebral volume in PTSD compared with matched controls, but they did not find hippocampal volume differences after correcting for overall brain volume. Nevertheless, to date

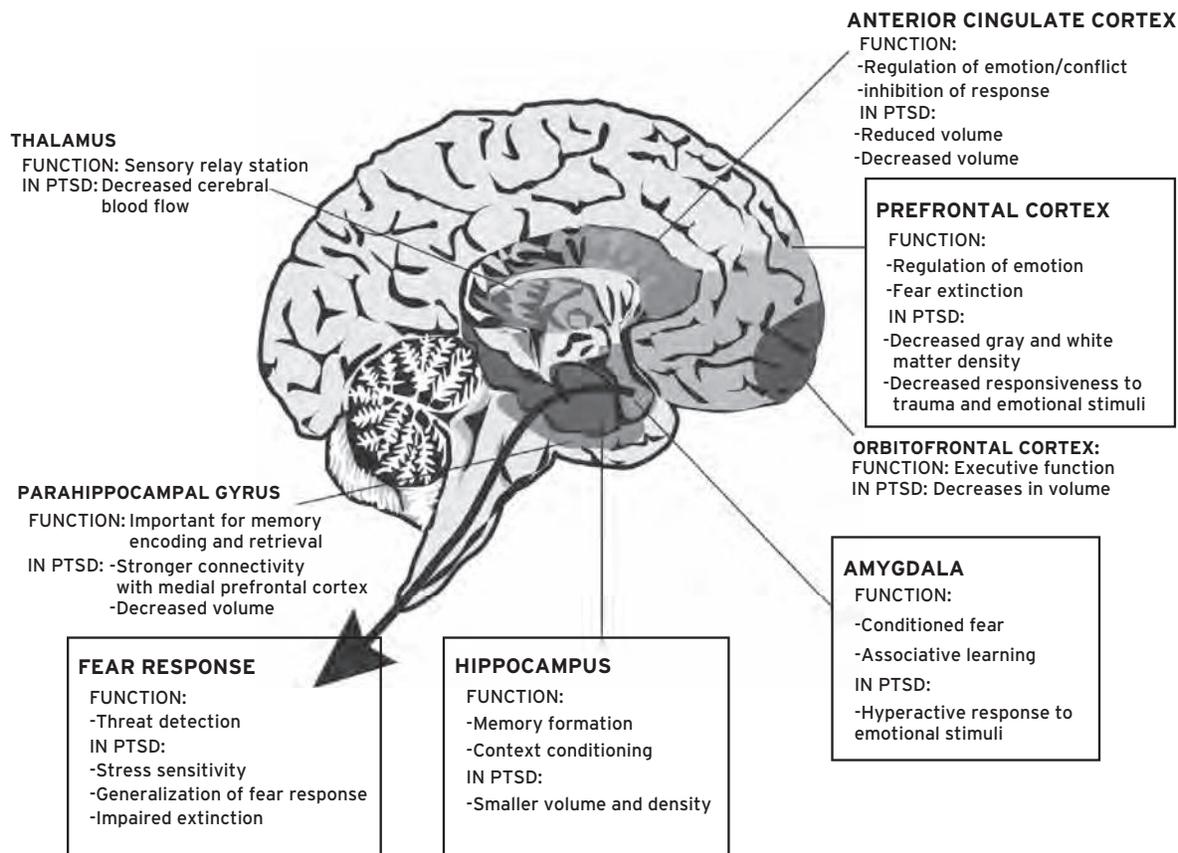

Figure 49.5 Structure and function of brain regions differentially involved in PTSD. Brain regions with the most up-to-date evidence to support their role in PTSD are highlighted, along with their presumptive roles, supported by preclinical and clinical studies in fear regulation. (Adapted from Mahan and Ressler, 2012.)

reduced hippocampal volume has been one of the most widely replicated findings in adult PTSD patients relative to trauma controls and healthy controls (Woon et al., 2010). Recent studies using higher resolution imaging techniques have indicated that reductions in specific subregions of the hippocampus, such as the cornu ammonis 3 (CA3) and dentate gyrus, are associated with PTSD (Wang et al., 2010). A question of particular interest, and source of some controversy, has been delineating whether a smaller hippocampus is a predisposing factor for developing PTSD, or induced by the stress of trauma exposure and PTSD. The strongest evidence for the former is a twin study by Pitman and colleagues showing reduced hippocampal volume in PTSD patients as well as their monozygotic twins who were unexposed to trauma (Gilbertson et al., 2002). Evidence for the latter, beyond the work in children, comes from a longitudinal study that found decreased gray matter density in the hippocampus using voxel-based morphometry in response to stressful life events (Papagni et al., 2011).

PTSD is also associated with alterations in hippocampal function. The first study to show deficits in hippocampal blood flow/activation in PTSD patients was conducted by Bremner and colleagues (2008), using personalized trauma scripts during PET imaging in women with childhood sexual abuse. Interestingly, and in partial contradiction (with notable differences in experimental and imaging setups) to Bremner's work, Shin and colleagues (2006) observed an increase in left

hippocampal activity using an fMRI emotional stroop paradigm with combat-related words in PTSD patients compared with controls. However, again using PET, Bremner and colleagues (2008) showed that healthy controls had increased blood flow to the left hippocampus compared with PTSD patients during a declarative working memory task. A recent review of functional neuroimaging in PTSD concluded that the relationship between PTSD symptoms and hippocampal activation may be dependent on the type of task employed (Hughes and Shin, 2011).

AMYGDALA

Based on the extensive work in animal models, the amygdala is known to play a central role in regulating fear responses to threatening and emotional stimuli (Davis, 1992). This area in the limbic system is also activated in humans in response to emotional cues (Phan et al., 2002). Unlike studies of the hippocampus, studies investigating amygdala volume in PTSD patients have no evidence of volume differences in the amygdala; however, the results show significant lateralization asymmetry (Woon and Hedges, 2009). In a final note on amygdala volume, at least one study showed bilateral volume reduction in PTSD patients who were part of the Tokyo subway attacks when compared with those survivors who did not develop PTSD (Rogers et al., 2009).

The strongest evidence for the role of the amygdala in PTSD comes from functional neuroimaging studies. As early as 1996, Rauch and colleagues (1996) used PET imaging to show that the right amygdala was more active in PTSD patients during a traumatic script-driven imagery condition compared with a neutral condition. Studies using fMRI have also found hyperactivation in the amygdala in PTSD patients compared with controls using emotionally salient stimuli such as fearful faces (Phan et al., 2002; Shin et al., 2006). Focusing on temporal dynamics, Protopopescu and colleagues (2005) analyzed early and late epochs of fMRI blood oxygen level-dependent (BOLD) responses, suggesting that the time course of the amygdala response is also altered in PTSD. Specifically, the study found greater initial amygdala reactivity to trauma-related words in PTSD patients compared with other words. Furthermore, PTSD patients did not show normal sensitization and habituation patterns of amygdala responses over repeated presentations of stimuli throughout the MRI session. Similar results were found by Shin and colleagues (2006) with regard to happy, fearful, and neutral faces.

The final line of evidence for the amygdala's involvement in PTSD comes from surgical case reports. For example, Adami and colleagues (2006) reported a case of a left amygdala-hippocampectomy in an epileptic patient with a history of childhood sexual abuse, but no PTSD. Two weeks after surgery, the patient manifested PTSD symptoms, suggesting a potential importance of the structural integrity of these regions for resilience to trauma. Similarly, Smith and colleagues (2008) reported on a patient who developed PTSD after a motor vehicle accident that occurred two years after having the left amygdala removed. Taken together, these studies strongly suggest that the amygdala is one of the crucial neuroanatomical areas involved in PTSD, and that patients exhibit exaggerated amygdala activity in response to emotional cues and trauma reminders.

MEDIAL PREFRONTAL CORTEX

The prefrontal cortex (PFC) has long been thought to play a role in behavioral inhibition. More than a decade ago, animal studies reported that lesions of the medial PFC (mPFC) prior to original fear conditioning retard extinction to a tone (Morgan et al., 1993). The prefrontal cortex can be subdivided into medial and orbitofrontal PFC. The anterior cingulate cortex (ACC), also referred to frequently as Brodmann areas 24 and 32, is part of the PFC and has both rostral and dorsal components. Brain development studies of healthy children and adolescents have indicated robust changes in gray and white matter in the prefrontal cortex, with gray matter decreasing and white matter increasing in volume from ages 9–18 (Giedd and Rapoport, 2010). A volumetric study that stratified PTSD and control subjects by sex demonstrated significant sex-by-group effects, with smaller cerebral volumes and corpus callosum in PTSD males (De Bellis and Keshavan, 2003). Using both volumetric and voxel-based morphometry (VBM) methods, Carrion and colleagues (2008) showed an increase in PFC volume and gray matter density in adolescents with PTSD. A number of studies to date have found reduction in gray matter volume and density in the ACC related to PTSD (Sekiguchi et al., 2012).

While the orbitofrontal cortex has more recently gained a lot of attention with regard to PTSD, some of the earliest evidence of its functional involvement was shown in the study by Rauch and colleagues (1996). Using PET during traumatic script-driven imagery, this study showed that combat veterans with PTSD demonstrate increased activation in the OFC and the ACC. Shin and colleagues (2006) found reduced medial PFC activity in PTSD patients compared with controls using different paradigms and trauma populations during PET imaging.

Several neuroimaging studies have used different paradigms that specifically activate the PFC; the simplest and most commonly used tasks involve response inhibition. Such tasks have been used in subjects with PTSD using fMRI measures (Carrion et al., 2008). This task reliably indicates decreased activation in PTSD subjects compared with controls in the rostral ACC, located at the genu of the corpus callosum. A recent meta-analysis of imaging studies during emotion processing in PTSD, social anxiety, and specific phobia indicated that the rostral ACC is less active in PTSD patients relative to controls, an effect not found in other anxiety disorders (Etkin and Wager, 2007). Studies that have examined functional connectivity between the PFC and the amygdala have demonstrated impaired inhibition of the amygdala in PTSD (Lanius et al., 2004). Finally, larger rostral ACC volume was found to predict positive outcomes to cognitive-behavior therapy for PTSD (Bryant et al., 2008).

INSULA

Located at the junction of the frontal and temporal lobes the insular cortex (Brodmann area 13) is another prominent cortical area associated with PTSD. This structure is involved in interoceptive stimuli and has been linked to processing of painful or noxious sensations (Critchley et al., 2004). Structural changes in the insula have been largely understudied but highly consistent in demonstrating decreased volume and gray matter density in PTSD patients compared with controls (Chen et al., 2006).

The early PET studies using script-driven imagery showed increased activation in the right insular cortex in PTSD patients when listening to traumatic scripts compared with neutral scripts (Rauch et al., 1996). Recent functional studies using various paradigms with emotional stimuli have found mixed results: some have found increased insula activation in PTSD compared with controls (Hopper et al., 2007), while others have found the inverse relationship (Bremner et al., 2008). Some of the discrepancies may be due to the type of stimuli used; in particular, studies that have used sensation-related cues have found increased insula activation in PTSD. For example, in a study of the role in olfaction in PTSD, Vermetten et al. (2007) showed that the smell of diesel fumes and hydrogen sulfide significantly increased insula activation in the PTSD patients compared with controls. Similarly, a recent study of neural correlates of painful stimulation found that women with PTSD resulting from domestic violence had increased insula activation (Strigo et al., 2010). Increased insula activation seems to be somewhat specific to PTSD; an fMRI study of script-driven imagery found that PTSD patients without

comorbid depression showed this increase, which patients with both disorders did not (Lanius et al., 2007).

TREATMENT OF PTSD

PTSD is a heterogeneous and highly disabling mental disorder that requires the tailoring of treatment strategies according to the needs of each patient. Future treatment strategies for PTSD may be governed by a shift toward personalized medicine based on an individual's environmental risk factors, genotypes, or gene expression patterns. As outlined earlier, the identification of potential genetic variants that increase susceptibility for developing psychiatric illness would be a particularly important tool for advancing treatment options for PTSD and related anxiety disorders. Current treatment regimens typically involve the combination of psychotherapy and pharmacotherapy (Friedman, 2006). Figure 49.6 shows a flowchart of treatment strategies for PTSD.

PSYCHOTHERAPEUTIC APPROACHES

The first-line, nonpharmacological treatment approach for PTSD has traditionally been psychological treatments including psychoeducation, individual psychotherapy, and group psychotherapy (Friedman, 2006). Psychoeducation, which is not intended to be a stand-alone intervention, is designed to provide a patient with information regarding the nature and course of PTSD to a traumatized individual presenting with

PTSD-related symptoms (Friedman, 2006). Individual psychotherapy is aimed at specific PTSD symptom clusters and includes cognitive behavioral therapy (CBT) techniques such as prolonged exposure (PE) (Rothbaum et al., 2000) and cognitive processing therapy (CPT). Of these, only exposure-based psychotherapy has met criteria for evidence-based treatment by the Institute of Medicine in 2008.

COGNITIVE BEHAVIOR THERAPY

The primary purpose of CBT is to deconstruct the PTSD-related aberrant thinking patterns that underlie avoidance. Effective PE techniques include imaginal and *in vivo* exposure to stimuli that are related to the traumatic event and a patient's memories of this event (Rothbaum et al., 2000). Imaginal exposure therapy requires the patient to narrate his or her traumatic experience during weekly sessions that continue for 8–10 weeks. An important step in imaginal exposure is for the patient to face contexts directly related to his or her traumatic experience during *in vivo* contact.

EXPOSURE THERAPY

Prolonged exposure therapy, which is based on the learning principles of fear extinction, requires repeated exposure to cues associated with the traumatic event within a safe, therapeutic context (Rothbaum et al., 2000). This repeated exposure might

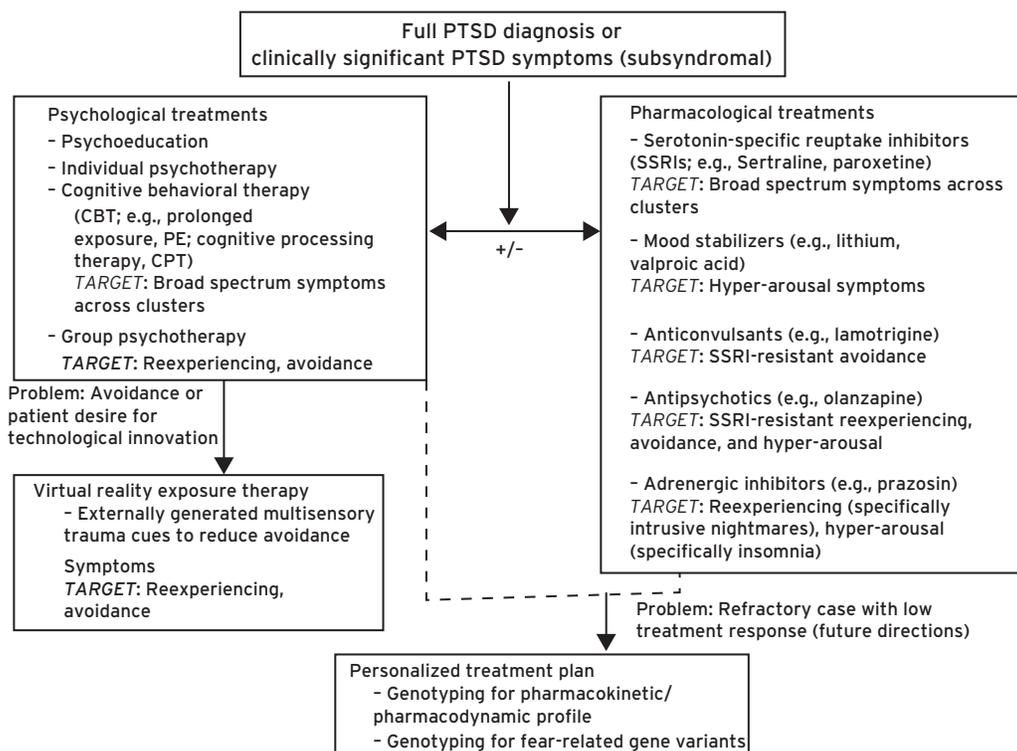

Figure 49.6 Treatment options for posttraumatic stress disorder (PTSD). Current PTSD treatment options include both psychological treatments (including CBT, exposure therapy, virtual reality exposure therapy, and other forms of individual and group talk therapy) and pharmacological (primarily SSRIs, mood stabilizers, and adrenergic blockers). (Adapted from Norrholm and Jovanovic, 2010.)

take the form of recorded self-narrations of the traumatic event coupled with cognitive measures to reduce the fear responses (anxiety symptoms) associated with the reminders. Exposure therapy is thought to rely on the same learning-based neural processes that underlie extinction learning as outlined previously (Fig. 49.3). Recent work has focused on the use of virtual reality exposure (VRE) therapy to treat combat-related PTSD (Gerardi et al., 2008). With this type of treatment, veterans are exposed to a virtual combat scenario (e.g., Iraq, Afghanistan) that includes cues such as explosions, insurgents, improvised explosive devices (IEDs), darkness, smoke, and low-flying aircraft. This type of therapy provides direct exposure to the feared stimuli, but without the negative outcomes experienced in combat. The novel approach of VRE represents an innovative alternative to traditional prolonged exposure methodologies.

PHARMACOLOGICAL APPROACHES

Many of the pharmacological studies that have informed drug treatments for PTSD have significant limitations including small sample size and reduced power, a lack of double-blinding and randomization, and inconsistent dosing regimens (Choi et al., 2010). In fact, a recent Institute of Medicine of the National Academies report concluded that there was insufficient evidence to support efficacy of pharmacological treatment for PTSD. In spite of these limitations, several classes of drugs have been used in the treatment of symptoms of this disorder. Multiple drug classes, including antipsychotics, anticonvulsants, adrenergic-inhibitors, opioids, and benzodiazepines, were rated according to the empirical support behind their therapeutic value for treating PTSD (Choi et al., 2010).

The first-line approach for pharmacological interventions for PTSD is antidepressants such as selective serotonin reuptake inhibitors (SSRIs; e.g., sertraline) and serotonin-norepinephrine reuptake inhibitors (SNRIs; e.g., venlafaxine) (Ravindran and Stein, 2010). Prescription drug treatments for PTSD target specific symptoms as required by clinical need. For example, antidepressants aid in elevating general mood and anxiety (and treating comorbid depression) whereas anticonvulsants, antipsychotics, anxiolytics, and adrenergic inhibitors may be used to treat specific symptoms such as irritability, intrusive thoughts, and insomnia (Ravindran and Stein, 2010).

Novel pharmacological approaches that enhance fear extinction are currently being evaluated for treatment efficacy in PTSD. The use of D-cycloserine (DCS), a partial N-methyl-D-aspartate (NMDA) receptor agonist, as a potential treatment for PTSD arose as a result of numerous preclinical studies implicating NMDA glutamate receptor activity in learning and memory processes. DCS has recently been investigated in combination with VRE therapy for the fear of heights (Ressler et al., 2004) along with a number of other fear-related disorders. After treatment, those patients that received DCS in combination with VRE showed greater improvement compared with those who received placebo and VRE. DCS is currently being investigated as adjunct to exposure therapy in panic disorder, social anxiety disorder, OCD, and PTSD. Additionally, other methods of augmenting NMDA receptor activity in conjunction with extinction are now being explored.

