This material is not intended to be, and should not be considered, a substitute for medical or other professional advice. Treatment for the conditions described in this material is highly dependent on the individual circumstances. And, while this material is designed to offer accurate information with respect to the subject matter covered and to be current as of the time it was written, research and knowledge about medical and health issues is constantly evolving and dose schedules for medications are being revised continually, with new side effects recognized and accounted for regularly. Readers must therefore always check the product information and clinical procedures with the most up-to-date published product information and data sheets provided by the manufacturers and the most recent codes of conduct and safety regulations. The publisher and the authors make no representations or warranties to readers, express or implied, as to the accuracy or completeness of this material. Without limiting the foregoing, the publisher and the authors make no representations or warranties as to the accuracy or efficacy of the drug dosages mentioned in the material. The authors and the publisher do not accept, and expressly disclaim, any responsibility for any liability, loss, or risk that may be claimed or incurred as a consequence of the use and/or application of any of the contents of this material.

PREFACE

These are exciting yet frustrating times for psychiatry. Our knowledge of basic brain function continues to increase at an accelerating pace as the tools of biology—from genetics and epigenetics to detailed exploration of brain circuits in animals and humans—become ever more powerful and penetrating. Yet this explosion of knowledge of the brain has not been translated into fundamental advances in our understanding of the pathophysiology of most major psychiatric syndromes, the diagnosis of these syndromes based on their underlying biological mechanisms, or the treatment and prevention of mental illness.

Why has there been such a divide between our basic knowledge and clinical advances? First and foremost, the brain has proved to be far more complicated than ever imagined a generation ago, and the disorders of the brain that manifest primarily in behavioral abnormalities (i.e., mental illness) are far more complicated too in terms of their genetic causes and the associated abnormalities at the epigenetic, cellular, and circuit levels. We have also learned that effective translation will not occur automatically or organically and will require a far more concerted effort than mounted thus far to link findings in basic neurobiology and genetics to the human syndromes. The good news is that leaders at the National Institutes of Health, academia, and industry recognize the need for such collaborations, with many exciting ventures now underway or planned to meet the challenges ahead.

We have completely revamped the fourth edition of *Neurobiology of Mental Illness* to address these challenging yet promising times. We have recruited two new book editors to add depth and breadth of expertise, and have engaged a team of all new section editors, each of whom represents a leader in his or her fields. Accordingly, new authors have been enlisted for a majority of the chapters that now comprise this book, with many new chapters added and old ones removed to reflect progress in the field. The result is a thoroughly updated view of the state of psychiatry, both its basic underpinnings and clinical evidence, with a view toward advances that can be expected in the coming years and the methodology that will bring us there.

As before, Section I provides an overview of basic neuroscience that is relevant to clinical psychiatry and expanding its foundations. Molecular neurobiology and molecular genetics are emphasized in the context of brain development, neuropharmacology, neuronal function, and neural networks

and plasticity, with an eye on their contribution to complex behaviors.

Section II reviews the methods used to examine the biological basis of mental illness in animal models and in humans. This part has been expanded to reflect critically important technical advances in complex genetics (including powerful sequencing technologies and related bioinformatics), epigenetics, stem cell biology, optogenetics, cognitive neuroscience, and brain imaging. We believe that this range of exciting methodologies offer unique opportunities for the translation of pre-clinical and clinical research into badly needed breakthroughs in our therapeutic toolkit.

The remaining parts of the book cover the neurobiology and genetics of major psychiatric disorders: psychoses (including bipolar disorder), mood disorders, anxiety disorders, substance abuse disorders, dementias, disorders of childhood onset, and special topic areas. Each of these parts has been augmented in several different areas as a reflection of research progress. The last section, on special topics, includes chapters that address diagnostic schemes for mental illness. The release of our new edition coincides with the publication of DSM-5 (*Diagnostic and Statistical Manual-5*) by the American Psychiatric Association. Unfortunately, the diagnostic classification system utilized by DSM-5 remains limited by necessity, because it is still based primarily on phenomenology rather than etiology and pathophysiology. Alternative perspectives on diagnosis, for example, RDoC (research domain criteria), are therefore also presented. We predict that the research advances reviewed in our textbook will ultimately lead to diagnostic systems in which genetic and neurobiological abnormalities have a primary role.

This edition of *Neurobiology of Mental Illness* reflects the continuing reintegration of psychiatry into the mainstream of biomedical science. The research tools that are transforming other branches of medicine—epidemiology, genetics, epigenetics, molecular and cell biology, imaging, and medicinal chemistry—will also one day transform psychiatry. It is our hope that, like us, the reader is optimistic that the progress in genetics and in molecular, cellular, and systems neuroscience described in this textbook will eventually break new ground in the diagnosis, treatment, and prevention of disabling psychiatric disorders.

SECTION I | INTRODUCTION TO BASIC NEUROSCIENCE

ERIC J. NESTLER

The first part of this book provides an overview of basic neuroscience and molecular biology. Each chapter represents an enormous body of material that could itself be the subject of an entire textbook. Accordingly, these chapters are not intended to be comprehensive reviews, but rather concise summaries of the fields that lay the foundation of basic biological principles required for the clinical material that is the main focus of the book.

Chapter 1 provides an overview of brain development. There is increasing evidence that certain neuropsychiatric disorders may involve abnormalities in the formation of the nervous system. Although the details of such abnormalities remain poorly understood, the chapter provides insights into the cellular and molecular processes that may be involved and the ways in which such processes can be influenced by genetic and external factors.

Chapter 2 describes the neurochemical organization of the brain. It summarizes the diverse types of molecules that neurons in the brain use as neurotransmitters and neurotrophic factors, and how these molecules are synthesized and metabolized. The chapter also presents the array of receptor proteins through which these molecules regulate target neuron functioning and the reuptake proteins that generally terminate the neurotransmitter signal. Today a large majority of all drugs used to treat psychiatric disorders, as well as most drugs of abuse, still have as their initial targets proteins involved directly in neurotransmitter function.

Chapter 3 summarizes the electrophysiological basis of neuronal function. Ultimately, brain function is mediated by interactions between nerve cells, and the readout of such interactions is an alteration in the electrical properties of the cells. Moreover, recent human genetic studies have identified variations in the genes that encode specific ion channels that are associated with various forms of mental illness, further demonstrating the importance of understanding the basis of neuronal excitability. The chapter reviews the several types of recording techniques that are commonly used to measure neuronal activity and then presents the many types of ion channels and receptors that control a neuron's electrophysiological responses.

Chapter 4 covers postreceptor intracellular messenger cascades through which neurotransmitters and neurotrophic factors, and their receptors, produce their diverse physiological effects. A major advance over the past generation of research has been an appreciation of the complex webs of intracellular

signaling pathways that control every aspect of a neuron's functioning, from neurotransmitter signaling to cell shape and motility to gene expression. Although only a small number of medications used in psychiatry today have as their initial target intracellular signaling proteins, it is likely that drug development efforts will look increasingly to such proteins for the discovery of novel medications with fundamentally new mechanisms of action.