Several pharmacological agents are being tested as early-intervention agents in the immediate aftermath of trauma for their potential in preventing PTSD. For example, glucocorticoids such as hydrocortisone were found to reduce PTSD symptoms and traumatic memories when administered in the emergency room (de Quervain and Margraf, 2008). Although this intervention is showing promise, the sample sizes are still too small. Another similarly acting drug, propranolol, which is involved in memory consolidation (Pitman et al., 2002), is being explored for its potential in treating PTSD symptoms, but large-size, controlled studies of this compound are still lacking, so no conclusions can be made. Other approaches hope to target reconsolidation, a period of potential vulnerability of fear memories to disruption, in the “erasure” of specific fear memories after a trauma. Overall, it is hoped that a further understanding of the molecular mechanisms of fear processing and extinction, as outlined in Figure 49.2, will lead to a number of more powerful ways to combine pharmacotherapy with the specific learning processes underlying recovery from fear and resilience.

NEUROBIOLOGICAL TARGETS FOR TREATMENT

There is an emerging body of literature assessing treatment-related structural and functional changes in the neural underpinnings of mental disorders. An early study using SPECT imaging pre- and posttreatment with SSRIs found significant changes in ACC and hippocampus after 12 weeks of treatment (Carey et al., 2004), and a more recent study found similar SSRI treatment effects in the orbitofrontal cortex using PET imaging during script-driven imagery (Fani et al., 2011). SSRIs have also shown efficacy in increasing hippocampus volume in PTSD patients (Vermetten et al., 2003). In a recent study of Iraq and Afghanistan combat soldiers with PTSD who underwent exposure therapy, increased neural activation in the ACC in response to treatment was associated with greater clinical improvement, even in the absence of large changes in PTSD symptoms (Roy et al., 2010). Interestingly, repeated high-frequency transcranial magnetic stimulation over the dorsolateral prefrontal cortex ameliorated PTSD core symptoms beyond sham stimulation or slow frequency stimulation (Cohen et al., 2004). In summary, these studies suggest neuroplasticity in the hippocampus, amygdala, and PFC with the potential for treatment-related modifications in activity (e.g., successfully attenuating amygdala-driven fear responses). Such findings offer great promise for improving available treatments for PTSD.

CONCLUSION

As this chapter details, PTSD is a common psychiatric disorder that has given rise to numerous clinical and animal model studies to understand both the disorder itself and how to treat it. As a disorder that is in part explained by disruption of normal fear regulation, it provides a particularly interesting and exciting intersection of the molecular neurobiology of fear processing that is being rapidly understood in animal models. The convergence of data from such preclinical studies with human

neuroimaging, neurophysiology, and genetic studies in humans is being combined with fear-modification therapies such as exposure therapy in human patients. Future work will build on the knowledge of animal fear studies, including greater understanding of consolidation, reconsolidation, and extinction processes, as well as genetic analyses and human neuroimaging studies to better treat and prevent PTSD in at-risk individuals.

DISCLOSURES

Ms. Murray, Mr. Keifer, Dr. Norrholm and Dr. Jovanovic declare no conflict of interest to disclose.

Dr. Ressler is a founding member of Extinction Pharmaceuticals/Therapade Technologies to develop d-cycloserine, a generically available compound, for use to augment the effectiveness of psychotherapy. He has received no equity or income from this relationship within at least the last 3 years.

This work was supported by NIMH, NIH, Howard Hughes Medical Institute, and the Burroughs Wellcome Fund.

SECTION VI | SUBSTANCE USE DISORDERS

ANTONELLO BONCI AND NORA D. VOLKOW

More than 80 million Americans have experienced use of nicotine and other drugs of abuse at a level that can create potentially harmful effects. This is why substance abuse and addiction represent a massive burden to society. The negative effects on health result from both the direct pharmacological effects of abused drugs and from the ways in which they are self-administered. A perfect example is the use of non-sterile needles, which has been linked to the increased incidence of transmission of HIV as well as of hepatitis B and C. Additional disorders that all too commonly result from drug use range from lung cancer and cirrhosis to the exacerbation of psychiatric disorders. Moreover substance use disorders (SUD) produce significant and long-term modifications in brain function and behavior that can create havoc in the individuals' life and in social systems including the enormous costs from lost educational opportunities, lost productivity, and associated accidents and the legal repercussions from their use. As a result of direct pharmacological effects and illegal drug trafficking, drugs are also a major cause of violence and crime. The nine chapters included in this section provide a comprehensive overview of the state of the art and the most recent discoveries in the many fields of investigations related to SUD, ranging from basic science to the most recent clinical discoveries.

The first chapter of this section (Chapter 50) provides a comprehensive review of the current animal models used to study drug reward and addiction. During the past decade, the field of behavioral neuroscience has produced more and more sophisticated non-human addiction models, which have greatly expanded our understanding of the complex cadre of symptoms that affect substance abusers. These models are particularly important because it is imperative for neuroscientists to understand the complex interactions between neuronal activity and behavioral aspects of addiction such as craving, drug self-administration, and relapse to drug seeking, which are influenced by environmental exposures (i.e., stressors) and genetics. Likewise, our understanding of the cellular and molecular mechanisms that underlie addictive behaviors has made tremendous progress since the last edition of this book, and will be discussed in Chapter 51. For example, it is well accepted now that drugs of abuse produce many forms of long-term memories at the cellular level, and that these cellular memories play a variety of roles in reorganizing the circuits of the brain and in solidifying pathological, addictive behaviors. Chapter 52 will discuss the recent expansion of knowledge on human genetic studies to better understand some of the fundamental questions that shape the very nature of SUD. This new knowledge includes the role of genetics in drug experimentation and addiction, the

mechanisms by which genetics mediate these effects through their modulation of brain development and function, and how this in turn influences response to the environment (i.e., drugs and stress) in ways that enhance susceptibility or support resilience toward SUD. Chapter 53 focuses on the importance of studying SUD during development, including characterizing the features that render the adolescent brain particularly susceptible to substance abuse.

Chapters 54, 55, and 56 provide a comprehensive review of the technological advances in brain imaging (PET, SPECT, fMRI, and spectroscopic imaging studies) and how these have been used to study the effects of drugs in the human brain. Technology has been used to understand the toxic effects of various drug classes, the mechanisms underlying the rewarding effects of drugs, and the neuroadaptations associated with repeated drug exposure that underlie the addictive process. More recently, studies have started to investigate how genes that increase vulnerability to SUD affect the anatomy, connectivity, and function of the human brain and what functional characteristics of the human brain in turn are associated with enhanced vulnerability (i.e., decreased prefrontal function and decreased striatal D2 receptors).

The many fields of neuroscience focused on SUD described above not only inform us on how the various brain regions are affected by drug exposure and natural rewards, but they have also generated novel therapeutic targets to inhibit drug reward to mitigate symptoms of addiction and prevent relapse. These targets and therapies are discussed in Chapter 57, wherein the authors review the complex issue of bringing novel and promising therapeutic targets from the bench to the bedside. Finally, in Chapter 58, Denise Kandel and coauthors will review recent data on the epidemiology of substance use disorders from both comparative and developmental perspectives, including a discussion of adolescence as a particularly vulnerable period for developing SUD.

The challenges facing investigators parallel those faced by researchers in the addiction field over the last 20 years to a degree, but maintain certain distinctions. A remaining challenge is the integration of discovery from the preclinical to the clinical, and then its translation into interventions that can be used to prevent, treat, and revert the adverse effects of drugs to the human brain. Success in animal models will require that these models more comprehensively emulate the complexity of social systems that influence drug taking and the transition to addiction in humans. Such models should also take into account the complex interactions among environment, genes, development, and the pharmacology of the abused

drug, as well as the relevance of studies on different species to human neurobiology. In clinical neuroscience, a new challenge is the standardization of protocols for image acquisition and phenotypic characterization of patients with SUD and their normative that will allow for the integration of imaging and genetic/epigenetic data sets from independent laboratories. Despite these challenges, the opportunities for discovery are greater than they have ever been. The enhanced access to larger

databases, more powerful technologies, and a greater understanding of the molecular, cellular, and functional connectivity of the brain allow us to address neurobiological questions that we would have not been able to do 10 years ago. In parallel, an enhanced awareness of the importance of translating neuroscientific findings into the clinic is likely to accelerate the use of that knowledge for more effective interventions for the prevention and treatment of SUD.

RAFAEL MALDONADO, J. DAVID JENTSCH, BRIGITTE L. KIEFFER, AND
CHRISTOPHER J. EVANS

Drug addiction, or substance use disorder (SUD), is a chronic brain disease characterized by the compulsive use of drugs, loss of control over drug-taking in spite of their adverse consequences, and relapse even after long periods of drug abstinence (Koob and Volkow, 2010; O'Brien et al., 1998). Substance use disorder is considered the result of a series of transitions from voluntary use in search of a hedonic effect, to loss of control over this behavior, and ultimately to compulsive behavior (Everitt et al., 2008). Important in the context of mental illness is the high comorbidity of depressive illness and anxiety with SUD and that drugs of abuse taken acutely often alleviate symptoms of these afflictions, yet during abstinence the symptoms of depression and anxiety are exacerbated. Indeed, SUD is comorbid with many psychiatric diseases (clinically referred to as dual diagnosis), including schizophrenia, where incidence of both cigarette and cannabinoid smoking is exceptionally high (Santucci, 2012). In current research of SUD, animal models recapitulate the phenotypes contributing to abuse susceptibility through initial drug taking, habitual drug taking, abstinence, and finally relapse (Fig. 50.1). These models have begun to unravel the molecular, cellular, and behavioral adaptations regulating addictive behaviors in research, which has greatly enriched our understanding of the neurocircuitry mediating learning, motivation, mood, and stress (Koob and Volkow, 2010; Russo et al., 2010). This chapter systematically explores animal models that contribute insights to the addiction cycle as outlined in Figure 50.1. We first cover models assessing reward-related and reinforcement behaviors. We follow this with descriptions of models for abstinence and relapse, and new genetic models that increasingly are facilitating addiction research. Finally, we discuss animal model contributions to susceptibility for initiating addictive behaviors.

Maladaptive patterns of reward-seeking and -taking involving natural rewards have been reported to share similarities with those observed in drug addicts. Animal models have revealed that natural rewards activate the mesocorticolimbic system, which mediates the hedonic and motivational aspects of different rewarding stimuli in a manner very similar to drugs of abuse. Repeated activation of this reward pathway leads to neuroadaptive changes that are involved in the progressive behavioral changes caused by natural rewards and drugs. Similar structural plasticity changes in the mesocorticolimbic system have recently been reported after repeated exposure to natural rewards, such as highly caloric food (Johnson and Kenny,

2010), palatable food (Guegan et al., 2012), or sex (Pitchers et al., 2010), all of which can drive the development of compulsive behavior. The similarities and differences among the behavioral disorders promoted by drugs and natural rewards represent a complex and fascinating topic that has been investigated in animal models. Although this area is out of the scope of this chapter, it has been reviewed elsewhere (Olsen, 2011).

MODELS OF REWARD AND REINFORCEMENT

Animal models of reward and reinforcement are the fundamental tools for substance abuse research. Drug consumption is promoted and maintained by the rewarding and reinforcing properties of the drug. These rewarding effects play a crucial role in the initiation of the addictive processes (Koob and Le Moal, 2008). However, it is important to note that although drug consumption is a requirement for the development of addiction, drug intake does not necessarily induce an addicted state. In fact, addiction is defined as a chronic relapsing mental disease and is difficult to comprehensively mimic with the animal models currently available. Most of the animal models described in this chapter have been designed for evaluating particular properties of drugs leading to the development of this disease (reward/reinforcing properties) or some specific manifestations of the disease (tolerance, withdrawal, or relapse).

Animal models for reward and reinforcement use either investigator administration of drug (non-contingent), or self-administration of drug (contingent) in which drug taking is under the control of the animal (Fig. 50.2). Contingent or non-contingent administration paradigms can elicit different behavioral responses that can be reflected at the level of neuronal adaptations. The analysis of drug-induced changes in dendritic spine density and dendritic branching that controls inter-neuronal communication is one example in which differential adaptations in multiple brain regions depend on whether the drug is given contingently or non-contingently (Robinson and Kolb, 2004). Human addictions are most effectively recapitulated in contingent models. However, the value of non-contingent models should not be discounted because they can provide information on adaptations that occur only because of the presence of the drug as well as insight into a subset of reward-related behaviors using uncomplicated drug administration procedures.

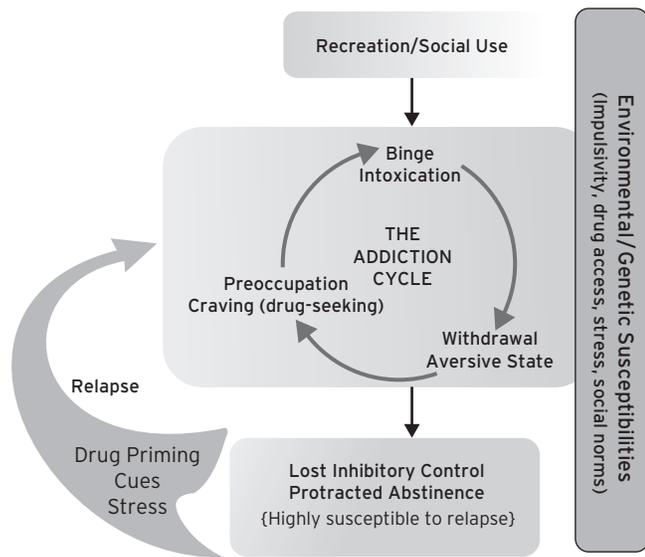

Figure 50.1 Addiction cycle. In addicted individuals, recreational drug use switches to compulsive drug intake. The addiction cycle typically includes intoxication/withdrawal/craving episodes (Koob and Volkow, 2010). Exiting the cycle requires maintenance of abstinence. Drug abstinence is characterized by a negative affect that strongly contributes to relapse and is often triggered by drug cues, the drug itself, or stress. All aspects of the cycle are subject to modification by genetic–environment interactions.

All animal models measuring reinforcement and reward require learning. Some acute models of drug administration engage only goal-directed learning, whereas others engage habit learning after extensive repetition of drug administration paradigms. Animal studies in recent years have identified different

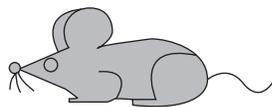

brain circuitry mediating goal-directed and habit learning with circuitry between the medial prefrontal cortex and dorso-medial striatum mediating goal-directed learning and the sensory-motor cortex to the dorsolateral striatum mediating habit learning (Balleine and O’Doherty, 2010). Reinforcement assays require instrumental actions to obtain the reward, and a learning curve is necessary to develop the instrumental association between an action (e.g., lever push, nose poke, or eye movement) and its contingent effect. Reinforcement can be demonstrated by an increase in responding to a rewarding stimulus (positive reinforcement) or responding to avoid or delay an aversive stimulus (negative reinforcement), and animals will clearly work for both. Models of drug self-administration may not readily distinguish between these two motivational states given that the cycle of addiction includes a dysphoric phase as a consequence of absence of the drug (see Fig. 50.1). Furthermore, certain intrinsic aspects of the models may be aversive (e.g., the anxiety of a novel environment or surgery for catheterization) and the drug may relieve these aversive components as a result of anxiolytic, analgesic, or dissociative properties. Modeling the relief of an aversive stimulus has important implications for certain aspects of human behavior in which amelioration of pain, depression, or anxiety favor drug use. However, the circuitry recruited for euphoric reward will undoubtedly differ from the circuitry recruited to obfuscate an aversive stimulus (Koob and Volkow, 2010).

SELF-ADMINISTRATION

Self-administration methods are considered the most reliable and predictive animal models to directly evaluate the

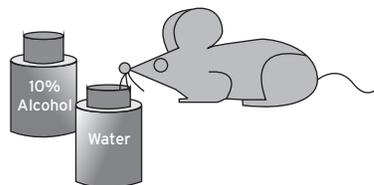

Investigator-administered (non-contingent)

Drug delivery
(via injection, oral [gavage], vapor)

Non-operant choice (contingent)

Drug delivery
(foods/liquids/alcohol)

Operant self-administration (contingent)

drug delivery (injection, oral)

reinforcing properties of a drug. These procedures mimic drug-taking behavior in humans and are widely used by many researchers. The neurobiological mechanisms involved in drug self-administration in animals are assumed to be similar to those underlying drug intake in humans (Maldonado et al., 2011). Operant and non-operant procedures can be used in these self-administration models. Non-operant paradigms involve the consumption of a freely available drug, are centered on the amount of drug consumed, and are restricted in rodents to oral self-administration. These non-operant methods are widely used to study alcohol-rewarding effects, and they have also been used less frequently with other drugs of abuse, such as nicotine, cocaine, amphetamine, and morphine (Sanchis-Segura and Spanagel, 2006). Oral ethanol non-operant self-administration procedures present high reliability and predictive value as models of human alcohol consumption. Indeed, rodents drink alcohol when using the oral route, whereas they hardly consume this drug through other routes of self-administration (Sanchis-Segura and Spanagel, 2006; Spanagel and Zieglgansberger, 1997). In contrast, rodents show only modest motivation to self-administer other drugs by the oral route, including opioids or psychostimulants (Meisch, 2001), and very specific and sometimes biased procedures are required to induce their oral consumption. Therefore, the behavioral responses evaluated in those particular situations do not necessarily reflect the rewarding properties of these drugs. In the most currently used oral alcohol self-administration procedures, rodents have simultaneous access to two bottles, one containing an aqueous alcohol solution and another containing water (Spanagel and Zieglgansberger, 1997). The consumption of alcohol in these paradigms is greatly influenced by the genetic background and animal species used. The alcohol concentration represents another critical factor that can even bias the outcome because low concentrations may have a mild-sweet taste, whereas overly high concentrations have an aversive flavor (Sanchis-Segura and Spanagel, 2006). Other critical factors in these paradigms are the temporal accessibility to alcohol (Vengeliene et al., 2012), and the kind and number of available bottles and/or other reinforcers (Tordoff and Bachmanov, 2003). In general, alcohol consumption increases when rodents are given restricted access to the drug (e.g., every other day) or a higher number of alternative alcohol solutions are presented.

Operant paradigms require that the animal performs an instrumental response to self-administer the drug. In these models, the animal learns to maintain a behavioral response, typically by pressing a lever or nose poking in a hole, to obtain a positive reinforcer (drug delivery) that is delivered contingently after completion of the schedule requirement (Maldonado et al., 2011). The operant chamber levers and nose poking holes also transmit operant response. The response in the active manipulandum is linked to the delivery of the drug, whereas the response in the inactive manipulandum results in the delivery of the drug vehicle or lacks any programmed consequence. These operant procedures are considered by most researchers to be reliable models of

drug consumption in humans with a high predictive value. The route of administration most commonly used in these operant procedures is intravenous delivery of all the prototypical drugs with the exception of alcohol, which usually requires the delivery of an oral solution. However, these operant procedures are not specifically associated with any route of administration, and multiple additional routes have been successfully used, such as intracranial, intraventricular, or intragastric delivery.

Different single and complex schedule requirements to obtain the reinforcer can be programmed in these operant paradigms. The schedules most frequently used are the fixed ratio and progressive ratio schedule of reinforcement programs. Under a fixed ratio schedule, the drug is delivered each time a preselected number of responses are completed in the active manipulandum. Under the progressive ratio schedule, the response requirement to deliver the drug escalates according to an arithmetic progression. The common index of performance evaluated in this last schedule is the highest number of responses that the animal accomplishes to obtain a single infusion of drug (the break point), which provides information about its motivation for the drug. The analysis of this instrumental response provides valuable data about different behavioral aspects of drug consumption. After acquisition of the operant task, the behavioral response can be extinguished by exposing the animals to an additional training in which the reward is no longer available. The operant behavior to seek the drug can be then reinstated by using different stimuli.

Rodents typically maintain an operant behavior to self-administer all the prototypical drugs of abuse, including opioids, psychostimulants, synthetic drugs, nicotine, and cannabinoids (Maldonado et al., 2011). In the case of cannabinoids, rodents self-administer synthetic cannabinoids but not Δ^9 -tetrahydrocannabinol, the main psychoactive component in *Cannabis sativa*, which is only self-administered by monkeys (Tanda et al., 2000). In rodents, these operant self-administration models were first validated in rats, and then adapted to mice. Reliable operant models of acquisition and relapse of morphine, cocaine, ecstasy, alcohol, nicotine, and synthetic cannabinoids self-administration are also now available in mice (Martin-Garcia et al., 2009; Mendizabal et al., 2006; Soria et al., 2008). Application of these new models to the different lines of genetically modified mice will yield more insights in the future.

CONDITIONED PLACE PREFERENCE

In these paradigms, the subjective effects of a drug are repeatedly paired to a previously neutral stimulus. Through this repeated conditioning process, the neutral stimulus acquires the ability to act as a conditioned stimulus, and the animal will prefer or avoid this conditioned stimulus depending on the rewarding or aversive effects produced by the drug (Fig. 50.3). The most commonly used paradigms apply a spatial environmental stimulus as the conditioned stimulus and the animal will show a conditioned place preference or aversion for the

Conditioned Place Preference

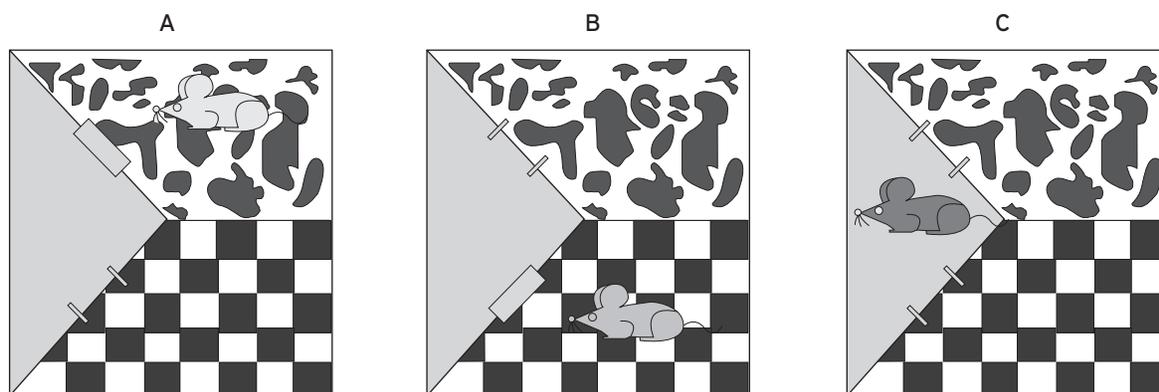

Figure 50.3 (A) Drug administered non-contingently (repeated three to five times on alternate days) and the animal confined to one compartment ("cow pattern" in this example but the side would be a randomized group). (B) Drug vehicle given to the animal confined to the other compartment ("checked pattern") on alternate days from drug. (C) Animal put in the neutral chamber (gray triangle) with access to both the drug- and vehicle-paired compartments.

environment associated with the effects of the drug or its withdrawal. Although a conditioned approach/avoidance toward specific stimuli can also occur in humans as a result of drug consumption (Bardo and Bevins 2000), the place conditioning paradigms are not primarily intended to model any particular feature of human behavior. These paradigms mainly represent an indirect assessment of the rewarding or aversive effects of a drug or its withdrawal, by measuring the response of the animal toward the conditioned stimulus. Drugs of abuse display a differential ability to produce conditioned place preference. Opioids and psychostimulants easily produce robust place preference over a wide range of experimental conditions, whereas other drugs, such as ethanol, cannabinoids, or nicotine, produce more inconsistent results. The caveats of the place preference assay are many, with issues of memory function, circadian rhythm, and that the animals non-contingently receive the drug in a novel environment, which has consequences for eliciting stress. Despite this, conditioned place preference has been an informative and widely utilized behavioral model for understanding parameters that disrupt or enhance the rewarding effects of abused drugs.

INTRACRANIAL SELF-STIMULATION

Intracranial electric self-stimulation (ICSS) procedures were essential in the discovery of the brain reward circuits. These paradigms are now widely used to study the effects of acute and chronic drugs of abuse administration and withdrawal in the activity of the reward circuits (Sanchis-Segura and Spanagel, 2006). In this paradigm, animals are trained to maintain an operant behavior so as to obtain an electric pulse through an electrode that has been previously implanted in a reward-related brain site, most frequently the lateral hypothalamic area. The threshold of the minimal current needed to promote intracranial electric self-stimulation is estimated. A drug that stimulates the reward circuit will decrease this threshold, which is related to its rewarding properties, whereas a drug having aversive effects will enhance the minimal current required to maintain the self-stimulation (Markou and Koob, 1993). The ICSS threshold

increases after prolonged drug administration and during withdrawal. This is interpreted as a desensitized reward system and parallels other behavioral and imaging evidence that SUD can, over time, attenuate the basal functioning of the dopaminergic reward circuitry (Kenny, 2007).

MODELS OF WITHDRAWAL AND RELAPSE

Withdrawal from drugs of abuse can be an important aspect of SUD because withdrawal can promote a state at both the behavioral and cellular level that supports negative reinforcement. Drug withdrawal has multiple phenotypes, including physical symptoms, craving, and the modulation of affect (Koob and Volkow, 2010). Symptoms of acute and protracted withdrawal are sensitizers for relapse and can serve as major drivers for the addiction cycle (see Fig. 50.1). Although the acute physical withdrawal behaviors caused by individual drugs appear very different, the prolonged withdrawal phenotype (negative affect, craving behavior, and vulnerability to stress) begin to emerge as common phenotypes. This is reflected by merging transcript profiles in the extended amygdala, one of the brain regions involved in emotional responses following protracted abstinence of several drugs of abuse (Le Merrer et al., 2012).

PHYSICAL WITHDRAWAL

Depressant drugs such as opioids, alcohol, or benzodiazepines have dramatic acute withdrawal symptoms. In the case of alcohol and benzodiazepines these result in seizures, which can be lethal. In acute withdrawal from opioids, there are a classical set of physical symptoms that can be readily measured in rodents and include jumping, wet dog shakes, weight loss, paw tremors, diarrhea, and piloerection. In the most frequently used model of opioid withdrawal, the symptoms are triggered by administration of an opioid receptor antagonist such as naloxone. Similar antagonist-precipitated withdrawal assays have been used for measures of nicotine and cannabinoid

physical withdrawal, although the symptoms are considerably less robust than opioid withdrawal (Trigo et al., 2010). Cocaine and other psychostimulants do not elicit physical withdrawal symptoms that can be easily measured in animal models or human subjects. This demonstrates that physical withdrawal is not a predicate for addiction.

WITHDRAWAL AND AFFECTIVE STATE/CRAVING

Although many studies have focused on the physical aspects of withdrawal, the affective state and drug craving (the desire to attain the drug state) are aspects that deserve focus, given their role in triggering relapse and modeling the primary mental affliction of SUD. In the case of opioid withdrawal, antagonist precipitation cannot be used to assess changes in affect because antagonists such as naloxone and naltrexone are highly aversive in rodents that have never been exposed to an opioid drug. This aversion in drug-naïve mice has been shown to be caused by a constitutive hedonic tone as a result of proenkephalin-derived opioid peptides activating mu-opioid receptors (Skoubis et al., 2005). Affective state and craving is best modeled in animals simply withdrawn from the drug. Recent studies have assessed animals during both acute and protracted withdrawal. Significantly, although physical signs of withdrawal diminish rapidly and within a few days after opioid withdrawal, some phenotypes strengthen, including social interaction deficits and depressive phenotypes (Goeldner et al., 2011). The strengthening of such behaviors after protracted abstinence is associated with deficits in serotonin and can be reversed with the serotonin membrane transporter blocker fluoxetine. Incubation after acute withdrawal also enhances drug-seeking induced by drug-related stimuli (Weiss, 2010).

RELAPSE

Relapse susceptibility is an extremely persistent and robust phenotype in both humans and animals (Wikler and Pescor, 1970) and can get progressively stronger in response to some triggers during abstinence (Weiss, 2010). Relapse models in animals first require the animal to learn a drug self-administration task, although a place-preference paradigm could also be used. The animal receives extinction training so as to erode the established associations, followed by test sessions in which behavior spontaneously recovers or is reinstated by a drug-related cue, the drug, or stress (Sinha et al., 2011). The use of extinction training is not an optimum method to reduce drug-seeking behavior because it does not accurately recapitulate the human experience and, in fact, changes the underlying neuroadaptations mediating drug-seeking and -taking. However, without extinction, extinguishing drug-seeking may not be practically feasible given the strength and longevity of reward-related behaviors. In humans, relapse happens when the motivation to abstain is overwhelmed by the motivation to take the drug. This stands in contrast to animal models in which the motivation to take the drug overwhelms extinction-related learning. New research should focus on the development of models that emphasize conflict between the motivational states that excite and inhibit drug-taking and the role for cognitive control circuitry in these circumstances.

MODELS OF DRUG ADDICTION

As discussed, the animal models available for evaluating drug reward and reinforcement, as well as withdrawal, have been very useful in clarifying the neurobiological basis of drug taking and specific features of the addictive process. However, addiction is a chronic relapsing disorder characterized by compulsive drug use maintained despite adverse consequences for the user (O'Brien et al., 1998). Behavioral models that resemble the main diagnostic criteria for addiction have only recently been studied using animal models. Two independent research groups have validated behavioral models of compulsive drug-seeking in rodents, resembling addictive behavior in humans (Belin et al., 2008; Deroche-Gamonet et al., 2004; Vanderschuren and Everitt, 2004). These models evaluate the persistence of drug-seeking and -taking in the face of punishment, resistance to extinction, and exaggerated motivation to obtain the drug. In one animal model, the motivation for the drug determined by the break point (the maximal amount of work that the animal performs before cessation of responding) was abnormally high under these conditions. Indeed, a break point greater than 500 operant actions to obtain a single cocaine injection in "addict rats" was reported in these models (Deroche-Gamonet et al., 2004). Although there is significant promise in this area of work, it remains relatively underutilized and studied.

GENETIC ANIMAL MODELS FOR ADDICTION RESEARCH

Multiple studies in humans (family twin and adoption studies) point to a major genetic component in the etiologies of SUD (Ho et al., 2010). Rodent models have been developed to identify genes and pathways related to this disease. Three major approaches are well exemplified in alcohol research (Crabbe, 2008). The first approach has used inbred lines with different SUD propensity. A second approach has used genetic selection for phenotypes related to SUD. A third approach has been the targeted modification of the genome, a strategy that has probably been the most informative in identification of relevant primary targets and reward-dependent mechanisms. What is becoming clear from genetic association analysis in both human and animal subjects is that SUD is an exceptionally complex disorder with multiple genetic contributions that modify susceptibility to different drugs and different aspects of the disorder in selective environments (Ho et al., 2010). This complexity of genetic contribution and interaction with environment makes human analysis an ominous task requiring large cohorts for valid analysis. However, recently the identification of one locus in a cluster of nicotinic receptors, the *CHRNA5-A3-B4* cluster on chromosome 15, has been repeatedly associated with both lung cancer and smoking (Bierut, 2010). Ongoing research is elucidating how this locus modulates disease susceptibility in animal models with genetically down- or up-regulated levels of the nicotinic receptor subunits in this area of the genome (Fowler et al., 2011; Gallego et al., 2012).

During the past decade there has been an explosion of genetically modified mouse models to determine the effects of specific genes on SUD. The endogenous opioid system provides an outstanding example of progress that can be achieved with targeted modification of genome (Le Merrer et al., 2009). The genetic ablation of the mu-opioid receptor (mu knockout mice) eliminates the place preference, self-administration, and analgesic effects of drugs such as morphine and fentanyl. Intriguingly the mu knockouts additionally exhibit diminished or abolished reward-associated behaviors for nicotine, alcohol, and cannabinoids, which do not directly activate opioid receptors. These data are suggestive of the recruitment of the endogenous opioid system for the rewarding experience by several non-opioid drugs. Indeed proenkephalin knockout mice, which lack one of the three precursors of endogenous opioid peptides, exhibit the same reduced-reward phenotype as mu-opioid receptor knockout mice.

Genetically modified mice have also contributed to our understanding of the dark side of addiction. Kappa-opioid receptor knockout mice as well as mice null for the gene encoding kappa-opioid receptor ligands (prodynorphin), both exhibit a phenotype of reduced stress (Bruchas et al., 2010). Mice null for the endogenous kappa-opioid system do not show stress-induced relapse for cocaine and relieve the aversive component of tetrahydrocannabinol in place preference assays (Maldonado et al., 2011). Kappa antagonists are now a major focus for drug development for the treatment of relapse and other stress-related disorders. The era of developing new animal models by genetic modification has not ended and the new era of conditional knockout and knockin models are revealing cell types, circuits, and brain regions involved in selective aspects of SUD. Furthermore, as genetic analysis begins to reveal new genes of interest, such as in the case of the alpha 5 nicotinic receptor for smoking, animal models provide the tools to understand the genetic influence mechanistically and perhaps enlighten therapeutic approaches.

ANIMAL MODELS OF ADDICTION SUSCEPTIBILITY

A variety of biological and environmental factors have been hypothesized to prospectively (causally) influence SUD. These hypothesized relationships can often be studied in a controlled, experimental manner in animal models because of the capacity to selectively manipulate all factors but the one under study and prospectively examine the characteristics of the phenotypic relationship. These procedures overcome the confounds associated with covariation of phenotypes (Lynch et al., 2002) in human subjects as well as the limitations of purely retrospective analyses.

SEX

In many ways, the potential for animal models of vulnerability to drug abuse is best demonstrated by studies of sex effects on drug reinforcement. In most Western societies, the use of licit and illicit substances with addiction liability is more common

in males than females (Lynch et al., 2002). On the other hand, it has been suggested that among those persons who sample the drug, the development of a compulsive, clinically significant form of drug-seeking and -taking occurs more readily in females (Lynch et al., 2002). Because of the absence of social factors that likely inhibit drug sampling in human females, rodent models are useful in interrogating the influence of purely biological dimensions of sex on the phases of drug use, abuse, and dependence that follow initial sampling. Significantly, female rats have been shown, in multiple laboratories and using multiple preparations, to more readily acquire drug self-administration, self-administer larger amounts of drug, to reinstate drug self-administration, and develop inflexible patterns of drug intake (Lynch et al., 2002; Perry and Carroll, 2008). Subsequent studies have revealed the partial contributions of estrogenic hormones to these differences (Lynch et al., 2002), but it remains unknown how genetic aspects of sex contribute to gender differences. These results demonstrate the potential for animal models to reveal important biological predetermining factors, particularly when those factors are sometimes overriden by environmental or psychosocial factors.

BIOBEHAVIORAL PHENOTYPES

Substance use disorders cosegregate with a number of biobehavioral preclinical or clinical phenotypes. One such relationship is the apparent comorbidity between SUD and several mental disorders, including attention deficit/hyperactivity disorder (ADHD) (Groman et al., 2009). Children diagnosed with ADHD are at greater risk for the development of a SUD during their lifetime, particularly if they are not successfully medicated. There are many theories regarding the causal basis of this comorbidity. On one hand, some argue that substance use in the teenage and adult years represents a form of “self-medication” in which patients consume nicotine and/or stimulants because of their ability to remediate inattentive and/or hyperactive symptoms. A different view, however, is that individuals with ADHD are susceptible for substance misuse because they exhibit novelty seeking, behavioral impulsivity, and/or differential reward sensitivity, which independently predispose them for dyscontrolled reward-seeking behaviors (Groman et al., 2009). These and other phenotypes that segregate with SUD may represent predisposing factors that are worthy of causal and biological dissection in animal models.

NOVELTY-SEEKING

Novelty-seeking traits in humans—defined as the propensity to be attracted to environments associated with novelty, sensation, and/or risk—are associated with SUD, and novelty reactivity in rats has been conceptually linked with novelty-seeking in humans (Dellu et al., 1996). One of the earliest demonstrations that traits related to novelty reactivity predict individual differences in response to illicit substances of abuse was that, in outbred rats, the magnitude of the locomotor response evoked by a novel environment positively predicted subsequent acquisition of an instrumental response reinforced by drugs (Piazza et al., 1989). This relationship is present in both

male and female subjects, and is under genetic control in that it can be enriched by breeding for the phenotype. So-called “high responders” (in the novel environment) are therefore more susceptible to the reinforcing effects of stimulants and opiates under some circumstances.

On the other hand, psychomotor reactivity to novelty may only be one dimension of novelty-seeking in humans because the trait is primarily defined as the propensity to seek out and participate in novel and exciting circumstances. With that in mind, it is interesting that individual differences in novelty preference or novelty reinforcement in rats has also been linked to drug self-administration phenotypes in a manner that extends beyond the explanatory value of simple novelty reactivity (Belin et al., 2011), suggesting that the overall relationship is quite complex.

IMPULSIVITY

Novelty-seeking has been conceptually linked to another dimension of temperament often referred to as impulsivity—a tendency to act or react with limited forethought and/or a tendency of one’s behavior to be driven by immediate, rather than delayed, outcomes associated with behavior (Evenden, 1999). High impulsivity is itself a phenotype that segregates with SUD and that likely explains the dysregulated pattern of drug intake in some individuals with drug abuse and dependence (Jentsch and Taylor, 1999). Because of evidence that exposure to drugs of abuse is sufficient to elicit impulsive patterns of responding (Izquierdo and Jentsch, 2012; Jentsch and Taylor, 1999), it was unclear that impulsivity in SUD was a preexisting vulnerability factor.

Recent studies in rodents, however, have dramatically clarified this view. Rapid response impulsivity (acting without forethought) and impulsive choice (diminished sensitivity to delayed, as opposed to immediate, outcomes) both predict high liability for drug self-administration (Dalley et al., 2007; Izquierdo and Jentsch, 2012; Perry and Carroll, 2008), although different aspects of impulsivity have been revealed to dissociably relate to distinct aspects of self-administration (e.g., initial acquisition versus motivation to consume the drug versus escalation versus extinction versus reinstatement). Impulsivity traits in animal models are under genetic control and are linked to reduced dopamine D2-like receptor availability/function in brain (Dalley et al., 2007; Laughlin et al., 2011). Although all the details of this relationship remain to be exposed, it is clear that a multidimensional model that incorporates both the phenotypic complexity of impulsivity and drug reinforcement is required. In this sense, the results of the animal models not only generally clarify the causal nature of the relationship between impulsivity and drug abuse phenotypes, but can also generate new hypotheses about the behavioral and molecular architecture of this relationship that can be subsequently tested in humans.

REWARD SENSITIVITY

It has been suggested that individual differences in the positive subjective response to reward is an independent predictor

of liability for SUD and that so-called reward sensitivity can be phenotypically indexed by specific behavioral paradigms, such as the sweet flavor preference (Carroll et al., 2008). In other words, high preference for sweet flavors indicates high reward sensitivity, and the hypothesis is that reward sensitivity in turn translates into individual differences in sensitivity to drug reward and/or reinforcement. In a comprehensive series of studies, Carroll and colleagues have provided empirical support for this hypothesis in rat models. Saccharin preference (a phenotype that indicates sweet, but not calorie, preference) is a genetically influenced trait, in the sense that it can be enriched by breeding for the phenotype. Rats bred for high saccharin preference more readily self-administer cocaine and opioids, compared with rats bred for low saccharin preference, with a greater effect in females than males (Perry and Carroll, 2008).