Chapter 5 describes prominent mechanisms of neural plasticity, that is, ways in which neurons adapt over time in response to environmental perturbations. It is this capacity for adaptation (or maladaptation) that makes it possible for the brain not only to learn and think but also to get sick. The chapter focuses on the several different ways in which experience alters the function of specific synapses (synaptic plasticity), including long-term potentiation and depression, as well as the inherent excitability of nerve cells (whole cell or homeostatic plasticity), along with the ever-increasing knowledge of their underlying molecular mechanisms.

Chapter 6 provides an overview of the genetic basis of the nervous system. The chapter covers the structure of DNA and chromatin in the nucleus, how genes encode messenger RNAs and proteins, and the mechanisms (e.g., alternative splicing and posttranslational processing) by which numerous proteins can be generated from individual genes. The chapter also describes how this process of gene expression is under dynamic regulation throughout the adult life of an organism via the regulation of transcription factors and other nuclear proteins, and how such mechanisms contribute in important ways to long-lived neural plasticity.

Chapter 7 covers epigenetic mechanisms in psychiatry. Epigenetic regulation in neurons describes a process in which the activity of a particular gene is controlled by the structure of chromatin in that gene's proximity. Recent work has demonstrated the dynamic nature of chromatin remodeling in the nervous system and its importance for the normal development of the nervous system as well as the brain's capacity to adapt over time to environmental challenges. Abnormalities in chromatin remodeling have also been implicated in a growing number of neurological and psychiatric disorders.

A great deal has been written recently about the need for translational research in psychiatry. Yet we all know how uniquely difficult translational research is in our field. This is due to several factors, including the unique complexity of the brain, the lack of ready access to the brains of our patients, and

the complexity of psychiatric disorders with respect to etiology and pathophysiology. As a result, it is currently difficult, if not impossible, to relate most of the material covered in this first part of the book to studies of the clinical disorders. How does one study, for example, the transcription factor *cyclic adenosine monophosphate response element binding protein* (CREB) or changes in dendritic spine density, implicated in animal models of several psychiatric conditions, in living patients? We view this

difficulty, though very real today, as a time-limited obstacle. As advances in human genetics and brain imaging progress, it will become possible to analyze diverse neurotransmitter and neurotrophic factor systems, intracellular signaling proteins, and even gene expression and chromatin profiles in our patients and ultimately within discrete brain regions implicated in disease pathophysiology. Such methodologies will complete psychiatry's transformation into a field of modern molecular medicine.

1 | OVERVIEW OF BRAIN DEVELOPMENT

JOHN L. R. RUBENSTEIN

There is increasing evidence that abnormalities in the development of the brain either predispose or directly cause some psychiatric disorders. Although it is not surprising that childhood disorders, such as autism, are caused by neurodevelopmental abnormalities, disorders that display their most characteristic symptoms during or after adolescence may be influenced by developmental abnormalities. For instance, several lines of evidence suggest that schizophrenia is a neurodevelopment disorder. Thus, there is a compelling rationale for behavioral scientists and clinicians to understand the basic mechanisms that regulate assembly of the brain, as this information may be critical in understanding the etiology and perhaps the prevention and treatment of major psychiatric disorders.

This chapter highlights many of the major processes involved in brain development, including: induction of the central nervous system (CNS), patterning of the primordia of major brain regions, proliferation of neuroepithelial cells, differentiation and migration of immature neurons and glia, formation of axon tracts and synapses, and the establishment and plasticity of neuronal networks. Although much of the information described in this chapter is based on studies in non-primate mammals, it is likely that these findings are pertinent to developing human brain. For a comprehensive resource on neural development see the series edited by Rubenstein and Rakic (2013).

INDUCTION AND PATTERNING OF THE EMBRYONIC CNS

Early CNS development involves an ordered sequence of inductive processes that begin with the formation of the neural plate followed by a hierarchical series of fate specification steps that lead to regionally distinct developmental programs (Hoch et al., 2009). Inductive processes generally involve two tissues; one is the target of induction and the other, called the *organizer*, produces the molecular signals that carry out the induction. The node is the first organizer, and regulates inductions during gastrulation. These molecular signals, which generally are proteins, induce in the target tissues a new pattern of gene expression that dictates their subsequent developmental program.

Development of the CNS begins during gastrulation by a process called *neural induction*. Proteins produced by organizer tissues cause the embryonic ectoderm to differentiate into a neural fate. This process involves activation of receptor tyrosine kinases, perhaps through fibroblast growth factors

(FGFs), and inhibition of transforming growth factor- β (TGF- β) signaling through the noggin and chordin proteins that bind to bone morphogenetic proteins (BMPs) (Stern, 2006). In addition, inhibition of wingless (WNT) signaling is required, at least in some species (Stern, 2006). Induction of the neural ectoderm generates the neural plate, which will give rise to the entire CNS (Fig. 1.1); its lateral edges produce neurogenic placodes (for the olfactory epithelium and inner ear) and the neural crest, which gives rise to most of the peripheral nervous system (PNS) and contributes to the head skeleton.

Beginning during neural induction, inductive processes subdivide the neural plate into molecularly distinct domains that are the primordia of the major subdivisions of the CNS. One can distinguish three types of inductive processes during CNS regionalization: (1) anterior-posterior or A-P, (2) mediolateral or M-L, and (3) local. The A-P regionalization subdivides the neural plate into transverse domains. The principal transverse subdivisions of the brain are the prosencephalon (forebrain), mesencephalon (midbrain), and rhombencephalon (hindbrain) (Fig. 1.2). Further refinements of A-P regionalization subdivide the rhombencephalon into segment-like domains called *neuromeres* (*rhombomeres*). Part of the forebrain may also have neuromeric subdivisions called *prosomeres*. The inductive mechanisms underlying A-P regionalization are poorly understood but probably include vertical inductions (from underlying tissues) from mesoderm and endoderm, and planar inductions (from substances that transmit their effects in the plane of the neural plate), perhaps from the node.

The M-L regionalization produces distinct tissues that are longitudinally aligned along the long (A-P) axis of the CNS (Fig. 1.1). Medial inductions are regulated by substances produced by the axial mesodermal organizers: the notochord and prechordal plate. These organizers are midline structures that lie underneath the middle of the neural plate and produce substances, such as sonic hedgehog, that induce the medial neural plate to form the primordia of the floor plate and basal plate (see Fig. 1.1). Lateral inductions are mediated by substances such as TGF- β proteins (that include the BMPs), which are produced along the rim of the neural plate by the non-neural ectoderm. Lateral inductions participate in the development of the neural crest, roof plate, and alar plate (see Fig. 1.1).