SUMMARY

The concept that animal models can disambiguate the causal nature of the relationship between putative biological and behavioral susceptibility factors and SUD is not new, but recent years have seen a dramatic increase in the sophisticated use of these systems to do so. For those relationships now exposed (e.g., among novelty-seeking, impulsivity, reward sensitivity, and drug self-administration), it is now possible to begin taking apart the genetic, molecular, and circuit mechanisms that mediate the relationship. Presumably, these biological factors are useful for a variety of reasons, including their ability to serve as biomarkers of risk and as targets for prevention of SUD.

DISCLOSURES

Dr. Maldonado receives financial support and/or research contracts from Laboratorios Esteve SA, Ferrer SA, Pharmaleads, and a grant from Marató TV3. He currently holds a patent under exploitation by Panlab SA.

Dr. Jentsch and Dr. Evans have no conflicts of interest to disclose. They are both funded by the NIDA and NINDS.

Dr. Kieffer has no conflicts of interests to disclose. She is funded by academic institutions (CNRS, INSERM and Université de Strasbourg and the National Institutes of Health (National Institute of Drug Addiction, grant #05010 and National Institute on Alcohol Abuse and Alcoholism, grant #16658).

51 | CELLULAR AND MOLECULAR MECHANISMS OF ADDICTION

KATHRYN J. REISSNER AND PETER W. KALIVAS

The social, economic, and public health impact of addiction to drugs of abuse is well addressed throughout this volume. Indeed, the public health cost of addiction to substances both legal and illicit places tremendous burden on the individual and society. The estimated monetary cost of addiction within the United States reaches \$500 billion per year (Abuse, 2011; Koob et al., 2009; Uhl and Grow, 2004). Of the 2.4 million deaths in the United States in 2000, more than 450,000 were attributed to smoking, 67,000 to alcohol-related deaths, and nearly 10,000 to illicit drug use (Keeney, 2008). In 2009, illicit drug-related deaths had increased to nearly 37,000 per annum (Kochanek et al., 2011). These statistics underscore the importance of understanding and treating addiction disorders. Thus, a majority priority of addiction research is to investigate the nature of drug-dependent pathology at the behavioral, neuroanatomical, and cellular levels, as they contribute to the biological mechanisms responsible for the transition from social use through stages of abuse and compulsive drug seeking.

Addiction to drugs of abuse is characterized not only by increased motivation to obtain the drug, but also by decreased motivation to obtain natural reward and loss of control over behavior. The enduring changes that occur in regions of reward neurocircuitry and mediate the drug seeking characteristic of an addiction disorder occur over time and repeated exposures. Drug use typically escalates in a series of steps beginning with social use and transitions to regulated relapse, which is followed by compulsive relapse (Kalivas and O'Brien, 2008) (Fig. 51.1). In this chapter we will discuss the cellular and molecular changes and engagement of neural circuits that occur loosely on a timescale correlated with stages of use and drug seeking, and consider how these changes may mediate the uncontrollable drive to use that characterizes an addiction disorder. It is however important to note that these are not clear delineations. For example, although we present pronounced dopamine (DA) signaling as a hallmark feature associated with reinforcing effects of social drug use, dopaminergic mechanisms persist throughout all stages of addiction disorder.

NEUROCIRCUITRY OF ADDICTION

STAGE I: REWARD NEUROCIRCUITRY AND SOCIAL USE

An overview of the neurocircuitry of addiction is essential for any discussion of the cellular and molecular mechanisms,

because identifying relevant brain loci of change is imperative. The elucidation of the neurocircuitry of addiction has underscored the growing appreciation that addiction involves a pathology of reward learning (Hyman et al., 2006; LaLumiere and Kalivas, 2007). Reward learning can be defined as the adaptive associations between the environment and rewarding stimuli (e.g. food, sex, social interaction), and in a broader context includes the modulation of reward learning by motivational drive and decision making. Reward learning is a critical component of survival and evolutionary success, governing the necessary associations of reinforcement with context and behavior.

Early understanding of the neurocircuitry of reward learning was provided by the seminal work of Olds and Milner, who described the rewarding effects of electrical self-stimulation, with most pronounced effects in regions of the brain including the septum and tegmentum (Olds and Milner, 1954). Subsequent studies by Olds and others identified a number of other reward centers, most particularly along the medial forebrain bundle, which extends from the ventral tegmental area (VTA) through the lateral hypothalamus to the nucleus accumbens (Wise, 1998) (Fig. 51.2).

Shortly thereafter in 1957, Arvid Carlsson determined that dopamine (DA) functions as a neurotransmitter in the brain, as opposed to simply as a precursor for norepinephrine (Carlsson et al., 1957). This finding allowed for the inclusion of DA among the signaling candidates responsible for the activation of reward circuitry. A number of subsequent studies performed in the 1970s and 1980s determined that anatomical or pharmacological inhibition of DA signaling was found to impair a myriad of reward-related behaviors including feeding, electrical stimulation, sexual contact, and ultimately, pursuit of drugs of abuse (for review, see Wise, 1998, 2004). These studies established the framework within which to investigate dopaminergic mechanisms of reinforcement and hypotheses of addiction neurobiology.

By the late 1980s it had become clear that the reward pathway was multisynaptic, that DA antagonists blocked the rewarding effects of brain stimulation, and that the majority of drugs of abuse caused release of DA within the mesolimbic projections, particularly into the nucleus accumbens (NAc) (Di Chiara and Imperato, 1988; Wise and Rompre, 1989). Thus, the rewarding effects of drugs of abuse have been attributed to an increase in DA signaling within the mesolimbic reward centers of the brain, particularly the NAc and prefrontal cortex

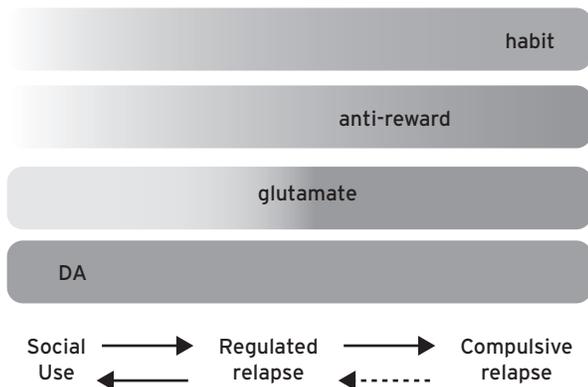

Figure 51.1 Behavior stages in the development of an addiction disorder overlaid with corresponding categories of cellular changes. Extension of darker shading indicates the engaged or continued requirement for each mechanism in stages of addiction development. Changes in DA signaling are observed after an acute exposure to many drugs of abuse, and continue to be observed following multiple exposures (solid dark gray). Over time and repeated exposures/withdrawal, changes in glutamatergic signaling and plasticity are also observed, and contribute to the development of regulated drug seeking. As drug abuse continues, the brain “anti-reward” system is activated, and ultimately dorsal striatal habit circuitry, in the later stages of compulsive relapse. (Adapted from Kalivas P.W., O’Brien C. 2008. Drug addiction as a pathology of staged neuroplasticity. *Neuropsychopharmacology*, 33: 166–180.)

(PFC). Drug-dependent DA release in the NAc and PFC, as well as the amygdala and hippocampus, is now known to be a critical mediator of the rewarding effects of drugs of abuse, a necessary early step in the development of addiction disorders, the mechanisms of which will be discussed in depth in the following section.

STAGE 2: REGULATED RELAPSE

Because activation of the mesocorticolimbic DA system mediates responsiveness to the effects of drugs of abuse as well as natural rewards, the development of changes within the structures receiving DA following chronic drug exposure can mediate elements of drug craving and seeking, which are associated with the appearance of regulated relapse (Feltenstein and See, 2008). In particular, the NAc is a structure receiving input from not only the VTA, but also from the PFC, amygdala, and hippocampus, and is a critical mediator of reward seeking (Feltenstein and See, 2008; Mogenson et al., 1980) (see Fig. 51.2). The NAc is comprised of core and shell subcompartments, from which GABAergic projections are sent to the ventral pallidum, which in turn project back to the NAc and VTA, as well as to the subthalamic nucleus and the dorsomedial nucleus of the thalamus.

The NAc core and shell differ with respect to histological markers, and afferent and efferent connectivity (Ambroggi et al., 2011). Moreover, the cellular consequences of drug exposure differ in the NAc subcompartments, and consequently these subregions may mediate different elements of the addiction process (Peters et al., 2008). In the absence of drug exposure, the NAc core is associated with instrumental behaviors and is functionally connected with motor output systems,

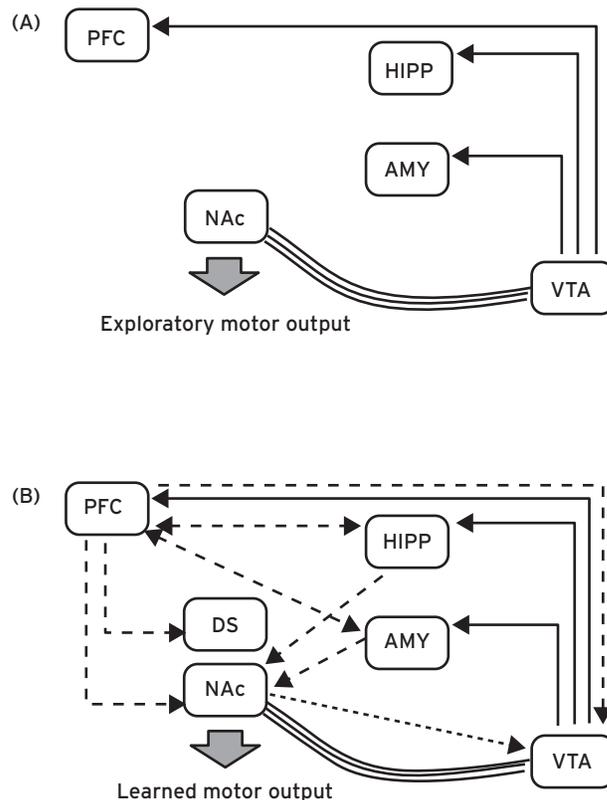

Figure 51.2 Reward and addiction neurocircuitry. Established circuit connections in the neuropathology of drug abuse are shown. Solid lines indicate DA transmission, dashed lines indicate glutamatergic transmission, dotted line represents GABA; arrows indicate directionality of neurotransmission. (A) Ascending reward neurocircuitry engaged by both natural rewards and isolated exposure to drugs of abuse. Triplet lines indicate median forebrain bundle. (B) Additional nuclei and structures are engaged following repeated drug exposure and mediate regulated relapse and increasingly compulsive drug seeking behavior. Enduring adaptations emerge within these structures, which underlie the pathophysiology of addiction. AMY, amygdala; DS, dorsal striatum; HIPP, hippocampus; NAc, nucleus accumbens; PFC, prefrontal cortex; VP, ventral pallidum; VTA, ventral tegmental area. For clarity, not included are nuclei included in the section on additional structures. For further discussion of the neurocircuitry of addiction, see Feltenstein and See, 2008; Koob and Volkow, 2010; McGinty et al., 2011.

whereas the shell plays a role in emotional modulation and appetitive motivations (Kelley, 2004; Sesack and Grace, 2010).

The prefrontal cortex is another major recipient of DA from the VTA, and inactivation of the PFC impairs drug self-administration and relapse related behaviors (McLaughlin and See, 2003). Regions within the PFC implicated in the neuropathology of addiction include the prelimbic cortex (PL), orbitofrontal cortex (OFC), and anterior cingulate cortex. Relapse-related behaviors of animals trained to self-administer drugs of abuse, followed by drug-abstinent extinction training, is particularly dependent on the activation of the synapse between the PL and NAc core (Kalivas et al., 2005; McLaughlin and See, 2003). Importantly, the PFC as well as the NAc send projections back to the VTA to regulate continued firing of DA neurons under adaptive learning conditions.

The amygdala is another major mesolimbic DA recipient and is composed of nuclei including the basolateral amygdala (BLA), central nucleus, medial nucleus, and cortical nucleus

(Freese and Amaral, 2009). With respect to drug cue-dependent relapse in preclinical animal models, synaptic connections between the BLA and NAc core, as well as the PL and NAc core, appear to be particularly important (Feltenstein and See, 2008). In addition, the extended amygdala is a composite of structures including the central nucleus of the amygdala, the bed nucleus of the stria terminalis, and the NAc shell, which are largely associated with stress-induced relapse to drug seeking (Kalivas and McFarland, 2003).

STAGE III: COMPULSIVE DRUG SEEKING

The compulsive drug-seeking characteristic of addiction is further associated with brain stress systems including the extended amygdala (comprised of the central nucleus of the amygdala, bed nucleus of the stria terminalis, and the NAc shell), and the hypothalamic–pituitary–adrenal (HPA) axis (composed of the paraventricular nucleus of the *hypothalamus*, the anterior lobe of the *pituitary gland*, and the *adrenal gland*). The extended amygdala and the HPA axis secrete neuropeptides and stress hormones, most notably corticotropin-releasing hormone (CRF), orexin, dynorphin, and vasopressin (Koob, 2008). The action of these molecules affects the physiology of structures affiliated with anti-reward systems and become activated during and following cessation of drug use (Koob and Le Moal, 2005). In particular CRF is released into the VTA in response to stress (Koob, 2008; Sarnyai et al., 2001). Release of CRF onto VTA dopaminergic neurons exerts a number of cellular effects including increased excitability and enhanced NMDA receptor mediated synaptic currents (Borgland et al., 2010). Preclinical models of stress reveal release of CRF into the VTA and consequent increased release of DA. These effects, as well as stress-induced reinstatement of drug seeking, are blocked by administration of a CRF receptor antagonist in the VTA (Borgland et al., 2010; Wang et al., 2005).

ADDITIONAL BRAIN CIRCUITS

Brain regions beyond those described earlier whose activation and/or inactivation may contribute to addiction-related behaviors include the habenula, insula, and septum. The habenula is located medial and posterior to the thalamus and projects to the VTA and substantia nigra pars compacta (SNc), and receives inputs from structures including the lateral hypothalamus, septum and dorsal striatum (Hikosaka, 2010). Stimulation of neurons within the lateral habenula inhibits activation of DA neurons in the SNc and VTA (Fowler et al., 2011). Accordingly, lateral habenula neurons fire in the absence of an expected reward to inhibit VTA DA release (McGinty et al., 2011). Thus, the lateral habenula has been proposed to serve as a control center for negative reward prediction. However, rats will seek electrical stimulation of the lateral habenula, and lesions of the lateral habenula decrease self-stimulation of the lateral hypothalamus and VTA (McGinty et al., 2011).

The insula, also known as the insular cortex, is a region of the cerebral cortex outside the PFC, located between the frontal and temporal lobes, that is associated with interoception and decision making (Naqvi and Bechara, 2009). Interoception refers to

a perception of state of being, often considered as a measure of well-being, and is influenced by external environmental stimuli as well as internal awareness of emotions, stress, and energy level. The insula receives input from a number of structures implicated in addiction pathology including the anterior cingulate cortex, ventromedial PFC, amygdala, and ventral striatum. Activation of the insula is associated with craving for nicotine, cocaine, alcohol, and heroin; moreover, inactivation of the insula in preclinical animal models impairs measures of relapse to nicotine and methamphetamine (Naqvi and Bechara, 2010).

Lastly, the septum was one of the earliest structures identified by Olds and Milner in their original self-stimulation study (Olds and Milner, 1954); however, comparatively little work in animal models of reward learning and drug abuse has been performed since then. The lateral septum projects to the lateral hypothalamic orexin field, and inhibition of the lateral septum blocks conditioned place preference to cocaine (Aston-Jones et al., 2010; Sartor and Aston-Jones, 2012).

Comparatively little is currently known about cellular events induced in these structures by exposure to drugs of abuse, even though they have been clearly implicated in the neurocircuitry of addiction and illustrate the complexity of neuroanatomical substrates of reward-related behaviors and pathologies. The preponderance of data in the cellular biology of addiction show changes in the NAc and VTA, which are in some cases both necessary and sufficient to drive drug seeking, even following extended abstinence. These studies provide important insight into molecular mechanisms of addiction and craving, and will be the primary focus of the remainder of this chapter. Nonetheless, it is important to acknowledge that drug-dependent changes in the structures previously described almost certainly contribute to the complex cellular dynamics that comprise an addiction disorder.

RECEPTOR-MEDIATED SIGNALING

STAGE I: SOCIAL USE

As mentioned previously, exposure to most drugs of abuse results in pharmacological release of DA from the VTA onto neurons within the PFC, NA, amygdala, and hippocampus. However, although acute hyperdopaminergia is a common mechanism of the rewarding effects of most drugs of abuse, it occurs via distinct mechanisms (Nestler, 2005; Woolverton and Johnson, 1992). For example, psychostimulants cocaine and (meth)amphetamine lead to a surge of DA by inhibiting and reversing the activity of the dopamine transporter (Torres et al., 2003). Opiates stimulate opiate receptors (μ , κ , δ), which reduce GABAergic inhibition on DA-releasing neurons of the VTA, whereas nicotine causes DA release through signaling downstream of nicotinic acetylcholine receptors on VTA neurons (Cami and Farre, 2003; Mansvelder and McGehee, 2002; Woolverton and Johnson, 1992). The primary psychoactive ingredient in marijuana, Δ^9 tetrahydrocannabinol (THC), binds to endogenous CB₁ cannabinoid receptors, which are coexpressed on GABAergic neurons that innervate the VTA (Robbe et al., 2001). Thus, akin to opiate-mediated inhibition of GABAergic input to the VTA, marijuana also

leads to decreased inhibition onto dopaminergic neurons. It is important to note that the pleasurable, reinforcing effects of drugs including opiates and THC are not exclusive to the effects of DA, and that not all drugs of abuse have profound effects on DA (e.g., non-DAergic mechanisms contribute to the effects of alcohol and benzodiazepines) (Wise, 2004). However, the initiation of cellular mechanisms that contribute to a generalized substance abuse disorder are believed to be mediated by repeated excessive hyperdopaminergia.

SIGNALING INDUCED BY DA RECEPTOR ACTIVATION

Increased DA signaling following drug use or natural rewards is observed in structures which receive afferent input from the VTA; of particular relevance are the PFC, NAc, amygdala, and hippocampus (Koob and Volkow, 2010). Importantly, although this response subsides with repeated exposures to natural rewards, increased DA signaling is pharmacologically stimulated with each exposure to drug (Cami and Farre, 2003; LaLumiere and Kalivas, 2007). This critical difference may underlie the initiation of pathology by drugs of abuse as opposed to natural rewards.

Dopamine receptors are members of the D1 (D1 and D5) or D2 (D2S, D2L, D3, and D4) G-protein coupled receptor families, and are positively and negatively coupled to adenylyl cyclase, respectively. With respect to the cellular effects of drugs of abuse, one of the most widely studied DA receptor effector molecules is Dopamine and cAMP-Regulated Phosphoprotein of 32 kDa (DARPP-32) (Svenningsson et al., 2005) (Fig. 51.3). DARPP-32 is highly expressed in medium spiny neurons of the striatum, including the NAc. Activation of DARPP-32 by PKA phosphorylation leads to inhibition of the phosphatase PPI1, which controls the phosphorylation state of a number of signal transduction molecules. DARPP-32 is also a substrate for cyclin-dependent kinase 5 (Cdk5/p35), which in turn inhibits the ability of PKA to phosphorylate DARPP-32. Both acute and chronic exposure to cocaine, amphetamine, opiates, nicotine, and alcohol modulate the phosphorylation of DARPP-32, and DARPP-32 knockout mice demonstrate altered behavioral responses, including locomotor sensitization and place preference, to cocaine, amphetamine, and alcohol, as well as self-administration of ethanol (Fienberg and Greengard, 2000; Fienberg et al., 1998; Risinger et al., 2001). One of the cellular roles of DARPP-32 activation is modulation of gene transcription by control of transcription factors. Indeed, activation CREB (cAMP response element binding protein), c-Fos, and Δ FosB, three transcription factors all heavily implicated in the cellular mechanism of addiction, are decreased in DARPP-32 knockout mice in response to DA (Svenningsson et al., 2000, 2005; Yan et al., 1999). These important pathways will be discussed more extensively in the section on transcriptional mechanisms of addiction.

STAGES II & III: RELAPSE

Over time and repeated exposures, social use may progress to regulated relapse (Kalivas and O'Brien, 2008). Continued use is associated with the engagement of receptors and signaling

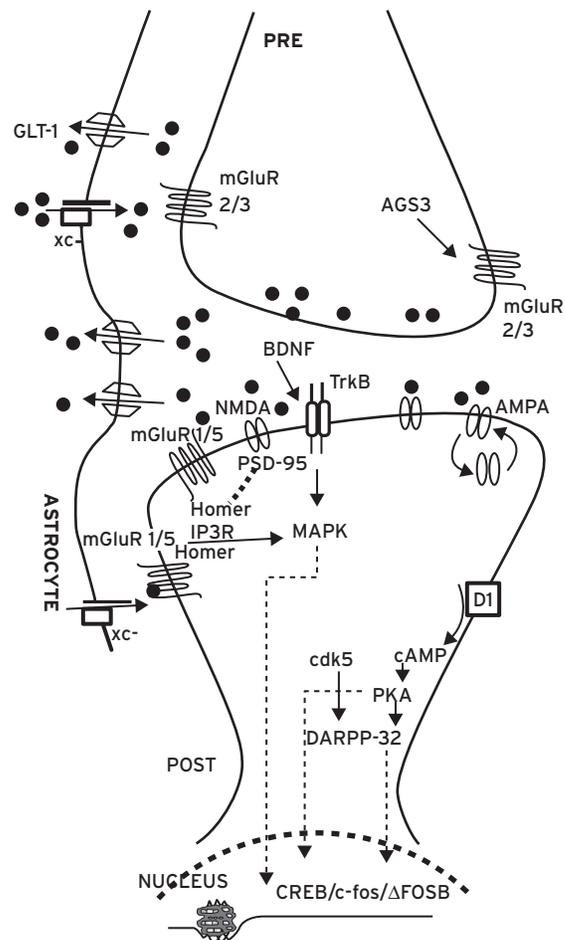

Figure 51.3 Receptor-mediated signaling pathways affected by acute and chronic exposure to drugs of abuse. Representative pathways shown in a schematic medium spiny neuron (MSN) of the NAc, surrounded by astrocytes expressing glutamate transporter GLT-1 and glutamate antiporter system xc-. Arrows indicate directionality of glutamate transport or molecular signaling. Shown on the presynaptic face, activator of G-protein signaling 3 (AGS3) proteins are upregulated following multiple drugs of abuse. AGS3 proteins are inhibitory to Gi coupled receptors, such as GluR2/3 receptors, and thus increased expression promotes synaptic glutamate release probability in the PFC-NAc synapse. On the postsynaptic side, activation of D1 receptors leads to stimulation of adenylyl cyclase and enhanced cAMP production, leading to increased PKA activity. D2 receptors are inhibitory to ac activation and are expressed in MSN populations independent of D1-expressing neurons in the NAc. Both PKA and cdk5 activity are regulated by chronic cocaine, and both phosphorylate numerous substrates, including DARPP-32. DARPP-32 exerts downstream effects on transcription, as evidenced by decreased activation of CREB, FosB, and Δ FosB in DARPP-32 mice (Svenningsson et al., 2005). Both scaffolding and signaling molecules linked to iGluR and mGluR receptors are also influenced by chronic drug use. In particular, expression of Homer proteins is regulated by cocaine use. Homer proteins bind to the C-terminal tail of postsynaptic group I mGluR proteins and share an indirect interaction with NMDA receptor binding protein PSD-95. Not shown are additional scaffolding proteins of the postsynaptic density which form glutamate receptor complexes, including AMPA receptors. Membrane trafficking of AMPA receptors is also affected by chronic drug use, indicated by cyclic arrows. The coordinated activity of many signaling proteins including MAPK, PKA, and DARPP-32 influence activity of transcriptional regulators in the nucleus via activation of transcription factors including CREB, c-fos/ Δ FosB, NFkB. Chromatin remodeling is also strongly affected by chronic cocaine exposure, via modifications to both DNA and histones, allowing for increased (or decreased) promoter availability for transcription factor binding. Depiction of histone octamer wrapped in DNA is schematized at bottom. For additional discussion of these and other pathways, see Dietz et al., 2009; Kalivas, 2009; McGinty et al., 2010; Robison and Nestler, 2011; Thomas et al., 2008.

pathways beyond DA, most notably glutamate and neuropeptides, which may mediate the next behavioral stage of addiction, regulated relapse. Repeated drug use results in repeated release of DA from the VTA into structures described earlier, most notably the PFC, NAc, and amygdala (see Fig. 51.2). In parallel, for the addiction-vulnerable individual, repeated social use leads to regulated relapse associated with seeking out of the drug. Repeated exposures also lead to a variety of changes in glutamatergic signaling pathways, associated with a disruption of glutamate homeostasis (Baker et al., 2003).

GLUTAMATE HOMEOSTASIS HYPOTHESIS OF ADDICTION

Glutamate homeostasis refers to the regulation of extracellular glutamate in the synaptic and perisynaptic environment by both glia and neurons. Extracellular glutamate levels regulate synaptic activity and plasticity, and thus disruptions of glutamate homeostasis can have considerable effect on synaptic strength and function (Danbolt, 2001; Haydon, 2001; Kalivas, 2009). Basal levels of glutamate, which are predominantly extrasynaptic in origin, are reduced in the NA core of rats following long-term cocaine self-administration but not heroin or alcohol administration (Baker et al., 2003; LaLumiere and Kalivas, 2008; McFarland et al., 2003; Melendez et al., 2005). This reduction in extrasynaptic glutamate, in turn, provides less tonic inhibition of the mGluR2/3 receptors that are located on the presynaptic glutamatergic terminals (Moran et al., 2005). Less tonic inhibition in turn results in increased synaptic transmission in response to a drug-related stimulus, and contributes to the potentiated glutamate release observed in the NAc following a cocaine prime in withdrawn animals trained to self-administer cocaine. The cocaine prime- or stress-induced increase in glutamate is prevented by inactivation of the dorsal medial prefrontal cortex (mPFC) (McFarland et al., 2003, 2004) indicating an important regulatory role for the dorsal mPFC following long-term cocaine self-administration. A similar glutamate overflow occurs during reinstated heroin-seeking that also depends on mPFC activation (LaLumiere and Kalivas, 2008).

The regulation of extrasynaptic glutamate is predominantly dependent on the coordinated activity of the cystine-glutamate exchanger (system xc⁻) and high affinity glutamate transporters (Baker et al., 2002; McBean, 2002; Reissner and Kalivas, 2010) (see Fig. 51.3). Release of glutamate is accomplished by system xc⁻, in which one molecule of glutamate is released in exchange for the uptake of one extracellular cystine molecule. The exchanger exists as a heterodimer of a light catalytic subunit xCT and heavy subunit 4F2. Expression of the catalytic subunit xCT is decreased following cocaine self-administration in animals, resulting in decreased basal extracellular glutamate in the NAc of cocaine-withdrawn rats (Baker et al., 2002; Knackstedt et al., 2010a). Glutamate uptake from the extracellular space is primarily accomplished by the high affinity glutamate transporters. Expression of the astroglial glutamate transporters, EAAT2/GLT-1 and EAAT1/GLAST are also decreased following cocaine, heroin, and nicotine self-administration, thus compromising the ability of NAc synapses to accommodate the potentiated glutamate release observed during relapse to cocaine seeking in rats (Knackstedt et al., 2010a; Reissner et al., 2011).

Expression of xCT and GLT1 can be restored by treatment with *N*-acetylcysteine and ceftriaxone, which also inhibits relapse in the reinstatement/self-administration animal model (Baker et al., 2003; Zhou and Kalivas, 2008; Knackstedt et al., 2010a).

RELAPSE IS MEDIATED BY GLUTAMATE RECEPTOR ACTIVITY

Considerable evidence supports a role for striatal glutamate receptors in the reinforcement of long-lasting drug-seeking behaviors (Uys and Reissner, 2011). Specifically, three main lines of evidence implicate ionotropic glutamate receptor involvement in addictive behaviors in a rat self-administration model of addiction. First, a drug prime following self-administration of either cocaine or heroin followed by extinction results in potentiated glutamate release in the NAc (Baker et al., 2003; LaLumiere and Kalivas, 2008). Second, glutamatergic PFC-NAc synapses exist in a baseline potentiated state following self-administration and withdrawal (Kourrich et al., 2007; Moussawi et al., 2009). Third, inhibition of α -amino-3-hydroxy-5-methyl-4-isoxazole-propionate (AMPA)-type glutamate receptors in the NAc inhibits self-administration and reinstatement to cocaine and heroin, whereas activation of these receptors potentiates drug seeking (Backstrom and Hyytia, 2007; Cornish and Kalivas, 2000; Di Ciano and Everitt, 2001; LaLumiere and Kalivas, 2008; Ping et al., 2008; Suto et al., 2009). These findings collectively suggest a glutamate receptor-dependent mechanism in the neuroplasticity of addiction and underscore the involvement of glutamatergic mechanisms of relapse.

IONOTROPIC GLUTAMATE RECEPTORS

Ionotropic glutamate receptors are of the AMPA, *N*-methyl-D-aspartic acid (NMDA), and kainite receptor types (Dingledine et al., 1999). AMPA receptors exist as homo- or heterotetramers, most often composed of sets of two subunits (GluR1, GluR2, GluR3, GluR4). Increases in synaptic strength are largely associated with increased surface expression of AMPA receptors, particularly GluR1, whereas conversely, decreases in synaptic strength are caused by internalization or decreased surface expression (Kauer and Malenka, 2007). In addition, receptor subunit composition can affect the biophysics of glutamate-mediated currents; for example, all AMPA receptors not containing GluR2 subunits are permeable to calcium; however, GluR2-containing AMPA receptors are calcium impermeable.

A number of studies using preclinical animal models have revealed complex AMPA receptor dynamics in different stages of self-administration, extinction/abstinence, and relapse (for review, see Wolf and Ferrario, 2010). In one seminal study, although no change in AMPA receptor expression was observed one day after the end of self-administration, an increase in surface and total GluR1 receptors was found 45 days after the last cocaine self-administration session (Conrad et al., 2008). Moreover, a functional increase in GluR2-lacking receptors was found in the NAc following self-cocaine administration at this time point, indicating a role for GluR2-lacking receptors in the incubation of cocaine craving (Grimm et al., 2001; Lu et al., 2004).

Changes in GluR1 and GluR2 trafficking are also observed after an acute drug challenge following chronic abuse and withdrawal. For example, thirty minutes after a cocaine challenge, increased surface expression of GluR1 is observed in the NAc shell (Anderson et al., 2008). Moreover, increased GluR2 phosphorylation (consistent with internalization) was also observed 30 minutes after a cocaine prime (Famous et al., 2008), collectively suggesting a mechanism in which, in a self-administration model of addiction, a cocaine challenge leads to an increase in surface GluR1 in exchange for surface GluR2 (Wolf and Ferrario, 2010). Numerous studies have also found effects on expression of NMDA receptor subunits following exposure to cocaine, and effects of NMDA receptor agonists and antagonists on drug-seeking behaviors (Huang et al., 2009; Ma et al., 2009; Schmidt and Pierce, 2010). The dynamics of both NMDA and AMPA receptors that occur within the reward circuitry following prolonged drug use, withdrawal, and relapse indicate a complex and critical contribution to cellular mechanisms of addiction.

METABOTROPIC GLUTAMATE RECEPTORS

In addition to ionotropic glutamate receptors, metabotropic glutamate receptors also contribute to mechanisms of neuroplasticity associated with addiction to drugs of abuse. Group I mGluRs include mGluR1 and mGluR5 receptors, which are excitatory Gq-coupled receptors and are localized predominantly postsynaptically (Shigemoto et al., 1997). In contrast, group II receptors (mGluR2 and mGluR3) are Gi/Go-coupled, and are predominantly presynaptic (Shigemoto et al., 1997; Tamaru et al., 2001; Testa et al., 1998). Presynaptic group II mGluRs are inhibitory to synaptic transmission (Anwyl, 1999; Cartmell and Schoepp, 2000) as are group III receptors (mGluR4-8).

Reflecting the differential expression and effects on cellular activity, group I and group II mGluR receptors exert opposing effects on the drug-dependent cellular physiology and drug-seeking behaviors. Inhibition of group I mGluRs, particularly mGluR5, has been thoroughly described as inhibitory to drug seeking (Backstrom et al., 2004; Besheer et al., 2008; Carroll, 2008; Gass et al., 2009; Kumaresan et al., 2009; Liechti and Markou, 2008; Paterson and Markou, 2005; Platt et al., 2008). And in support of this, mGluR5 knockout mice demonstrate no cocaine-induced changes in locomotor activity, and do not self-administer cocaine (Chiamulera et al., 2001).

Alternatively, mGluR2/3 activation is inhibitory to drug-seeking behaviors associated with several drugs of abuse including heroin, cocaine, nicotine, and alcohol (Bossert et al., 2005, 2006; Liechti et al., 2007; Moussawi and Kalivas, 2010; Peters and Kalivas, 2006; Xie and Steketee, 2009; Zhao et al., 2006). Genetic deletion of mGluR2 receptors results in increased behavioral sensitization and conditioned place preference following exposure to cocaine (Morishima et al., 2005). Moreover, a reduction of group II mGluR receptor function has been observed following exposure to multiple drugs of abuse, including cocaine and nicotine (Liechti et al., 2007; Xi et al., 2002; Xie and Steketee, 2008).

Akin to the cellular signaling pathways initiated by D1 and D2 receptor stimulation, glutamate receptor engagement following repeated use leads to changes in signaling pathways downstream of glutamate receptors, both ionotropic and metabotropic (see Fig. 51.3). After extended drug use and withdrawal, it is in some cases not entirely clear whether relevant signaling cascades are dependent on activation of DA or glutamate receptors, or both, or whether specific cascades may be particularly relevant for some or all of the behavioral stages discussed. Nonetheless, the following pathways are central to the behavioral pathology of relapse in the drug-dependent animal and provide critical insight into the cell biology of drug abuse.

For example, Homer 1a is an immediate early gene that is rapidly upregulated in response to an acute exposure to cocaine (Brakeman et al., 1997). In neurons, Homer proteins are found in the glutamatergic postsynaptic density where they serve both scaffolding and signaling roles, binding directly to a number of proteins including group I metabotropic glutamate receptors, inositol trisphosphate receptors (IP3R), Shank, and dynamin III (Lu et al., 2007; Tu et al., 1998; Tu et al., 1999) (see Fig. 51.3).

Although the immediate early splice variant of Homer is upregulated following exposure to cocaine, the constitutively-expressed form of Homer, Homer 1, demonstrates more complex regulation. Homer 1 is decreased following experimenter-administered cocaine, but upregulated in the NAc after extinction, but not abstinence, following cocaine self-administration (Knackstedt et al., 2010b; Szumlinski et al., 2006a, 2006b). Genetic deletion of Homer proteins leads to reduced extrasynaptic glutamate, similarly as does chronic cocaine exposure (see preceding), and increased sensitivity to the physiological effects of cocaine in the Homer1 KO mice is rescued by viral-mediated overexpression of Homer proteins (Szumlinski et al., 2004).

G protein-coupled signaling pathways are also highly affected by exposure to drugs of abuse. Activator of G-protein signaling 3 (AGS3) is a member of the AGS family of proteins, which function to facilitate G-protein coupled receptor (GPCR) activation of heterotrimeric G-proteins (Lanier, 2004). AGS3 is upregulated following chronic exposure to cocaine, opiates, and alcohol, and is required for reinstatement in the self-administration model of addiction (Bowers et al., 2004, 2008; Fan et al., 2009; Yao et al., 2005).

Brain derived neurotrophic factor (BDNF) mediated signaling represents another seminal pathway influenced by drugs of abuse, particularly cocaine (McGinty et al., 2010). Although cocaine-mediated BDNF expression in the NAc promotes drug seeking (Graham et al., 2007), an infusion of BDNF in the PFC following self-administration is sufficient to suppress reinstatement behavior several weeks later (Whitfield et al., 2011). BDNF receptor binding leads to conversion of several signaling pathways that influence gene expression, particularly via changes in CREB-mediated transcription, via mitogen activated protein kinase (MAPK) (Robison and Nestler, 2011; Russo et al., 2009). Contributions of transcriptional regulation by CREB are discussed in more detail subsequently, in the section on transcriptional mechanisms.

CELLULAR PHYSIOLOGY

STAGE I: SYNAPTIC PLASTICITY IN THE VENTRAL TEGMENTAL AREA

Changes in synaptic strength are believed to represent a cellular mechanism for behavioral plasticity, particularly memory formation (Mayford et al., 2012). Accordingly, changes in synaptic strength within the VTA are observed after natural rewards (Chen et al., 2008; Stuber et al., 2008) as well as drugs of abuse (Ungless et al., 2001). The most widely used measure for increased synaptic strength is long-term potentiation (LTP), which typically reflects an increased presentation of AMPA currents relative to NMDA currents in the glutamatergic EPSC. A single noncontingent exposure to many drugs of abuse results in LTP in the VTA lasting for 5–10 days, an effect that is not seen with fluoxetine or carbamazepine (Saal et al., 2003; Ungless et al., 2001). This LTP is mediated by the biphasic insertion of homomeric GluR1 AMPA receptors, followed by insertion of GluR2/3-containing AMPA receptors (Stuber et al., 2010). More enduring increases in synaptic strength in the VTA have been observed following extended self-administration of cocaine, for at least three months after cessation of drug use (Chen et al., 2008).

STAGE II: PLASTICITY WITHIN THE NUCLEUS ACCUMBENS

In contrast to the VTA, changes in synaptic strength are not observed in the NAc following a single cocaine exposure (Chen et al., 2010; Thomas et al., 2001). However, potentiated synapses are observed in the NAc core *in vivo* after self-administration and extinction training (Moussawi et al., 2009) and are depressed in the NAc shell 24 hours following a cocaine challenge after noncontingent administration and abstinence (Thomas et al., 2001). Importantly, despite changes in baseline synaptic strength following drug history, synapses are resistant to protocols that normally induce synaptic plasticity (Martin et al., 2006; Moussawi et al., 2009).

Although the results obtained from these studies are complex, they also illustrate two fundamentally important points about the nature of drug abuse and synaptic plasticity. First, chronic self-administration of drugs of abuse leads to enduring changes in synaptic strength throughout the mesocorticolimbic system, and second, drug-exposed synapses are resistant to adaptive changes in synaptic strength.

Interestingly, evidence suggests that the plasticity in the VTA observed after acute cocaine is mechanistically linked to the plasticity observed in the NAc following chronic exposure (Mameli et al., 2009). By manipulating mGluR1 function in the VTA, Mameli et al. (2009) were able to extend the duration of LTP in the VTA following a single injection of cocaine and consequently observe synaptic depression in the NAc that would otherwise not be observed following a single cocaine exposure.