The combination of A-P and M-L patterning generates a checkerboard organization of brain subdivisions (Fig. 1.2), each of which expresses a distinct combination of regulatory genes. Superimposed on this pattern are the local inductive

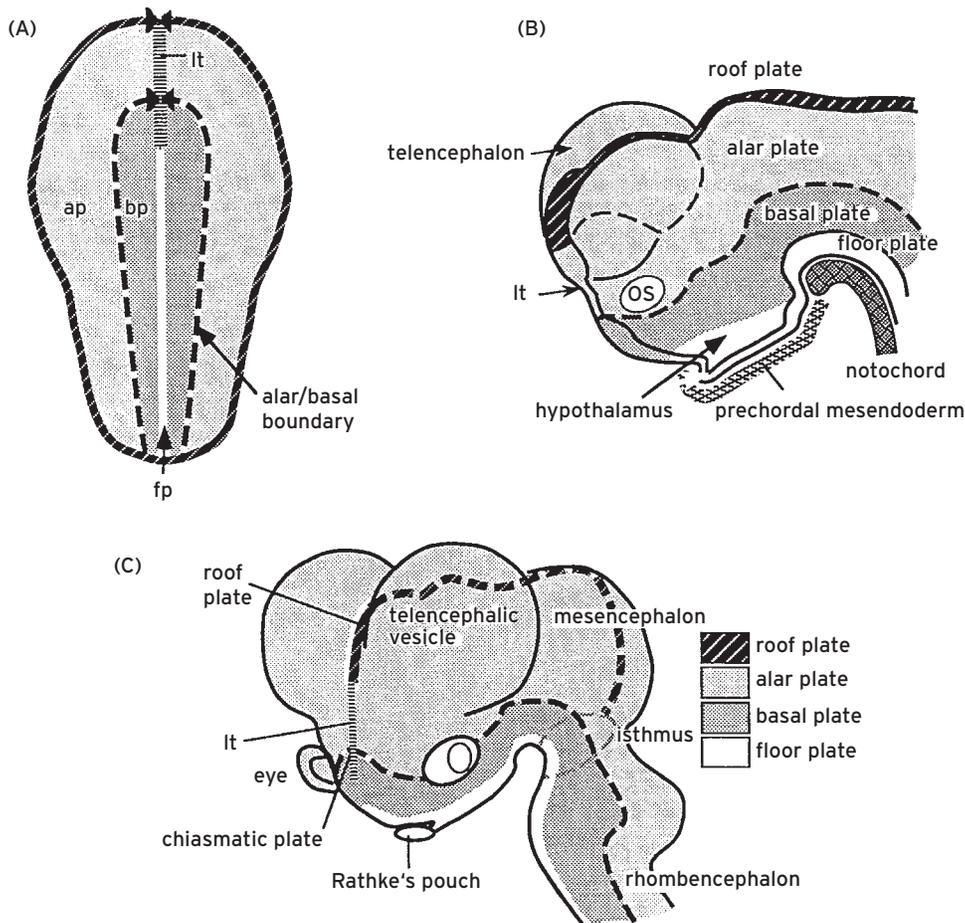

Figure 1.1 Schemas of the longitudinal organization of the brain (Shimamura et al., 1995). (A) Model of the longitudinal domains of the neural plate, including the primordia of the floor plate (fp), basal plate (bp), alar plate (ap), and roof plate (most lateral domain). (B) Medial view of the neural tube. (C) Rostro-lateral view of the neural tube. lt: lamina terminalis; os: optic stalk.

signals that are essential for the formation of the vesicles that evaginate from the brain such as the telencephalon, eyes, and posterior pituitary. Evidence suggests that signals originating from ectodermal tissues (lens placode, anterior neural ridge, and anterior pituitary, respectively) adjacent to these structures produce signals that induce their formation.

Although the process of regionalization subdivides the neural plate into the primordia of the major brain regions, the process of morphogenesis transforms the shape of the neural plate into a tube that additionally has flexures and evaginations. Note that the folding of the neural plate into the neural tube converts the lateromedial dimension of the neural plate into the dorsoventral (D-V) dimension of the neural tube (Fig. 1.1).

A cross section through the D-V axis of the neural tube transects its four primary longitudinal subdivisions (Fig. 1.3). From ventral to dorsal these longitudinal columns are the floor, basal, alar, and roof plates. Each of these longitudinal columns may extend along the entire A-P axis of the CNS and contribute to distinct functional elements of the nervous system. The basal plate is the primordia for the motor neurons. The alar plate is the primordia for the secondary sensory neurons. The floor plate has several functions that are required during development. Like the notochord, the floor plate produces

sonic hedgehog and is believed to serve as a secondary ventral (medial) organizer where it also, in combination with chemotropic molecules such as netrins, guides the growth of axon tracts (Kolodkin and Tessier-Lavigne, 2011). Most of the roof plate forms the non-neuronal dorsal midline, which in some regions gives rise to specialized structures such as the choroid plexus and the pineal gland. The roof plate is marked by its high expression of BMPs and WNTs.

The regionalization process continues after neurulation (neural tube formation) to further subdivide large primordial regions into their constituent domains. These aspects of regionalization are probably carried out by planar inductive mechanisms via organizers that are within the neural tube. For example, secondary D-V patterning can be regulated by the floor plate (see the next section), whereas secondary A-P patterning can be regulated by the isthmus. The isthmus is a region between the mid- and hindbrain that produces inductive substances such as FGFs and WNT that regulate development of the midbrain and cerebellum. Primary cilia, an appendage on most cells, detects extracellular signals including sonic hedgehog and WNT. Mutations affecting cilia function are implicated in neurodevelopmental disorders affecting patterning and function of the brain (Louvi and Grove, 2011).