Importantly, changes in synaptic strength have also been observed in other structures receiving synaptic input from the VTA, notably the amygdala and PFC (Luscher and Malenka, 2011; Stuber et al., 2010). In addition, while the majority of studies on synaptic strength within the mesolimbic system

have been performed following exposure to cocaine, increases in synaptic strength have been reported in the NAc core following a heroin challenge after chronic self-administration and extinction (Shen et al., 2011) and cannabinoids elicit LTD in the NAc and hippocampus (Han et al., 2012; Robbe et al., 2002). Moreover, a considerable body of evidence indicates that alcohol results in changes in synaptic strength in a number of structures including the PFC, NAc, and hippocampus (Abernathy et al., 2010; Kroener et al., 2012; Mishra et al., 2012). These findings underscore the importance of circuitry in the cellular biology of addiction, and the cumulative effect of chronic hyperdopaminergia on glutamatergic plasticity. A current challenge of the field, then, is to determine whether restoration of synaptic plasticity may provide a cellular target for behavioral and pharmacotherapeutic intervention for addiction (Chen et al., 2010).

CHANGES IN STRUCTURAL PLASTICITY

Beyond changes in functional synaptic strength, morphological synaptic changes are also observed in response to multiple drugs of abuse, including opiates, nicotine, alcohol, and psychostimulants (Robinson and Kolb, 2004; Russo et al., 2010). Intriguingly however, psychostimulants and opiates, which exert markedly different physiological effects, also exert generally opposing baseline effects on cell body size and spine size and density; whereas psychostimulant use leads to increases in the number and size of dendritic spines, opiate exposure leads to decreases (Russo et al., 2010). However, a drug challenge following withdrawal from both drugs leads to a transient increase in spine head size (Shen et al., 2009, 2011).

Several studies have reported an increase in overall spine size and/or density in the NAc following exposure to cocaine (Dumitriu et al., 2012; Ferrario et al., 2005; Lee et al., 2006; Norrholm et al., 2003; Pulipparacharuvil et al., 2008; Shen et al., 2009). Moreover, following an acute cocaine challenge, dynamic changes in the morphology of dendritic spines are observed in animals with a chronic cocaine (but not saline) history (Shen et al., 2009). These changes are associated with changes in the expression of cytoskeletal proteins within the postsynaptic density, and indicate that a cocaine history results in a priming of synapses leading to enhanced responsiveness following later exposure to drug (Dietz et al., 2012; Shen et al., 2009; Toda et al., 2006). Moreover, the nature of spine changes in the NAc varies between neurons which express D1 versus D2 DA receptors (Lee et al., 2006). After extended exposure to cocaine, although dendritic spine density was increased in both populations, enduring changes were only observed in D1-positive neurons. Interestingly, animals receiving an acute cocaine exposure following chronic saline did not demonstrate these effects, indicating that changes in spine morphology likely do not mediate acute effects associated with social drug use, but develop over time and with repeated use.

STAGE III: LOSS OF COGNITIVE CONTROL

In the progression of an addiction disorder, following a period of regulated relapse and escalating drug use, the individual

becomes preoccupied with pursuit of drug (Kalivas and O'Brien, 2008; Koob and Volkow, 2010). This stage of addiction is associated with a continued compulsive drive to obtain and use drugs, despite often clear and adverse consequences. It is likely that many of the cellular changes previously outlined are responsible not only for the craving responsible for regulated relapse (Stage II) but contribute to the transition to behaviors associated with a true addiction to drugs of abuse. There are however, further changes that are in particular attributed to uncontrolled pursuit of drug use.

For example, one of the hallmark features of an addiction disorder is loss of cognitive or executive control. This is reflected in brain scans from human addicts following abuse of a myriad of drugs, in which a decreased baseline in metabolic activity is observed in subregions of the PFC including the OFC, cingulate gyrus, and dorsolateral prefrontal cortex (Volkow et al., 2004, 2007a). Because these regions of the PFC are important for cognitive and executive control, decreased metabolic function may indicate impaired cognitive control in the addicted individual (Spiga et al., 2008; Volkow et al., 2004). Interestingly, in a number of structures showing impaired activity at baseline, activity is increased during presentation of a drug-associated cue (Volkow et al., 2005). The cue-induced increased activity in the OFC has been correlated with craving caused by drug paraphernalia or memories of drug use (Childress et al., 1999; Grant et al., 1996; Martin-Soelch et al., 2001; Wang et al., 1999). Thus, although hypoactivity in regions of the PFC may well contribute to diminished cognitive capability in the addicted user, these same regions may be overactive in the uncontrolled drive to use.

To understand the cellular mechanisms of addiction, it is important thus to consider what mechanism(s) may underlie these changes in metabolic activity. Although this remains largely unclear, the decrease in baseline activity correlates with a decrease of dopamine D2 receptor availability in the striatum (Volkow et al., 1993, 2002, 2007a, 2007b). Receptor availability assessed by PET imaging provides an indication of radiolabeled ligand-receptor interaction and can be affected by density of receptors, or by increased endogenous neurotransmitter levels (Nader and Czoty, 2005). The decrease in D2 receptor availability persists for up to four months in drug abstinent addicts, by which time all subjects had relapsed (Volkow et al., 1990). The decrease in D2 receptor availability correlated with decreased basal activation state of the OFC and reports of dysphoria (Volkow et al., 1993), suggesting that D2 availability may contribute to activation state and/or affect of the addicted individual. This point is particularly relevant, given the frequent reports by abstinent addicts that drug seeking is fueled by the desire to escape negative affect (Koob, 2009). Interestingly, a decrease in D2/3 receptor availability is also observed in rhesus macaque monkey and rats following extended cocaine self-administration (Dalley et al., 2009; Dalley et al., 2011; Nader et al., 2006).

Besides a decrease in cognitive control, compulsive drug seeking is also associated with powerful activation of habit circuitry (Everitt and Robbins, 2005; Gerdeman et al., 2003). This concept was briefly introduced within the neurocircuitry of addiction section. Decreased activation of prefrontal

regions responsible for goal directed behavior is exchanged for increased dominance of established drug-seeking habits. Whereas adaptations earlier in the addiction process occur in regions of the ventral striatum, particularly NAc, over time engagement of the habit circuitry including the dorsal striatum is observed (Belin and Everitt, 2008). At the cellular level, ascending cortical loops exist between the ventral and dorsal striatum that may be responsible for this transition (Belin and Everitt, 2008; Haber et al., 2000; Ikemoto, 2007; Voorn et al., 2004). Indeed, changes in dendritic spine morphology in the dorsal striatum have been observed months after methamphetamine cessation (Cuzon Carlson et al., 2011; Jedynak et al., 2007).

In conclusion to considering the cellular physiology of addiction, it is worthwhile to make note of developing technologies that will enable interrogation of more sophisticated hypotheses. For example, techniques in optogenetics have been developed to investigate cellular mechanisms of reinforcement and addiction. Optogenetics utilizes the technology of light-activated channels to control cellular activity, and is discussed in detail in the Emerging Technologies section of this edition. Transgenic or viral-mediated expression of channelrhodopsin or halorhodopsin related proteins, respectively, allow for activation or silencing of cells with a high degree of spatial and temporal control (Fenno et al., 2011; LaLumiere, 2011). Use of optogenetics has recently begun to shed light on the cellular neuroscience of neurological diseases including mental illness, in particular anxiety and addiction (Bernstein and Boyden, 2011; Cao et al., 2011). For example, Lobo et al. (2010) expressed channelrhodopsin-2 selectively in D1- or D2-expressing neurons in the NAc, to control activation selectively in D1+ or D2+ neurons. Activation of D1+ neurons coincident with cocaine led to an increase in cocaine-conditioned place preference (CPP), whereas activation of D2+ neurons led to a reduction in time spent in the cocaine-paired chamber relative to controls, thus illustrating antagonizing roles for D1+ and D2+ neurons in the responsiveness to the rewarding effects of cocaine. In addition, optogenetic stimulation within the VTA has revealed a central role for DA firing patterns in the induction of CPP, as well as for control of reward consummatory behavior by specific populations of VTA GABA neurons respectively (Tsai et al., 2009; van Zessen et al., 2012). Finally, optical inhibition of the projection from the mPFC to the NAc core prevents cocaine reinstatement (Stefanik et al., 2013).

TRANSCRIPTIONAL MECHANISMS OF ADDICTION

TRANSCRIPTIONAL REGULATORS: Δ FosB AND CREB

Acute exposure to drugs of abuse, particularly cocaine, is known to activate expression of immediate early genes including FosB and Homer 1a (Brakeman et al., 1997; Young et al., 1991). However, these effects are transient and do not appear to exert enduring cellular effects that mediate lasting drug craving. In contrast, transcription factors Δ FosB and CREB

are activated by multiple drug exposures and have been implicated in the chronic effects of repeated drug use (Robison and Nestler, 2011). CREB (cAMP response element binding proteins) is responsible for transcription of hundreds to thousands of genes, many of which have been implicated in addiction to drugs of abuse (Barco and Marie, 2011). Activation of CREB is observed in response to alcohol, cocaine, methamphetamine, and nicotine, whereas biphasic effects on CREB activation have been reported in response to opiate exposure and withdrawal. Functional studies have indicated complex roles for CREB in the drug-associated behaviors following exposure to multiple classes of drugs, as well as in related behaviors including depression, anxiety, and stress response (Briand and Blendy, 2010; Carlezon et al., 2005). Thus, the engagement of CREB is likely not restricted to the pharmacological effects of drugs, but also to the contribution of environment and affect to drug seeking behaviors as well.

Similar to CREB, the transcription factor Δ FosB has been heavily implicated in the enduring adaptations induced by numerous drugs of abuse (Carlezon et al., 2005; McClung et al., 2004). An enduring increase in expression of Δ FosB is observed following chronic exposure to cocaine, morphine, amphetamine, nicotine, ethanol, as well as various types of stress and natural rewards. Although most Fos family proteins are short-lived immediate early genes, the Δ FosB variant exhibits unique protein stability, and thus increased expression can accumulate and endure for a period of weeks following chronic drug administration (McClung et al., 2004). Importantly, Δ FosB can act as a transcriptional activator or repressor, and exerts influence over the expression of a wide variety of genes following a chronic (versus acute) regimen of cocaine administration (McClung and Nestler, 2003).

EPIGENETIC MECHANISMS OF ADDICTION

Beyond control of transcriptional expression through the activity of transcription factors, epigenetic mechanisms provide genetic control of addiction related behaviors. From Greek for over, outer, or above (epi), epigenetics refers to a change in gene function that is not caused by changes in DNA sequence (Haig, 2004; Maze and Nestler, 2011). Examples of epigenetic changes include DNA methylation and histone modifications that regulate chromatin structure and consequently influence gene expression. Accumulating studies from the early 2000s indicate considerable epigenetic involvement in controlling experience dependent plasticity and behavior (Borrelli et al., 2008; Day and Sweatt, 2011). Because many epigenetic changes can be long lasting, through the lifespan of the animal and in many cases directly or indirectly inherited by offspring, these changes have been proposed to reflect a cellular marker for the changes in gene expression which persist long after cessation of drug use (Tsankova et al., 2007).

Chromatin regulation by post-translational modification of histones includes phosphorylation, acetylation, and methylation (Maze and Nestler, 2011). Acute and chronic exposure to cocaine leads to histone modifications associated with regulation of gene expression. In particular, acetylation of histones H3 and H4 leads to increased transcription, because

the posttranslational modification masks a charge-dependent interaction between histones and DNA, allowing opening of the chromatin (Maze and Nestler, 2011). Histone acetylation is reversed by histone deacetylases (HDACs). Pharmacological inhibition or genetic suppression of HDACs potentiates the locomotor effects of cocaine as well as time spent in a drug-associated context; conversely, viral overexpression of HDAC4 or HDAC5 (Class II HDACs) has the opposite effect, indicating behavioral effects for global histone acetylation modification (Kumar et al., 2005; Renthal et al., 2007). In contrast, manipulation of a class III HDAC has the opposite behavioral effect (Renthal et al., 2009). Further, HDAC inhibition given post drug exposure facilitates extinction of CPP and reduces CPP reinstatement, indicating that histone modification may influence learning of drug associations, as well as the rewarding effects (Malvaez et al., 2010). Importantly, genes whose expression is regulated following chronic exposure to cocaine, including BDNF and cdk5, demonstrated histone H3 acetylation following chronic cocaine use, which remains elevated one week following withdrawal (Kumar et al., 2005). Changes in the physical association of Δ FosB and CREB with promoters of genes in which histone acetylation was present was observed for a number of genes (Renthal et al., 2009), thereby supporting the importance of these transcription factors in the regulation of cocaine-dependent targets, as discussed earlier.

Opposite to the activity of HDACs, histone acetyltransferases (HATs) are responsible for adding acetyl groups to proteins, including H3. CREB binding protein (CBP) is an example of such a HAT. Deletion of CBP in the NAc leads to decreased histone acetylation and locomotor responses to cocaine as well as inhibition of CPP (Malvaez et al., 2011). Notably, this effect of inhibition of CBP HAT activity on CPP is opposite to that observed following HDAC inhibition, previously described.

Studies investigating the inhibition of HDAC activity in a self-administration paradigm have yielded complex results (Maze and Nestler, 2011). Although results from CPP studies suggest that HDAC inhibition should increase cocaine self-administration, multiple studies have yielded conflicting results indicating both increased and decreased responsiveness to cocaine (Romieu et al., 2008; Romieu et al., 2011; Sun et al., 2008; Wang et al., 2005). These conflicting results underscore the importance of which experimental paradigm is used; for example in this case variables included use of different HDAC inhibitors, method of inhibitor administration, and time of inhibition relative to training and drug administration.

In contrast to histone acetylation, histone methyltransferase activity is decreased following chronic cocaine exposure (Maze et al., 2010). Moreover, genetic diminution of histone methyltransferase G9a in the NAc increased response to social defeat stress and cocaine CPP, whereas overexpression of G9a protected against cocaine-dependent social avoidance and led to decreased preference for cocaine CPP (Covington et al., 2011; Maze et al., 2010).

Last, beyond epigenetic histone modifications, direct DNA methylation can also affect gene expression. Three weeks following cocaine exposure or social defeat stress, an increase in DNA methylating enzyme Dnmt3 was observed in the NAc

(LaPlant et al., 2010). Interestingly, overexpression of Dnmt3 appears to be inhibitory to cocaine CPP and increases depressive behavioral symptoms in mice, suggesting that DNA methylation of Dnmt3 targets represents an adaptive mechanism against the cellular consequences of stress or cocaine. This and related hypotheses will continue to be tested and provide important insight into the long-term cellular mechanisms of addiction.

It remains to be seen to what degree epigenetic mechanisms are engaged following exposure to drugs in addition to cocaine. However, the escalation of studies in this area underscores the importance of genetic mechanisms of addiction, and will continue to provide important insight into mechanisms of reward learning, as well as the long-lasting changes responsible for relapse to drug seeking.

CONCLUSIONS

Chronic exposure to drugs of abuse leads to enduring changes at the levels of behavior, neural circuitry, synaptic strength, dendritic size, cellular signaling, and gene expression. Presumably, these levels of analysis share a functional relationship; thus, an understanding of cellular and molecular mechanisms of addiction can provide insight into circuit and behavioral changes. As such, identification of the cellular mechanisms responsible for controlled, social drug use, as well the ability of drugs to usurp adaptive reward learning in exchange for maladaptive drug seeking, remains essential as we move toward development of effective behavioral and pharmacotherapeutic treatments for addiction.

DISCLOSURES

52 | THE GENETIC BASIS OF ADDICTIVE DISORDERS

DAVID GOLDMAN

Addictions share mechanisms subject to both genetic and environmental influences. Conversely, environmental, genetic, and psychophysiological vulnerability factors and individual choice play important, but differing roles, in addicted individuals, including ones addicted to the same agent. The inheritance of addictions ranges from moderate (40%) to high (70%), representing consequences of alleles (sequence variants) shared by descent. At all phases of the multistep process of addiction, gene \times environment interactions, including correlations between gene and environment, shape vulnerability. However, neither exposure nor consequent dependence necessarily leads to addiction. Many individuals use addictive agents without becoming addicted. Physical dependence (tolerance) often occurs to drugs administered in the course of medical care, followed by withdrawal and no consequent addiction.

Genetic susceptibility and resilience to addiction are attributable to alleles that are both substance-specific (e.g., variants that alter metabolism) and non-specific. Alleles that moderate reward, stress resiliency and executive cognitive control are among the factors that are non-specific to any particular agent. Cross-inheritance and shared etiology also partly explain the tendency of addictions to co-occur with other psychiatric diseases. From verified examples, alleles that alter propensity and resilience to addiction are diverse in molecular mechanisms, as well as in their abundances and effect sizes. Some are common, but most are probably rarer, and the strongest effects are probably produced by rarer alleles.

The genetic evolutionary context of addiction is poorly understood. However, there is as yet no evidence that vulnerability and protective alleles were directly selected by addiction itself, except in artificially selected model organisms wherein it must be admitted that the effects of selection are often surprisingly rapid. However, certain alleles that alter propensity to addiction appear to have been maintained at high frequency by balanced selection. These include alcohol metabolic enzyme variants in *ADH1B* and *ALDH2*, as well as alleles that alter cognition and emotion. Many common alleles that increase liability probably have counterbalancing positive values, if not in modern times then in the past. Certain genes influencing propensity to addiction can be accurately described as genes “for” behavior, although their effects on vulnerability to addictions may be secondary.

Three pathways to identify genes that alter propensity to addictions are candidate gene approaches, candidate gene approaches targeted to relevant psychophysiology and genome-wide approaches. The latter two paradigmatic methods

have been partially successful and are to some extent convergent, as genome-wide approaches are applied to psychophysiology and mechanisms of genes identified by GWA (genome-wide association) are defined. The combination of genetic tools with neuroscience techniques such as brain imaging enables exploration of mechanisms by which alleles alter risk. Functional alleles that partially account for interindividual differences in stress resiliency, and thereby addiction, are found at *SLC6A4*, *COMT*, *NPY*, and *MAOA*, all having been linked to activity of brain regions mediating stress response and emotion. Linkage analysis, including GWA, has enabled the hypothesis-free search for common variants moderating vulnerability. Via GWA, Asp398Asn, a common missense variant of *CHRNA5*, was discovered to influence risk of smoking and lung cancer consequent to smoking. Confirmation of this discovery validated the potential of GWA in addictions. However, at an early stage when GWA has been applied to relatively small numbers of samples, crudely phenotyped samples, and samples of heterogeneous origins, more than 95% of the genetic variance (heritability) in propensity remains unexplained, and replicated gene findings are primarily from candidate gene analyses.

The predictive value of any particular allele or genotype is low. The primary reasons for mismatch between heritability and strength of effect of individual alleles are twofold. Variation in several psychophysiological processes including drug metabolism, sensation, reward, anxiety and resilience, and executive cognition contribute to vulnerability, and each is itself a manifestation of the action of many genes in contexts of exposure. Second, addictions are currently defined as end-stage diagnoses, and the effects of genetic variants are diluted or confounded when queried against an amalgam of phenotypes with different etiologies. Recent advances in genomics including massively parallel sequencing at low cost have opened the possibility for systematic searches for rare variants that may have stronger effects. For example, stop codons moderating addiction through the mechanism of impulsivity, also a risk factor in other psychiatric diseases, have been discovered within both *MAOA* and *HTR2B*.

The predictive value of genotypes for treatment response will determine their value for development of personalized medicine, one goal of gene identification being individualization of prevention and treatment of addictions. Genotypes may have different predictive value for treatment response than for diagnosis, and the use of genetic predictors will require controlled studies with predefined treatment outcomes. However, and in advance of these prospective clinical trials, genotypes have been identified that appear useful for predicting treatment

response for alcoholism and nicotine addiction. For example, an *OPRM1* variant is associated with treatment response to naltrexone in alcoholism, and altered brain reward responses.

Addictions, including substance use disorders (SUDs), follow exposure to a wide variety of agents, and addictions are a worldwide phenomenon sparing no culture. Exposure to a diverse array of agents may lead to an *addicted state* through partially overlapping neurobiological pathways. However, although most or all people are exposed to addictive agents at multiple points in their lives only a minority become addicted. Even tolerance and dependence are not equivalent to addiction. For example, most patients receiving opioid drugs do not become addicted, although temporary tolerance and dependence are elicited. In both vulnerable and resilient (less vulnerable) individuals, repetitive exposures induce long-lasting neuroadaptative changes that alter behavior. In some individuals, tolerance, craving, withdrawal, and motivational shifts lead to persistent and uncontrolled patterns of use that constitute addiction. Addiction accesses different vulnerability mechanisms. Initially, motivation to drug seeking is driven by impulsivity and positive reward. Later, compulsivity and negative affect may more strongly motivate use. As defined in DSM IV, and probably in the next DSM, addictions are “end-stage” diagnoses based on behavior that began to emerge years earlier from preexisting vulnerability and exposure. The trajectory of addiction culminates in long-lasting and potentially irreversible neuroadaptative changes and constellations of behaviors and social impairments. Both the probability of initial use and progression are influenced by the nature of the addictive agent including its mode of administration, distribution, metabolism, and psychoactive properties, by intrinsic factors such as sex, age, age at first use, preexisting addictive disorder or other mental illness, and by extrinsic factors including parenting and childhood adversity, peer influences, social support and drug availability. Genes act within a matrix of factors.

Progress has been made to define clinical categories of addicted individuals who may also be more likely to share mechanisms of vulnerability, and both developmental trajectory and personality features have been incorporated into these schema. Genetic liability to addiction varies both quantitatively and qualitatively across the lifespan. Quantitatively, peer influences and family environment are most important for initial exposure and early patterns of use, and genetic factors and psychopathology are more important in the transition to problematic use. During adolescence the heritability of addiction rises, peaking in young adulthood and declining again in older age (Kendler et al., 2008). Qualitatively, childhood conduct disorder and antisocial behavior are associated with early abuse and dependence. These behaviors were incorporated into the Type I/Type II typology for alcoholism together with early age of onset and personality factors reflecting variation in brain function (Cloninger, 1987). The role of conduct disorder and antisociality on the one hand and anxiety on the other have long been recognized and some addiction-associated behaviors have been broadly described as internalizing (associated with behavioral inhibition), and others as externalizing (associated with disinhibition). However, regardless of whether they are antisocial and impulsive, addicted individuals, for example

alcoholics, tend to be anxious (Ducci et al., 2007). Overall, their greater anxiety may be caused by drug-induced allostatic change. Therefore it is important that adoptive studies and twin studies have pointed to the genetic transmission of vulnerability via both the externalizing and internalizing domains of behavior.

INHERITANCE OF ADDICTIONS

Family, adoption, and twin studies convergently establish the existence of genetic variation that determines genetic liability to addictions. Weighted mean heritabilities for addictions computed from large, epidemiologically ascertained cohorts of twins point to moderate to high heritabilities (0.39–0.72) (Goldman et al., 2005). These heritability values are within-population estimates and have not been deflated by including pairs of related individuals who would specifically capture variation in vulnerability that occurs across countries or across time, for example when an addictive agent becomes more readily available and vulnerability shifts as it might for example when use of an addictive agent is legalized. Both “no pathological drug use” and “initiation of use” are heritable, indicating that genetic variation also influences initiation (Kendler et al., 1999). Paradoxically, easing access to addicted agents may increase heritability by decreasing the environmental variance.

MODE OF INHERITANCE

Heritability directly implicates genes in causation; however, any particular heritable trait may be intractable to genetic analysis because of complexity of causation. In contrast, less heritable traits that are more narrowly defined or closer to the action of a gene may be more successfully parsed at the level of specific genetic loci that contribute to them. Therefore, two somewhat interrelated themes of this chapter are the mode of inheritance of addictions and the deconstruction (or redefinition) of addictions using neuroscience phenotypes on which genes may act more directly.

Genetic complexity arises from incomplete penetrance of alleles, phenocopies, variable expressivity, pleiotropy, gene-environment interactions, genetic heterogeneity, polygenicity, and epistasis. An epistatic model in which combinations of genetic variants determine addiction would seem consistent with the complex molecular architecture of the brain. However it is also possible that the molecular complexity of behavior could lead to a high degree of heterogeneity of genetic causation, with additive effects of the vulnerability variants. Epistatic interaction between alleles will tend to produce high MZ:DZ (monozygotic/dizygotic) twin concordance ratios, with identical twins resembling each other on the basis of common sharing of a constellation of variants but dizygotic twins being discordant because of the likelihood that some essential element of the constellation is not transmitted to the co-twin, disrupting the genotypic combination. For example if several dominantly acting alleles at different loci are required, the odds of this genotype being shared in a monozygotic co-twin would

be 100% but the odds of sharing in a dizygotic co-twin (or full sibling) would be $(1/2)^n$, where n is the number of alleles. Incompatible with the epistatic model, the risk of addiction in dizygotic twins and first-degree relatives of addicted probands (index cases) has been found to fall off proportionally to degree of relationship, rather than exponentially. For example, MZ:DZ concordance ratios are approximately 2:1 for various addictive disorders (Goldman et al., 2005). Also there is enhanced risk in individuals with first-degree relatives who are addicted, regardless of whether they have been adopted away in infancy. Two factors complicating this interpretation of MZ/DZ ratios are assortative mating, which can increase the likelihood of multilocus allelic combinations in first degree relatives, and multiple allelic combinations that might lead to the same phenotype. However, under the epistatic model there is as yet no good explanation for the linear correspondence between risk and degree of relationship to an affected proband.

A critical test of the epistatic model is the additivity of alleles with proven relationship to addiction. However, as yet few addiction genes have been identified. Perhaps by chance, but perhaps because additively acting loci are in some way more easily discovered, gene \times gene interactions in addictions are thus far consistent with the genetic heterogeneity and gene-gene additivity models. Two missense variants in *ADH1B* (Arg48) and *ALDH2* (Lys487) diminish risk of alcoholism via alcohol-induced flushing. Surprisingly, these alleles act additively (Thomasson et al., 1991) despite the fact that they affect consecutive steps in alcohol metabolism. Functional loci within *HTR3B* and the serotonin transporter (*SLC6A4*) together alter serotonin function but appear to act additively on risk for alcoholism comorbid with other SUDs (Enoch et al., 2011). Two variants associated with nicotine addiction, one in the *CHRNA5-CHRNA3-CHRNA4* nicotinic acetylcholine receptor subunit cluster found by GWA and the other in the *TTC12-ANKK1-DRD2* cluster, which includes *DRD2*, a dopamine receptor important in nicotine reward apparently, also appear to act additively (Ducci et al., 2011). The discovery of epistatic interactions in addiction may await the detection of novel loci as well as measurement of new addiction-related phenotypes on which allele effects may be epistatic; however, the quantitative genetic (transmission) and molecular genetic (gene action) data available thus far do not support reconceptualization of addiction to take into account epistasis.

CHANGES IN GENE EFFECTS ACROSS THE LIFESPAN

The risk, heritability, and specific factors that determine vulnerability to addiction vary across the lifespan and during development. Heritabilities of alcoholism, cannabis addiction, and nicotine addiction are low in early adolescence but gradually increase, peaking in young adulthood and declining with older age (Kendler et al., 2008). Reciprocally, family environment is most important in childhood and declines as adolescents increasingly shape their social environment. For addictions, and perhaps paradoxically, genotype becomes relatively more important as people are able to make their own choices and shape their environments in line with intrinsic predisposition.

Another explanation for the greater importance of inheritance in older children is that some genetic factors are important only after repetitive exposure to addictive agents. An intriguing possibility is that some alleles only alter responses of the adult or adolescent brain. *CHRNA5-CHRNA3-CHRNA4* genotypes have been reported to exert a stronger effect on smoking behavior in adulthood than in adolescence and to moderate the risk of a severe nicotine addiction in people who have already initiated use. In contrast, the *TTC12-ANKK1-DRD2* and *MAOA* genes appear to influence personality characteristics, such as novelty seeking and impulsivity, that promote initiation of use (Ducci et al., 2012).

SHARED AND UNSHARED INHERITANCE

Addictive disorders tend to co-occur (Kessler et al., 1997). However, the observation of comorbidity is insufficient to demonstrate causality. For example, comorbidity could be caused by common environmental factors, or the first addiction could increase the risk of the second. Comorbidity sometimes can arise because of the pleiotropic action of a single allele—one variant/multiple manifestations. The question of shared and agent-specific pathways to addiction will ultimately be answered at the level of individual genetic loci, some that alter risk for addiction to a specific agent and others that alter a mechanism, or mechanisms, common to multiple addictive agents. Substance-specific genes include metabolic enzymes for alcohol (*ALDH2*, *ADH1B*) and nicotine (*CYP*) as well as genes encoding gatekeeper molecules such as drug receptors (e.g. nicotinic receptors). Other genes influence mechanisms intrinsic to the action of multiple addictive agents or modulate an individual's likelihood of exposure or ability to quit.

Diverse aspects of addiction neurobiology that have been discovered to be modulated by functional genetic variation include anxiety, resilience, impulsivity, and reward. The genes implicated include rare stop codons and other functional variation in monoamine oxidase A (*MAOA*) and the serotonin *HTR2B* receptor, a serotonin transporter (*SLC6A4*) VNTR (*HTTLPR*) and a catechol-*O*-methyl transferase (*COMT*) missense variant Val158Met. These loci are also implicated in the shared genetic liability between addictions and other psychiatric diseases, and connect the inheritance of addictions to variation in specific aspects of brain function. Nevertheless, few genes influencing addiction vulnerability have been discovered, and therefore most knowledge of the relative importance of shared and unshared factors in inheritance is from quantitative studies of inheritance. Fortunately, these quantitative studies have been highly informative for the overall importance of shared and unshared genetic vulnerability factors.

Adoption, family, and twin studies distinguish between correlation and causation by measuring cross-transmission (Goldman and Bergen, 1998). Several large, methodologically sound twin studies have detected substantial cross-transmission of risk of addictions. For example, the risks of alcoholism and smoking are cross-transmitted. There is apparently more than one shared factor. In the Virginia twin sample two shared factors were found, one being identified as an illicit agent factor relevant to cannabis and cocaine dependence and the second

being a licit agent factor mainly explaining vulnerability to alcohol, caffeine, and nicotine (Kendler et al., 2007).

Addictions are also cross-transmitted with other mental illnesses with which they are frequently comorbid. Addictions are cross-transmitted with externalizing disorders, including conduct disorder (CD), antisocial personality disorder, borderline personality disorder, and attention deficit hyperactivity disorder (ADHD) (Kendler et al., 2003; Krueger et al., 2002). Preexisting CD and ADHD are risk factors for addiction. Anxiety and depression may be preexisting or consequent (Kendler et al., 2003). Some longitudinal studies have also found that anxiety disorders and anxiety-related personality traits predict alcohol problems in adolescents and young adults. The connection between addictions and internalizing disorders is interwoven with the role of genes in resilience, stress exposure being a powerful determinant of both addictions and internalizing disorders, as discussed next.

GENE × ENVIRONMENT INTERACTION IN ADDICTION

Two ways gene–environment independence is frequently violated are gene by environment interaction and gene by environment correlation.

GENE × ENVIRONMENT CORRELATION

Genotypes modulate the likelihood of exposures leading to correlation (r) of gene and environment, and creating a “genetics of the environment.” Note that gene × environment correlation is caused by a unidirectional interaction, environment not modulating genotype, although it may lead to widespread epigenetic change modulating gene expression. An example of gene × environment correlation is the ability of *CHRNA5* Asn398 to increase risk of lung cancer (Thorgeirsson et al., 2008) via its influence on heavy smoking, thereby leading to increased exposure of the lung to carcinogens. However, and as a possible example of pleiotropy, nicotine could also directly modulate cancer risk at the cellular level.

GENE × ENVIRONMENT INTERACTION

The effect of an environmental exposure can be modified by genotype (Caspi and Moffitt, 2006). Again, gene × environment interaction is caused by a unidirectional interaction, environment not modulating genotype, although it may lead to widespread epigenetic change modulating gene expression. Childhood adversity is an important risk factor for addiction and comorbid diseases, including antisocial personality disorder (ASPD), CD, borderline personality disorder, and anxiety disorders. As discovered by Rutter and others, not all people exposed to severe early trauma develop psychopathology, indicating differences in resiliency. Loci modifying stress resiliency are likely to be numerous and are at this point largely unknown. Several that have been identified are monoamine oxidase A (*MAOA*) (Ducci et al., 2008), the serotonin transporter (*SLC6A4*) (Caspi et al., 2003; Hariri et al., 2002), *COMT*

(Zubieta et al., 2003), neuropeptide Y (*NPY*, an anxiolytic neuropeptide) (Zhou et al., 2008), and *FKBP5* (an accessory protein for the glucocorticoid receptor) (Binder et al., 2008). These are functional loci, and most have been demonstrated to alter the relevant molecular and neuroscience-based intermediate phenotypes for stress response and emotion, as will next be discussed.

INTERMEDIATE PHENOTYPES IN ADDICTION

One strategy to discover gene effects for complex diseases that are amalgams of distinctly different pathologies is to split the lumped disease phenotypes or deconstruct them into etiologic components.

If it were readily feasible to parse addictions into subtypes based on clinical features, this would undoubtedly have already been done, because of the burden to society that addictions pose, and commendable efforts have been made in this area. However only a few clinical subtypes (e.g., Cloninger Type I/Type II) have been identified; these subtypes are themselves amalgams. Additional measures are needed. These include measures that do not reflect causal processes but are indicators of severity or response; for example, neuroimaging and neuropsychological indicators can track long-term damage consequent to exposure and that may impede recovery. These can be termed biomarkers. Other measures are intermediate phenotypes that access mediating mechanisms of genetic and environmental influences on the brain. For addictions these would include measures of emotional response and stress resiliency, reward, executive cognitive control and impulsivity, and metabolism and pharmacodynamic response. Furthermore, heritable, disease-associated, intermediate phenotypes are termed endophenotypes (Gottesman and Gould, 2003). Whether a particular biomarker, intermediate phenotype, or endophenotype is useful clinically or in genetic studies depends on multiple factors, including measurement properties, frequency, sensitivity, specificity, independence from other measures, and whether the measurement can be practically obtained from living patients or populations and families seen in the clinic or that might be enrolled in genetic studies.

Alcohol-induced flushing is an intermediate phenotype that is practically useful both clinically and for genetic studies. It is a protective alcohol-related endophenotype influenced by specific alleles mediating variation in ethanol metabolism, as will be discussed. Flushing is a clinically accessible, pharmacokinetic endophenotype that can be more thoroughly characterized and explained via psychophysiological measures, assays of alcohol metabolism, and genotyping of the variants that alter alcohol metabolism. Low pharmacodynamic response to alcohol is a genetically influenced intermediate phenotype that predicts enhanced risk (Heath et al., 1999). Level of response is mainly a result of intrinsic pharmacodynamic variation in neuronal response to alcohol rather than variation in metabolism (Schuckit et al., 1998). Some functional variants have been associated with low response to alcohol, including variants in the serotonin transporter gene (*SLC6A4*) and the gene

encoding the $\alpha 6$ subunit of the gamma-aminobutyric acid receptor A (*GABRA6*) (Hu et al., 2005). However, the genetic origins of variation in alcohol response are largely, or even entirely, unknown.

Many other intermediate phenotypes relevant to addictions are known, and several have been shown to be more strongly influenced by gene action than addiction itself. Focusing on brain-related measures, electrophysiologic, neuropsychologic, neuroendocrinologic, and neuroimaging measures have been tied to addictions. Electrophysiologic measures including both baseline EEG and evoked responses are both addiction-associated and heritable, baseline EEG power in different spectral bands being highly heritable (van Beijsterveldt and van Baal, 2002). Neuroimaging accesses the structure and activity of circuits underlying emotion, reward, and craving. Studies incorporating neuroimaging have indirectly linked genes to processes and neuronal networks relevant in addiction. Interindividual differences in emotional response are predicted by amygdala activation after exposure to emotional imagery and stressful stimuli, and thus the study of fMRI-detected metabolic activation of amygdala and functionally related regions such as hippocampus has captured effects of genes that influence emotion (Bevilacqua and Goldman, 2011). As will be discussed, *SLC6A4* and *MAOA* are among the genes influencing emotion and more strongly amygdala activation. Activations of frontal cortex by executive cognitive tasks are modulated by genetic variants of both *COMT* and *MAOA*, thus providing an important clue, again by indirect means, to impairments in impulse control that are important in predisposition to addiction. Recently it was discovered that a functional polymorphism of the mu-opioid receptor gene (*OPRM1 Asn398Asp*) modulates activation of the ventral striatum by reward, and this same polymorphism has directionally consistent effects on naltrexone response in alcoholics treated with this medication (Anton et al., 2008; Oslin et al., 2003) and controversial effects on risk of addictions. Depending on the properties of intermediate phenotypes including proximity to gene action, measurement error, and specificity, they offer an important starting point for unraveling the genetics of addiction, and arguably most of the successes in gene identification are directly tied to intermediate phenotypes and functional alleles that alter them in ways that are directionally consistent with physiology.

GENE IDENTIFICATION FOR ADDICTION

In candidate gene studies, genes influencing relevant physiology are rationally selected based on pathways, mechanisms and molecules of addiction or the pharmacokinetics and pharmacodynamics of the drug. A functional locus may be identified and specifically studied, representing a candidate locus, or allele. In genome-wide studies, the genome is interrogated in hypothesis-free fashion via an expanding array of methods including GWA, linkage in families, and genome and exome sequencing. For addictions, genes have primarily been identified via the candidate gene approach. However, GWA and deep sequencing has yielded several “hits,” including a functional locus altering nicotine addiction vulnerability. Both methods

are increasingly convergent as detailed information is developed on the locations of functional elements, for example in the ENCODE project, which aims to identify the functional elements genome-wide.

ALCOHOL METABOLIZING GENES:

ADH1B AND *ALDH2*

Polymorphisms of alcohol dehydrogenase IB (*ADH1B*) and aldehyde dehydrogenase 2 (*ALDH2*) influence alcohol consumption and risk of alcohol use disorders as well as damage secondary to alcohol exposure. In adults these enzymes catalyze consecutive steps in ethanol metabolism although other enzymes including catalase and cytochrome P450 also play significant roles. Acetaldehyde, the product of ADH, is toxic and potentially releases histamine thereby triggering flushing, an aversive reaction that can include headache, nausea, and palpitations. If aldehyde dehydrogenase is blocked by medications including metronidazole and disulfiram (a drug that is actually used to help alcoholics maintain abstinence), flushing follows the ingestion of small quantities of alcohol. Acetaldehyde is a mutagen, leading to increased risk of upper GI cancer in moderate drinkers who carry the dominantly acting *ALDH2* Lys487 allele, as some 500 million people do (Brooks et al., 2009).

At *ADH1B*, the His48 allele increases catalytic efficiency of the enzyme. In East Asian populations both *ADH1B* His48 and *ALDH2* Lys487 are highly abundant, and His48 is present in many individuals of Jewish ancestry. A protective effect of His48 on alcohol dependence has been demonstrated in European and African populations as well as East Asians, in whom this relationship was originally observed (Bierut et al., 2012), and both the *ADH1B* and *ALDH2* flushing alleles are associated with enhanced risk of upper GI cancers.