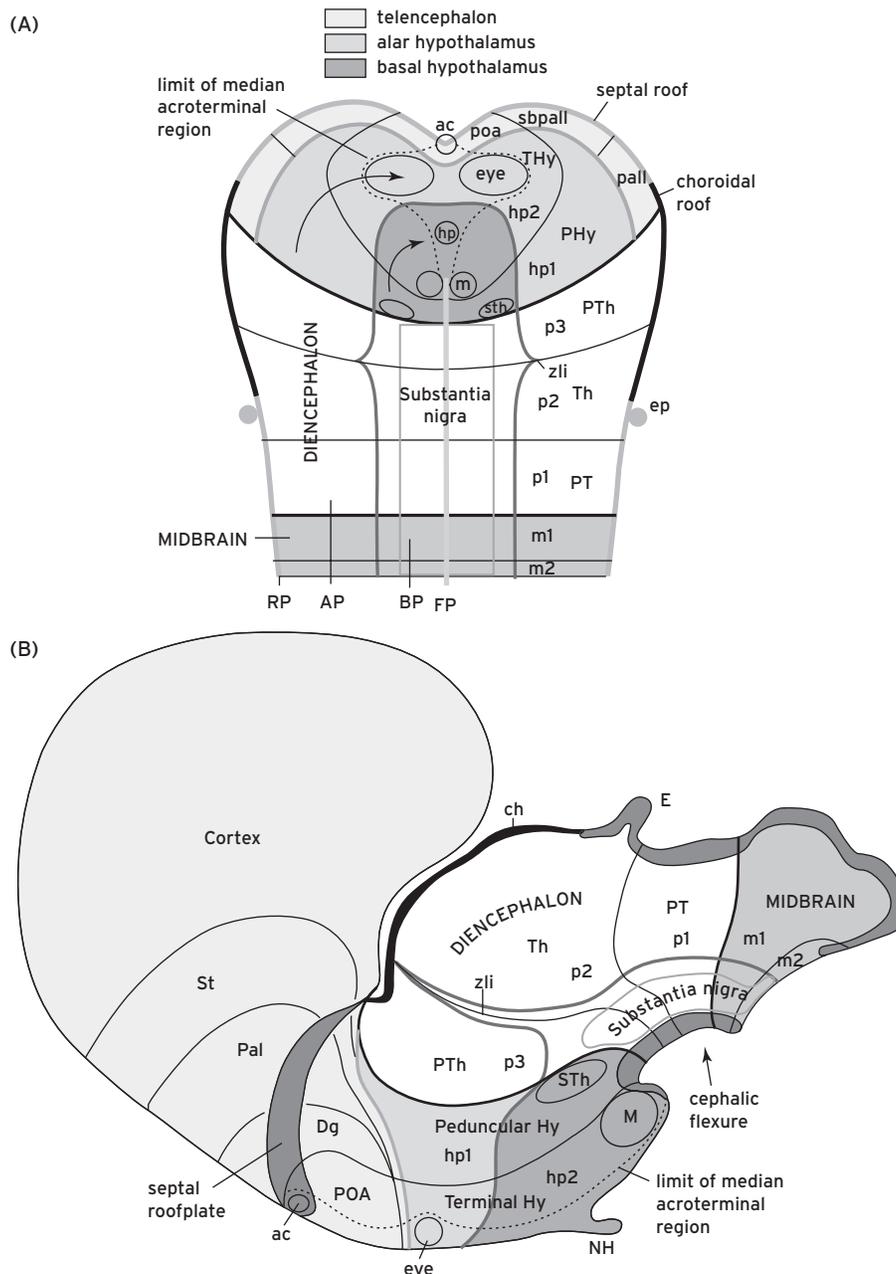

Figure 1.2 Schemas of the organization of the rostral neural plate and neural tube (modified from Puellas et al., 2011). Looking down at a flattened neural plate (A). Transverse subdivisions from caudal-to-rostral include the midbrain, diencephalon (three prosomeres, p1, p2, and p3), and secondary prosencephalon, which includes the basal hypothalamus, alar hypothalamus, and telencephalon. Longitudinal domains: floor plate (fp), basal plate (bp), alar plate (ap), and roof plate (rp). Medial view of a mid-sagittally dissected neural tube (B). Subdivisions of the telencephalon include the cortex (including the hippocampus), striatum (St), pallidum (Pal), diagonal band/nucleus basalis (Dg), and preoptic area (POA). The hypothalamus (Hy) is postulated to have two transverse subdivisions (terminal and peduncular; hp2 and hp1), whose basal plates include the mammillary body (M), subthalamic nucleus (STh), and the midline neurohypophysis (NH; posterior pituitary). The alar plate of the diencephalon constitutes component of the thalamus, including the prethalamus (PTh), the thalamus proper (Th) and the pretectum (PT). Diencephalic basal plate components include the substantia nigra, which extends through the midbrain. The roof components of the forebrain include the epiphysis (E, ep), choroid plexus (ch), and the septal roof plate, where telencephalic commissures cross the midline, including the anterior commissure (ac).

HISTOGENESIS OF BRAIN REGIONS: PROLIFERATION, CELL FATE DETERMINATION, MIGRATION, AND DIFFERENTIATION

The process of regionalization subdivides the CNS into the primordia of its major structures (e.g., cerebral cortex, striatum,

thalamus, cerebellum) and initiates within these primordia their genetic programs of histogenesis that regulate cell fate determination, proliferation, differentiation, and migration (for more extensive reviews of this subject, see Kriegstein and Alvarez-Buylla, 2009; Marin and Rubenstein, 2001). These processes take place in specific zones within the wall of the neural tube (Fig. 1.4). Proliferation occurs in the ventricular

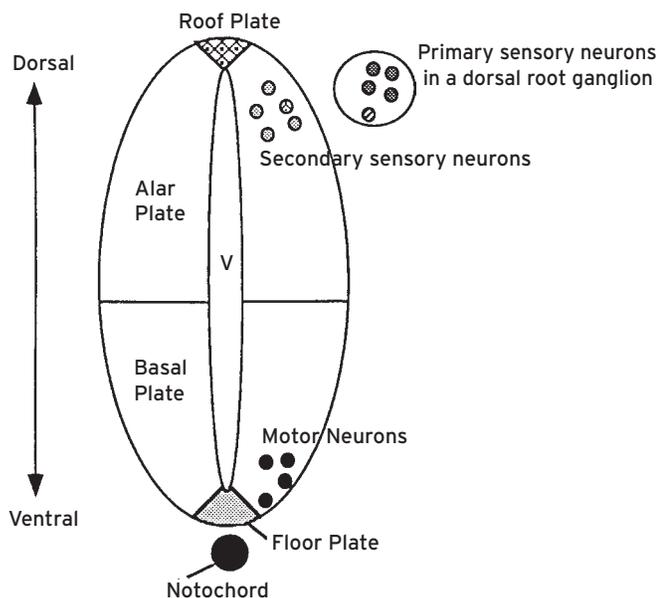

Figure 1.3 Schematic cross section of the dorsoventral (D-V) organization of the spinal cord. The floor plate is induced by the notochord; together they produce the sonic hedgehog protein, which patterns the basal plate of the spinal cord, including the motor neurons. Neural crest cells originate from the dorsal-most part of the spinal cord and generate the primary sensory neurons of the spinal ganglia. Secondary sensory neurons are produced in the alar plate. V, ventricle.

zone (VZ) and subventricular zone (SVZ), which line the inner surface of the neural tube, and are adjacent to the ventricular cavity. VZ progenitors, known as radial glia progenitors (RG) give rise to secondary (or intermediate) progenitors (IP), whose cell bodies generally reside in the SVZ. VZ and SVZ progenitors can both generate neurons and glia (astrocytes and oligodendrocytes). Newborn immature neurons produced in the progenitor zones migrate into the overlying mantle zone; in the case of the cerebral cortex, the mantle zone is called the cortical plate (Fig. 1.4a). In the developing human cerebral cortex, the progenitor domains are expanded compared to simpler mammals, such as rodents, and include an outer subventricular zone that has a large number of outer radial glial and intermediate progenitors (oRG and oIP) (Fig. 1.4b).