The *ADH1B* and *ALDH2* His48 and Lys487 alleles are ancient in the human lineage. They occur on characteristic and highly diverged haplotypes at these genes, are found at high frequency in particular populations, and are unlikely to have been selected to high frequency to protect against alcoholism. It has been hypothesized that they have been selected to high frequencies in East Asians because of their ability to alter susceptibility to protozoal infections, including infections of the gut such as amebiasis (Goldman and Enoch, 1990). This hypothesis is unproven; however, metronidazole is used to treat protozoal infections and potentially inhibits aldehyde dehydrogenase.

GENES MODERATING MONOAMINE NEUROTRANSMITTERS

Monoamine neurotransmitters modulate emotionality, cognition, and reward. Therefore, it would be predicted that genes that contain functional loci that can alter function of monoamine neurotransmitters should alter liability to addiction. Congruently, catechol-*O*-methyltransferase (*COMT*) and the serotonin transporter (*SLC6A4*), and *MAOA* (as already mentioned) have been implicated in vulnerability to addiction and other psychiatric diseases that share these etiologic mechanisms.

COMT plays an important role in the regulation of dopamine in the prefrontal cortex and metabolizes dopamine,

norepinephrine, and other catechols in various brain regions. The Val158Met polymorphism alters COMT activity via an effect on enzyme stability, the Met158 allele being three- to fourfold less active (Lachman et al., 1996). Because of the higher activity of the Val158 allele, it is predicted that it leads to lower frontal dopamine levels, and it has been associated with dopamine-modulated cognitive differences including inefficient frontal lobe function as seen by neuroimaging (Egan et al., 2001). Amphetamine improved executive cognitive function in val/val homozygotes, but not met/met homozygotes indicating that baseline dopamine levels of val/val homozygotes may be suboptimal for frontal cortical function (Mattay et al., 2003). Reciprocally, and leading to *COMT* being called a Warrior versus Worrier gene (Goldman, 2012), the Met158 allele has been associated with decreased stress resilience and increased emotionality, including anxiety in women (Enoch et al., 2003). Met 158 was associated with increased pain–stress induced brain activations as well a slower pain threshold and stronger affective response to pain (Zubieta et al., 2003). The evidence for association of *COMT* to addiction is mixed, including negative studies, studies implicating Val158, and others implicating Met158 (Tammimaki and Mannisto, 2010). These divergent results may be reconciled if the Val158Met polymorphism, which does affect behavior, has countervailing effects on different mechanisms of vulnerability to addiction. The Val158 allele was in excess among methamphetamine, nicotine, and polysubstance addicts (Vandenbergh et al., 1997). On the other hand, the Met158 allele was more common in late-onset alcoholics in Finland (Tiihonen et al., 1999).

Via reuptake, the serotonin transporter (SLC6A4) regulates synaptic serotonin. Reflecting the diverse effects of this neurotransmitter on mood, appetite, and impulse control, serotonin-specific reuptake inhibitors are widely prescribed for a variety of different mental illnesses. HTTLPR, a polymorphism located in the promoter region of this gene and involving variable numbers of an imperfect repeat located in tandem (a VNTR), probably remains the most studied locus in psychiatric genetics. Three relatively common HTTLPR alleles are functional, altering transcriptional efficiency (Hu et al., 2006) and expression of the transporter expression in the brain (Heinz et al., 2000). Reduction of function HTTLPR genotypes has been associated with anxiety, depression, and alcoholism, but inconsistently in the case of each disease. Overall, the predictive effect of HTTLPR on any clinically measured behavior is modest. However, the effects appear stronger in the context of stress exposure moderating impact of stressful life events on depression and suicidal behavior. Carriers of low-transcribing HTTLPR genotypes exhibited more depression and suicidality following stressful life events (Csapi et al., 2003).

Although contradictory meta-analyses have not clarified the GxEnvironment relationship of HTTLPR to behavior, neuroscience evidence has supported a role for *HTTLPR* regulation of emotion and response to stress, and provided clues to mechanism. Low activity HTTLPR genotypes predict stronger metabolic responses of brain regions intrinsically involved in processing of emotional stimuli and predict smaller volumes of some of these structures and diminished connectivity with regions that modulate their activity. The low-activity “s” allele predicts

increased amygdala reactivity to emotional stimuli under the passive viewing condition (Hariri et al., 2002) and also predicts reduced amygdala volume and reduced functional coupling between the amygdala and ventromedial prefrontal cortex (Heinz et al., 2005). The effects of reduction of function serotonin transporter alleles on emotion have been validated in two animal models. An orthologous polymorphism designated rs-5HTTLPR is found in the Rhesus macaque (*Macaca mulatta*). In macaques, early life stress exposure together with rs-HTTLPR again leads to enhanced stress response and emotionality later in life. Carriers of the low-expression genotype that were separated from their mothers at an early age were more stress reactive and drank more alcohol later in life (Barr et al., 2004), a difference that appears to be in part mediated by the hypothalamic–pituitary–adrenal axis.

GENOMIC APPROACHES IN ADDICTIONS

GENOME-WIDE ASSOCIATION

Genome-wide association is a genomic approach to the analysis of genetically influenced traits that queries all genes and unknown functional genetic elements in a hypothesis-free way for their potential effects. The importance of hypothesis-free, global approaches is emphasized by discoveries by the ENCODE consortium and others that there are many previously unrecognized functional elements in the genome, and many of these have poorly understood regulatory functions. Furthermore, GWA, when performed with appropriate attention to confounds such as ethnic stratification and other systematic errors that can upward bias statistical results, and with confirmation and validation, for example by identification of the functional locus, is a direct route to making causal inferences about the roles of genes in behavior. In other words, the implication of the genetic linkage is more than correlational: a locus, or one nearby the linked locus, modulates the behavior. The genome-wide significance threshold is usually approximately 10^{-8} corresponding to a single locus p value of 0.05. Within this statistical framework, GWA will detect the effects of common alleles (MAF >5%) of at least moderate effect (e.g., odds ratio >1.2), requiring thousands of cases and controls for such small effect sizes. As later discussed, less common alleles have been linked to addictions by resequencing and by linkage studies in families and founder populations in whom particular rare alleles are common. A salient advantage of GWA is that data can be combined across studies using a common pool of SNPs that are either directly genotyped or imputable.

Addictions GWA has yielded a confirmed functional locus for nicotine addiction, located in the *CHRNA5-CHRNA3-CHRNA4* gene-cluster on chromosome 15 (Bierut et al., 2007; Thorgeirsson et al., 2008). These genes encode subunits of the nicotinic acetylcholine receptor (nAChR), which is a ligand-gated ion channel activated by nicotine. A functional locus influencing nicotine addiction was identified in this region. *CHRNA5* Asp398Asn alters nicotine dependence/heavy smoking, pleasurable response to smoking, smoking quantity, and smoking persistence (Bierut et al., 2007; Thorgeirsson et al., 2008), as well as secondary susceptibilities to lung cancer and

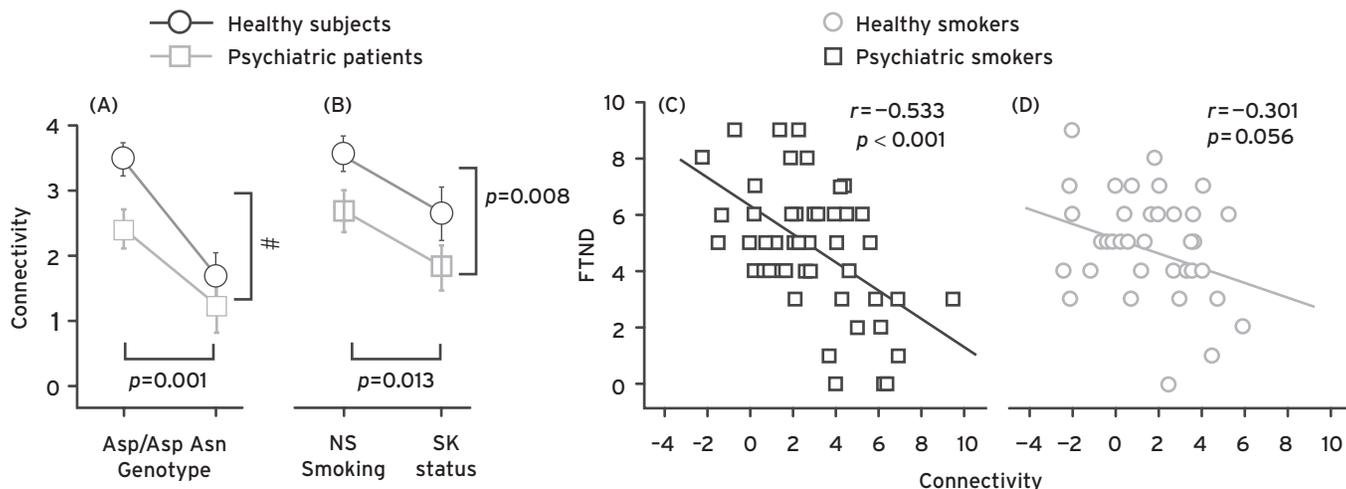

Figure 52.1 The *CHRNA5* Asn398 allele, identified as a risk factor in nicotine addiction by GWA, predicts weakness of a dorsal anterior cingulate/ventral striatal circuit whose weakness predicts nicotine craving. Right panel: Strength of the circuit, as measured by resting state functional connectivity (rsFC) predicts nicotine craving. Middle panel: the *CHRNA5* Asn398 allele predicts smoking status. Left panel: The Asn398 allele predicts weaker connectivity of the circuit. (From Hong et al. (2010). A genetically modulated, intrinsic cingulate circuit supports human nicotine addiction. *Proc Natl Acad Sci U S A.* 107(30):13509–13514.)

vascular disease (Amos et al., 2008) and smoking cessation (Munafo et al., 2011). The locus has a modest effect on addiction itself. Each copy of Asn398 accounts for ~0.5% of the variance in cigarettes smoked/day but more strongly predicts the strength of connectivity between anterior cingulate and ventral striatum (Hong et al., 2010) a circuit that in turn modulates nicotine craving, as shown in Figure 52.1.

Furthermore, $(\alpha4\beta2)_2\alpha5$ receptors that differed only in containing the *CHRNA5* Asn398 allelic form had altered response to agonist. Other studies have shown that Asp398 lowers calcium permeability and increases short-term desensitization, but does not alter receptor sensitivity to activation (Kuryatov et al., 2011). Whether the Asp398Asn polymorphism alters nicotine response or connectivity of reward circuits, or both, remains an open question.

For alcohol consumption, a meta-analysis of GWA in 12 European populations, totaling 26,316 individuals, identified the autism susceptibility 2 gene (*AUTS2*). The SNP implicated may moderate *AUTS2* expression in prefrontal cortex, and expression of *AUTS2* (Schumann et al., 2011). Several genome-wide significant loci were identified for resting EEG traits that are addiction-associated (Hodgkinson et al., 2010), illustrating the power of combining GWAS with intermediate phenotypes.

RARE AND UNCOMMON VARIANTS

The common disease/common variant paradigm has been disturbed by the failure of GWA to account for a substantial portion of inherited variation of complex disease, and by discovery of extensive rare and uncommon genetic variation in humans. These rarer variants of stronger effect may account for a large portion of genetic vulnerability to common diseases. Advances in DNA sequencing technologies facilitate the detection of rare variants; however, the full impact of this approach depends on study of effects of these variants in founder populations and families where they are common, statistical combination of

multiple rare allele with the same probable functional impact, and further development and use of other convergent information such as evidence of effect on molecular function or effects of homologous variants in model organisms including the mouse.

Rare variants relevant to addiction are known within the serotonin receptor 2B gene (*HTR2B*) (Bevilacqua et al., 2011), *MAOA* (Brunner et al., 1993), and *CYP*, the *CYP2A6* variants even predicting fMRI responses to smoking cues (Tang et al., 2012). Both *HTR2B* and *MAOA* influence impulsivity, findings involving these genes having close parallels in animal models, and the *CYP* alleles have pharmacogenetic effects on response to nicotine that are also lawfully expected due to alteration of nicotine metabolism.

MAOA, located on the X chromosome, encodes monoamine oxidase A, which metabolizes monoamine neurotransmitters including norepinephrine, dopamine, and serotonin. The main effect of a common allele leading to lower *MAOA* expression is enhanced impulsivity, an important mediating trait in addictions. A stop codon found in eight males in one Dutch family led to impulsivity, carrier females being unaffected (Brunner et al., 1993) A common *MAOA* variable-number tandem repeat polymorphism can lead to lower *MAOA* enzyme activity and has been a model for understanding the role of context in gene effects on complex behaviors in which impulsivity plays an important role. Gene \times environment interaction was observed in a longitudinally studied cohort of boys, with the lower expression allele and childhood adversity together predicting vulnerability to conduct disorder (Caspi et al., 2002) as confirmed by others. In women, who unlike males can be heterozygous for the low activity *MAOA* allele, results are mixed, and may depend on severity of adversity. A parallel G \times E effect on ASPD was observed in a sample of Native American women with a combined effect of childhood sexual abuse and low activity *MAOA* genotype on risk of both alcoholism and ASPD (Ducci et al., 2008), and an allele dosage effect in the presence of childhood sexual abuse. Complicating

the relationship of MAOA to impulsivity and aggression are other releasers of these behaviors. Testosterone independently predicts aggression, but males with high expression MAOA genotypes did not show the effect, which was limited to males with the low expression MAOA genotype that is apparently permissive for this behavior (Sjoberg et al., 2008). Similarly, MAOA genotype can interact with alcohol consumption, another disinhibitor of behavior (Tikkanen et al., 2009), and as will next be described, alcohol consumption also leads to impulsive aggression in carriers of a stop codon in *HTR2B* (Bevilacqua et al., 2010).

HTR2B is a serotonin receptor that, in part because of genetic studies implicating it in behavior, has been discovered to be widely expressed in the brain wherein it is found on approximately 40% of dopamine neurons in VTA, where it regulates dopamine release (L. Maroteaux, submitted). A stop codon disabling *HTR2B* (Q20*) is common in Finland, but rare or absent in other populations surveyed worldwide. The stop codon is linked to severe impulsive aggression, ASPD, and alcoholism, with an effect on impulsive aggression that is strongly modulated, or dependent, on inebriation. This *HTR2B* stop codon was discovered by sequencing impulsive and aggressive offenders who underwent psychiatric evaluation because of the extreme nature of their crimes. The stop codon is several times as common in these individuals as in Finnish controls, and is cotransmitted with impulsive behavior, including alcoholism, in families. Carriers of the stop codon who committed violent crimes did so while inebriated with alcohol, and were cognitively normal. In the Finnish population, most carriers are unaffected, indicating the *20 is a factor in impulsive behavior and addiction but not sufficient itself. *Htr2b* *-/-* mice exhibit higher novelty seeking and impulsivity, and enhanced responses to activating drugs including a D1 dopamine receptor agonist and cocaine.

Variants, many of which are rare, of *CYP2A6* (cytochrome P450, Family 2, subfamily A, polypeptide 6) alter risk of nicotine addiction via metabolism, the enzyme accounting for 70% of initial nicotine metabolism.

CONCLUSIONS

Vulnerability to addictive agents is widespread because addictive agents activate natural reward systems and abuse is kindled by variations in executive cognitive control and emotional response that are widespread in populations. Addictive agents of a variety of types are readily accessible, and in fact access is increasing, with legalization of gambling and marijuana, development of designer drugs and new ways to administer drugs, and the nearly universal availability of the internet and electronic devices to which people can become addicted. For these reasons, it seems paradoxical that addictions are moderately to highly heritable. However, there are many sources of resilience against addiction. These include social norms, positive family and peer influences, the diversity of rewarding activities available to most people, and conscious decisions to reduce harm and limit exposures. Because there are many routes to addictions, protective and predisposing genetic variants have diverse

actions. Furthermore, no single genetic variant is likely to be highly predictive for an addiction, and indeed no highly predictive locus emerged from GWA studies that provide a global view of the relative contribution of individual loci.

Our state of knowledge of the complex causal landscape of genetic effects on addictions is limited and insufficient for diagnostic prediction. However, the status quo is subject to change. Although it would be unwise to predict a timeline, it is likely that addictions will be redefined via a combination of neuroscience-based measures, improved understanding of the behavioral interface with the environment, and by cataloging the genetic variations that influence risk and understanding their mechanisms.

Addiction is a categorical end-diagnosis, assuming a cutoff between normal and abnormal, although many non-addicted individuals have the same predisposing factors and even sub-threshold addictive behaviors. Other complex diagnostic amalgams, syndromes, and chief complaints have been successfully refined and redefined at the etiological level. For example, deafness was deconstructed and reconstructed into a series of better defined diseases through a combination of clinical, neuroanatomic, psychophysiologic, cellular, and genetic approaches. We recognize that the same functional consequence—namely hearing loss—has many distinct causes ranging from exposure to chemicals and loud noises to adverse panoply of genetic variants, with profound implications for prevention and intervention. As compared to the ear, the brain is a more complex organ. However, the brain's structures, functions, and outputs, both behavioral and molecular, are increasingly amenable to measurement, and as discussed earlier, the genetic study of these measures, many which represent intermediate phenotypes for addiction, offers a different and potentially better path to the identification of genes that alter vulnerability, as illustrated (Fig. 52.2). However, and as also indicated in the figure, because addictions are clinically defined, the genes that exert large effects on intermediate phenotypes such as executive cognition, stress resilience, and reward may not be strong clinical predictors of addictions as presently defined. In similar fashion, none of the deafness genes explains a large portion of deafness as a whole.

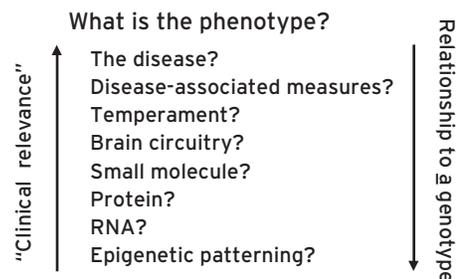

Figure 52.2 As presently defined, addictions are heritable but remote to the action of particular genes. This is because of intervening effects of environmental context and different mechanisms of vulnerability. These mechanisms, including differences in brain emotional response, reward, executive cognitive function, and drug metabolism have become partially accessible in the form of molecular and psychophysiologic intermediate phenotypes.

What might be the impact of gene identification in addiction? The *CFTR* gene does not strongly predict pneumonia, or fever, because it is found in only a fraction of patients presenting with these problems. However, *CFTR* is the defining factor in cystic fibrosis, a disease that with fuller understanding also involves pancreatic insufficiency, infertility, and non-genetic factors that critically shape clinical course. Although a gene therapy for cystic fibrosis has not emerged, careful attention to non-genetic factors in cystic fibrosis patients has revolutionized the care, and clinical course, of this distinct genetically defined subgroup. The same general approach may also be effective in addictions—the genetically-based diagnosis serving to identify a population to which intensive intervention has to be targeted. For addictions, there are now some positive indications that identification of specific genetic influences is a step towards individualization of treatment. For example, a common functional missense variant of the mu-opioid receptor (*OPRM1* Asn40Asp) is associated with altered reward function (Ramchandani et al., 2011) and alcoholic carriers of the Asp40 allele showed greater clinical improvement when treated with the opioid antagonist naltrexone (Anton et al., 2008; Oslin et al., 2003). Similarly, *CHRNA5* Asn398Asp (Munafo et al., 2011) and other genes have been reported to influence response to smoking cessation treatment.