VZ progenitors are the most undifferentiated and mitotically active progenitors. Each brain region has a distinct proliferation program that regulates the rate of cell division, the number of times VZ cells divide, and the character of the cell division. Cell division can be symmetrical, producing daughter cells that are identical or asymmetrical, producing daughter cells that are non-identical. Symmetrical divisions produce daughter cells that, like their mother, continue to proliferate or, unlike their mother, differentiate or die. Asymmetric division can produce one daughter cell that differentiates and one daughter cell that continues to proliferate. The regulation of these processes is integral to controlling how many cells are

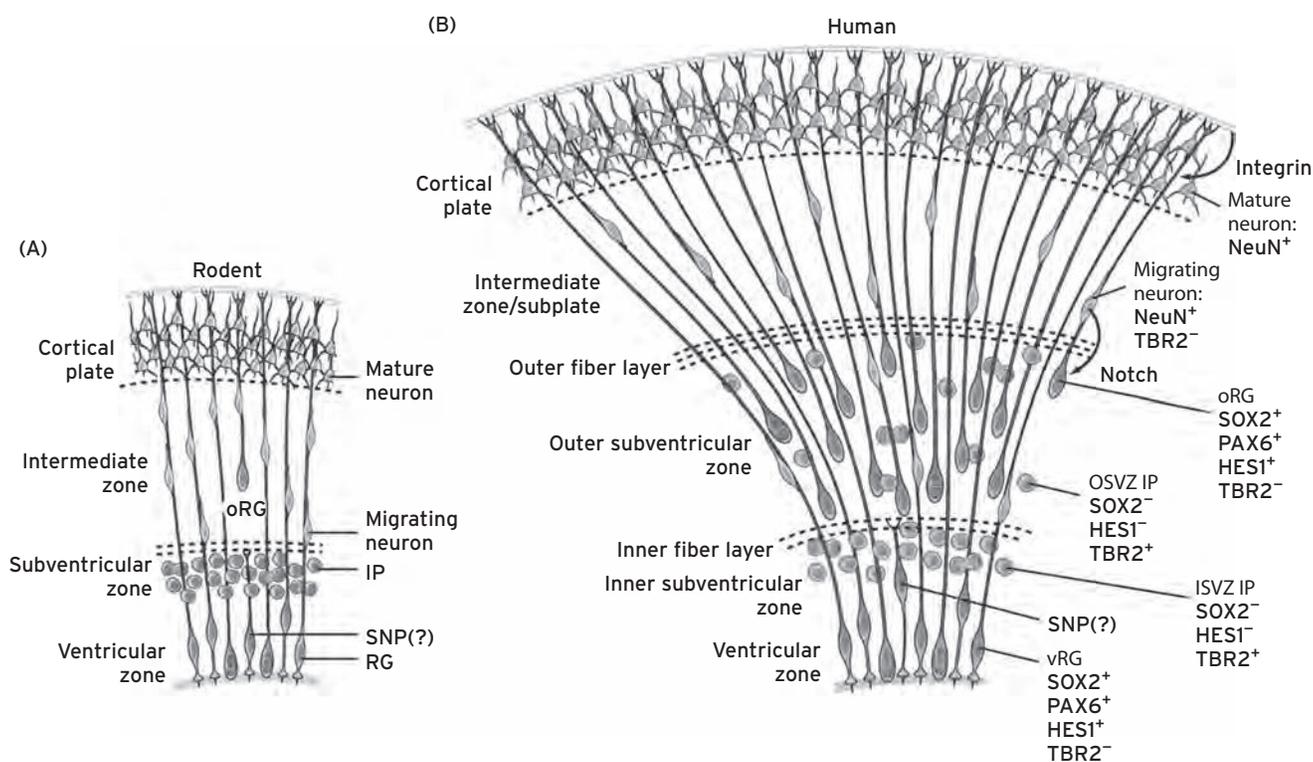

Figure 1.4 Organization of progenitor and migration zones in the developing neocortex of rodents (A) and humans (B). (Taken with permission from Lui et al., 2011). Laminal divisions include the ventricular zone (VZ), subventricular zone (SVZ; inner and outer), intermediate zone (IZ), inner and outer fiber layers, subplate, and cortical plate. Transcription factors that are expressed in specific types of progenitors are listed: HES1, NeuN, PAX6, SOX1, TBR2. IP, intermediate progenitors; ISVZ, inner SVZ; oRG, outer radial glia progenitors; oSVZ, SNP, short neural precursor; outer SVZ progenitors; RG, radial glia progenitors; vRG, ventricular zone radial glia progenitors.

produced in each region and when these cells are made. For example, the expansion of the cerebral cortex in primates may relate to increased numbers of symmetrical divisions of neuron-producing progenitors in the cortical SVZ (Liu et al., 2011).

There are many types of cells that make up the CNS; the two basic classes are neurons and glia (Lemke, 2001; Rowitch and Kriegstein, 2010). There are two general types of neurons: projection neurons, whose axons migrate to distant territories, and local circuit neurons (interneurons), whose axons ramify nearby. Within these general categories, there are distinct types of projection and local circuit neurons that differ by neurochemistry, firing characteristics, and connectivity (Wonders and Anderson, 2006). There are two types of CNS-derived glia, astrocytes and oligodendrocytes, whereas the other major glial type, the microglia, is mesodermally derived (Colognato and French-Constant, 2004). Astrocytes regulate the local chemical milieu and appear to regulate synapse formation and elimination (Eroglu and Barres, 2010). Oligodendrocytes produce the myelin sheaths that surround many axons; these sheaths function as insulators that increase the velocity of action potentials. Microglia are related to macrophages and subserve a phagocytic role to remove dead cells from the CNS.

Different types of neurons are generated at distinct D-V positions in the CNS. For instance, within the spinal cord, motor neurons are generated by ventral progenitors, whereas sensory neurons are generated by dorsal progenitors (Dessaud et al., 2008). Likewise, in the telencephalon, ventral progenitors produce neurons of the basal ganglia, whereas dorsal progenitors produce cortical neurons (Hebert and Fishell, 2008). This arrangement is the result of the D-V patterning mechanisms described earlier in this chapter. Although patterning of the nervous system produces separate primordia of major brain regions (e.g., cerebral cortex and basal ganglia), cell migration processes “mix” certain cell types between these primordia (see following paragraphs).

The mechanisms underlying cell fate decisions in the nervous system involve molecules within the cells (intrinsic signals controlled by proteins such as transcription factors; see Chapter 6) as well as molecules outside of the cells (extrinsic signals controlled by proteins such as growth/differentiation factors and their receptors). These proteins have integral roles in regulating whether a cell continues to divide, whether it undergoes symmetrical or asymmetrical division, whether the daughter cells go on to differentiate, and what type of cell they will become.

Notch signaling is an example of extrinsic control of differentiation and is mediated by *Notch* receptors and their ligands (e.g., Delta) (Justice and Jan, 2002). Activation of *Notch* by its ligand biases a cell not to differentiate into a neuron; thus neurogenesis requires inhibition of *Notch* signaling. *Notch* signaling controls the rate and timing of neuron production. Furthermore, high levels of *Notch* signaling biases progenitors toward an astrocytic fate. *Notch* signaling activates a cascade of molecular switches that culminates in the induction of transcription factors that change gene expression in the differentiating cell (Bertrand et al., 2002).

Although *Notch* signaling largely operates through basic helix-loop-helix transcription factors, many other types of

transcription factors have central roles in brain development. These include *Homeobox*, *Sox*, *T-box*, *Winged-Helix*, and *HMG-box* families. Each family consists of subfamilies; for instance, key homeobox genes include *Arx*, *Dlx*, *Emx*, *Lhx*, *Nkx*, *Otx*, *Pax*, and *POU*, which control such processes as regional fate, cell type identity, neuronal maturation, and cell migration (Briscoe et al., 2000; Wilson and Rubenstein, 2000).

Once neurons are generated, the next step in their differentiation program is their migration to the appropriate destination (Ayala et al., 2007). Each brain region has a specific migration program. In cortical structures (e.g., cerebral cortex and superior colliculus) migrations are orchestrated to form layered or laminar structures. In most subcortical regions migrations form nuclear structures. There are two general types of migration: radial and tangential. Radial migration is movement perpendicular to the plane of the ventricle and toward the pial surface; tangential migration is movement parallel to the plane of the ventricle and pial surface.

Radial migration involves the interaction between the elongated processes of radial glial (RG) cells and the migrating immature neurons (Fig. 1.4). The immature neurons migrate through the subventricular and intermediate zones (Fig. 1.4) to specified locations within the wall of the neural tube where they disengage from the radial glial cell and continue to differentiate. Historically, an important molecule regulating this process was identified through analysis of the *reeler* mutant mouse (Rice and Curran, 2001). In the cerebral cortex of *reeler* mice, later-born neurons fail to migrate past their earlier-born siblings, leading to partial inversion of the usual inside-out lamination. The *reeler* gene encodes a secreted protein named *reelin* that can promote dissociation of neuroblasts from radial glia. Two low-density lipoprotein receptors (VLDLR and ApoER2) are receptors for reelin. Humans with *reelin* mutations can have neuropsychiatric disorders including mental retardation and epilepsy; changes in reelin function or levels may be associated with schizophrenia and autism.

Nervous system development also depends on tangential migration. This has long been known to occur in the cerebellum and in the rostral migratory stream (RMS) of the olfactory bulb, where adult neurogenesis is best characterized. In addition, most GABAergic local circuit neurons of the telencephalon are generated in the basal ganglia primordia and then tangentially migrate to the cerebral cortex and hippocampus (Marin and Rubenstein, 2001). This process results in mixing of gamma-aminobutyric acid (GABA)ergic neurons from the basal ganglia anlage with glutamatergic projection neurons of the cerebral cortex. GABAergic neurons are required for inhibitory regulation of excitatory transmission. Guidance cues for tangentially migrating interneurons include neuregulin1 (a schizophrenia risk gene), the CXCL12 cytokine, and semaphorins (Marin et al., 2001; Flames et al., 2004; Wang et al., 2011).

Progress has also been made in identifying genes that control cytoskeletal processes that are essential for migration. Several of these genes were first identified as causing neuronal migration defects in humans, including *Lisencephaly-1*, *Doublecortin*, and *Filamin* (Mochida and Walsh, 2004).

The time when a neuron is born (newborn neurons are not mitotically active and migrate away from the VZ) has an

important influence on its fate (the type of neuron it becomes and its location within the brain). For instance, in the cerebral cortex there are seven layers: layers 1, 2, 3, 4, 5, 6, and the subplate. Layer 1 is the most superficial, and the subplate is closest to the VZ. In the cerebral cortex, cells that are born first populate the deepest layers; this produces the so-called inside-out pattern of histogenesis. Each layer has distinct functions. For instance, the subplate is believed to provide signals that direct the incoming thalamic axons to their appropriate cortical target zone; layers 5 and 6 contain neurons that project out of the cortex; neurons in layer 4 receive input from the thalamus; neurons in layers 2 and 3 have intracortical projections; reelin-secreting layer 1 neurons participate in regulating cortical histogenesis by modulating the radial migration process (Tissir and Goffinet, 2003).

WIRING OF THE BRAIN: FORMATION OF AXON PATHWAYS AND SYNAPSES

As the immature neurons and glia migrate from the proliferative zone to the differentiation zone (the mantle), they elaborate more complex cellular structures. Neurons extend several thin processes away from their cell body; these include multiple dendrites and a single axon. Perhaps the most distinctive feature of the nervous system is how axon processes navigate long distances to find their targets (Charron and Tessier-Lavigne, 2005; Guan and Rao, 2003). The growing tip of the axon is called the *growth cone*. This dynamic structure extends filopodia that explore their environment, searching for cues that either attract or repel them.

Molecules and their receptors have been identified that are chemoattractants or repellents for growing axons. These can function as long-range or as local signals. Some local signals are found on the surface of glial cells that serve as guideposts for the axons. The earliest axon pathways that develop create a scaffold for later-arriving axons. Through a process called *fasciculation*, later-arriving axons can adhere to axons that are already in an axon pathway. Molecules on the surface of the axons, some of which are related to immunoglobulins, can regulate selective fasciculation to generate axon bundles with common properties. When an axon has reached its target, a process called *defasciculation* enables the axon to separate from the axon bundle.

As axons grow and navigate, their plasma membrane contains guidance receptors that recognize molecules expressed by neighboring cells (Charron and Tessier-Lavigne, 2005; Guan and Rao, 2003). Guidance processes operate as growth cones grow along specific pathways. Important pathways that connect the left and right side of the CNS are midline structures (commissures), such as the optic chiasm and corpus callosum. Activation of guidance receptors determines whether an axon grows toward or away from a target cell. At least four conserved families of guidance molecules have been identified. The semaphorins comprise a 20-member family of soluble and membrane-bound molecules that elicit repulsive signals through two receptor families, neuropilins and plexins. The slit family of proteins consists of three members in mammals

and acts through Robo receptors in commissural axons to prevent these axons from recrossing the midline. Whereas the slits and semaphorins are repulsive, members of the netrin family can be repulsive or attractive for a growth cone, depending on the types of receptors expressed by the axon (receptor complexes containing either the colorectal cancer [DCC] or the neogenin protein lead to attraction; UNC-5-related protein leads to repulsion). Members of the ephrin family of ligands are membrane-bound and interact with two families of receptors, EphA and EphB (Kullander and Klein, 2002). EphrinB ligands, when bound to EphB receptors, are capable of bidirectional signaling whereby the cytoplasmic domain of the Ephrin ligand transmits a phosphorylation signal. In addition to regulating axon pathfinding, semaphorins, slits, netrins, and ephrins control neuronal migrations.

Upon reaching its target, the growth cone is further modified as it forms a part of the synapse (Sanes and Lichtman, 2001). Reciprocal signals between the growth cone and the postsynaptic target cell induce the production of molecules and membranous specializations found in synapses (Benson et al., 2001). Presynaptic cells produce synaptic vesicles filled with neurotransmitters, and the postsynaptic cells form dendrites with specialized domains containing neurotransmitter receptors (Jan and Jan, 2001). There is evidence that defects in synapse development and maintenance underlie some forms of autism (Walsh et al., 2008). Proteins of the neurexin/neurologin families are of particular interest, as they are critical in dictating the types of synapses that form, and mutations in this class of genes are associated with a variety of neuropsychiatric disorders (Peñagarikano et al., 2011; Sudhof, 2008). Assembly and function of the synapse requires proteins such as Shank3, mutations of which can cause autism and schizophrenia (Herbert, 2011). Transduction of synaptic activity depends on ion channels; defects of these can contribute to autism susceptibility as in CACNA1C mutations, which recently have been characterized in induced pluripotent stem cells (iPSCs) from Timothy syndrome patients (Pasca et al., 2011).

In the 1950s, nerve growth factor (NGF) was discovered, the first of four so-called neurotrophins that provide signals that control such processes as neuronal survival and synapse strength (Huang and Reichardt, 2001). By the end of the 1980s the neurotrophic hypothesis was firmly entrenched, and it suggested that postsynaptic cells are responsible for releasing neurotrophins that the presynaptic neuronal process was attracted to via its expression of a so-called Trk receptor. The amount of neurotrophin released by a given cell determined whether a cell reached a given target and formed a synapse or otherwise was destined for “programmed death.” The mechanisms underlying programmed cell death, or apoptosis, have recently been elucidated (Kuan et al., 2000).

The biochemical nature of apoptosis was first discovered by studying the nematode *Caenorhabditis elegans*. A genetic analysis identified a cascade of proteases, known as *caspases*, that control programmed cell death in all animals. Subsequently, mitochondrial-associated proteins have also emerged as important regulators of apoptosis including the Bcl-2 family, APAF, and cytochrome C. Apoptosis is recognized as a

fundamental process that, together with progenitor cell proliferation, controls neuronal numbers during development. Presently, researchers are investigating whether some neurodegenerative disorders may be the result of aberrant apoptosis or neurotrophin signaling and whether neurotrophins or apoptosis inhibitors can be used clinically to treat neurodegenerative abnormalities.

The wiring of complex CNS systems requires the connection of multiple cell types that are located in different positions. The wiring diagram of the visual system is an instructive example of this process. The neural retina contains primary sensory receptor neurons (rods and cones), interneurons (e.g., amacrine, bipolar, and horizontal cells), glia (Müller cells), and projection neurons called *retinal ganglion cells*. The retinal ganglion cells extend axons that must make several choices on the path to their targets. First, they exit the eye through the optic nerve and confront the optic chiasmatic plate, a structure at the front of the hypothalamus. Axons from the temporal retina do not cross at the chiasm, whereas axons from the nasal retina do cross. Intrinsic signals that distinguish nasal and temporal cells (e.g., the brain factor-1 and -2 transcription factors) permit the growing axons to sort themselves out to follow the correct pathway. There appear to be signals that the axons detect in the chiasmatic plate that direct the axon traffic. Upon exiting the chiasm, the optic axons grow posteriorly toward their two main targets: the thalamus and the superior colliculus. The optic tracts grow along the surface of the hypothalamic mantle zone, passing many nuclei, until they reach the thalamus. Branches perpendicular to the trajectory of the optic tracts grow out from the axons. These branches then specifically enter the visual centers of the thalamus, principally the lateral geniculate nucleus (LGN), where they form synapses with the LGN neurons. Before describing the LGN in greater detail, it is important to point out that some optic axons continue to grow more posteriorly into the midbrain, where they form branches into the superior colliculus (or optic tectum). Here, the optic axons synapse in specific locations; axons from the temporal retina synapse in the anterior tectum, whereas axons from the nasal retina synapse in the posterior tectum. Molecules that may regulate this retinotopic map on the optic tectum are membrane-bound Eph-type receptors (found on the axons) and their membrane-bound protein ligands (found on the target cells). The Eph proteins probably make up part of the molecular system that orchestrates the precise mapping of axonal projections onto the target tissues in all CNS regions.

In the LGN, the optic axons also form a retinotopic map. In higher mammals, the LGN is a laminar structure; each layer in the adult is connected with only one eye. However, during development, axons from both eyes have processes that extend into many LGN layers. Experimental evidence suggests that neuronal activity is required for the sorting-out process that eliminates branches in some layers and strengthens the synapses in others. Neuronal activity-dependent processes and critical periods have an essential role in many steps that refine the patterns of connections in the CNS; these are addressed further below.

The projection neurons in the LGN send axons anteriorly into the telencephalon, where they traverse the striatum in the

internal capsule and enter their target: the cerebral neocortex. The thalamocortical fibers enter the cortex while neurogenesis is still actively occurring and grow into a layer called the *intermediate zone* that is interposed between the proliferative (VZ and SVZ) and mantle (cortical plate) zones (Fig. 1.4). The thalamocortical fibers' next task is to innervate the correct region of the neocortex. The neocortex is subdivided into functionally distinct areas, each with a distinctive set of inputs. The LGN axons must innervate the primary visual cortex. Evidence suggests that some of the positional information that regulates this process is found in a transient layer of cortical neurons called the *subplate cells*. These are among the first cortical neurons to differentiate, and they are located in the deepest layer of the cortical plate, adjacent to the intermediate zone. The axons from different thalamic nuclei form transient synapses with the subplate cells in distinct cortical domains. The LGN fibers grow to a caudal position in the cortex, which will become the primary visual cortex. There the LGN axons form synapses with the subplate cells and wait in this location until the cerebral cortex has further matured. Then the LGN fibers leave the subplate, grow into the cortex, and form synapses with neurons in layer 4. After the axons leave the subplate, most of these cells die, leaving no trace of this important step in neurodevelopment.

Initially, inputs from both eyes converge within the same areas in layer 4 of the primary visual cortex. Then the axons from each eye segregate into distinct alternating domains called the *ocular dominance columns*. Evidence suggests that formation of these columns requires neuronal activity and that correlated activity from subregions of each eye plays a role in this process (see Katz and Shatz, 1996, for a review of this subject). Because ocular dominance formation occurs in utero, the neuronal activity is not induced by visual experience but is probably regulated by intrinsic neuronal discharges within the retina.

As the thalamocortical circuit is maturing, local connections between cortical layers 1–6 form a columnar intracortical circuit that is the basic unit of cortical function. Each region of visual space is represented in these cortical columns, and the ensemble of these columns becomes the primary visual cortex. Through processes that are beyond the scope of this chapter, the primary visual cortex regulates the development of secondary visual centers that are concerned with more complex aspects of processing and integrating visual information. These areas project to cortical association areas that integrate visual and other information, which then influences motor output areas of the cortex. Forming and refining of these more complex intracortical circuits continues into postnatal life. These postnatal aspects of CNS development are greatly influenced by visual experience.

POSTNATAL DEVELOPMENTAL PROCESSES

Many aspects of neuronal development continue throughout life, especially the elaboration and refinement of neuronal connections that are required to generate sensory maps, neural

circuit assemblies that mediate sensory-motor integration and responses, and higher order cognitive and emotional representations. There is evidence that experiential activity-dependent processes are essential for the postnatal spatial assembly of the sensory map in the olfactory cortex (Franks et al., 2011), and therefore may underlie the assembly of higher order circuits. Furthermore, in adult animals, when peripheral sensory inputs are eliminated, such as through amputation of a finger, the cortical regions that previously received input from the removed finger now receive sensory inputs from the adjacent fingers. This alteration in the neocortical somatosensory map appears to result from changes in the sizes and shapes of axonal processes and the distribution of synapses. Thus, the synaptic connectivity of the adult cortex is capable of reorganization.

In addition to the ability of neuronal processes to continue to grow and change in shape in postnatal animals, there are at least two brain regions that postnatally produce neurons and glia. For instance, in rodents the SVZ of the lateral ventricles produces interneurons of the olfactory bulb, and the hippocampal subgranular zone continues to make new granular neurons; it is important to note that there may be less postnatal neurogenesis in the human olfactory bulb as the rostral migratory stream appears to disappear in infancy (Sanai et al., 2011). Adult neurogenesis in the hippocampal dentate gyrus is reduced by stress and may be important for spatial memory as well as aspects of antidepressant response (Perera et al., 2007).

Gliogenesis is also active postnatally. Oligodendrocytes continue to myelinate axons postnatally; some circuits are not fully myelinated until young adulthood. The degree of myelination is a critical determinant of action potential velocity, and therefore can have important consequences for circuit function. Furthermore, oligodendrocytes and astrocytes are essential for neuronal and synaptic integrity (Nave, 2010).

The neonatal brain is exposed to diverse sensory information; these experience-driven processes gain salience in neural circuit development and function. Experience-based learning involves alterations in the number and distribution of synapses, and molecular changes in synapses alter the strength of synaptic signaling. Processes such as *long-term potentiation* and *long-term depression* are regulated in part by changes in the numbers and types of neurotransmitter receptors (see Chapter 5).

For some types of experience-dependent learning there are limited time windows (*critical periods*) during which major changes to the brain's wiring diagram is plastic. For instance, early in postnatal development the primary visual cortex loses its ability to form eye-specific subdomains following closure of the critical period (Hensch, 2005). Closure of the critical period is regulated at least in part by the maturation of GABAergic cortical interneurons. These neurons are essential for creating the proper *excitation/inhibition balance* that is optimal for signal detection and for restraining uncontrolled excitation; defects in the development/function of cortical interneurons can cause epilepsy (Cobos et al., 2005), and are postulated to contribute to autism and schizophrenia (Rubenstein and Merzenich, 2003; Marin, 2012). For instance, neuregulin/ErbB4 signaling in GABAergic cortical interneurons regulates their ability to receive excitatory synapses and

to form inhibitory synapses (Marin, 2012). Defects in synaptic development and function may underlie a substantial fraction of neuropsychiatric disorders. Indeed, single gene disorders that contribute to autism appear to largely encode proteins that affect the synapse (Walsh et al., 2008). In addition, mechanisms that globally control the transcriptional state of a cell through modulating the *epigenome* (chromatin state and covalent modifications to DNA) are implicated in psychiatric disorders. For instance, the MeCP2 protein binds methylated DNA; MeCP2 mutations cause Rett syndrome (autism spectrum disorder), in part through reducing GABAergic signaling (Chao et al., 2010). Of note, MeCP2 is part of the genomic machinery regulating how a neuron responds to incoming activity (Cohen and Greenberg, 2008).

PERSPECTIVE

There has been tremendous progress in understanding the mechanisms governing development of the brain. These insights now form the foundation for interpreting genomic modifications that are associated with neuropsychiatric disease risk, and with environmental perturbations that alter specific developmental processes. The convergence of these efforts promises further progress in elucidating etiology, identifying individuals at risk, and discovering modalities for prevention and therapy (through molecular and experiential interventions).

2 | NEUROCHEMICAL SYSTEMS IN THE CENTRAL NERVOUS SYSTEM

ARIEL Y. DEUTCH AND ROBERT H. ROTH

It has been more than a century since the introduction of the neuron doctrine by Santiago Ramon y Cajal marked the beginning of the modern neuroscience and positioned the neuron as the individual unit of the brain (see Valenstein, 2005). It has taken most of the subsequent century for investigators to begin to address how these individual neurons communicate. Although battles on the nature of the primary mode of communication, electrical or chemical, raged for more than 50 years after Cajal received the Nobel Prize in 1906, by the middle of the 20th century there was widespread acceptance that chemical signals were the primary means of interaction between two neurons. The “classic” view of transmission of signals between neurons was that transmitter molecules synthesized by the presynaptic neurons are released into the synaptic cleft when the neuronal membrane is depolarized, with the transmitter subsequently binding to specific postsynaptic receptors that are coupled to intracellular second messengers.

Although many thought the defining principles of neural transmission were worked out by the beginning of the 21st century, the past decade has been as scientifically tumultuous as any of the previous 100 years, with several findings challenging certain long-held and cherished beliefs about neurotransmitters.

WHAT DEFINES A NEUROTRANSMITTER?

Several criteria have been established that define a *neurotransmitter* (Iversen et al., 2008). These include the following: (1) a neurotransmitter should be synthesized in the neuron from which it is released; (2) the substance released from neurons should be present in a chemically or pharmacologically identifiable form: it should be capable of being measured and identified; (3) exogenous application of the neurotransmitter in physiologically relevant concentrations should elicit changes in the postsynaptic neuron that mimic the effects of stimulation of the presynaptic neuron; (4) the actions of a neurotransmitter should act on specific neuronal receptors and should therefore be blocked by administration of specific antagonists; and (5) there should be appropriate active mechanisms to terminate the actions of the neurotransmitter.

These criteria are based largely on studies of acetylcholine (ACh), the first neurotransmitter identified. The

experimental steps required to advance a transmitter role for ACh were relatively simple because ACh is the transmitter at the neuromuscular junction. The ability to expose and maintain preparations of the neuromuscular junction, a peripheral site, permitted electrophysiological and biochemical studies of synaptic transmission. Physiological studies revealed fast excitatory responses of muscle fibers in response to stimulation of the nerve innervating the muscle, similar to the effects of ACh. Moreover, miniature end-plate potentials were observed, which Fatt and Katz (1952) demonstrated to be due to the “leakage” of the contents of individual ACh-containing vesicles from the presynaptic terminal. In contrast, overt depolarization is due to an increased number of quanta released over a set period of time. Finally, studies of the neuromuscular junction and another peripheral site, the superior cervical ganglion, allowed detailed analyses of the enzymatic inactivation of ACh. These studies of ACh established the standard to which subsequent studies of neurotransmitters would be held.

Many of the rules that were uncovered in studies of ACh apply to other transmitters. For example, the concept of the quantal nature of neurotransmission is central to current ideas of transmitter release. However, in the past generation, our ideas about the defining characteristics and functions of neurotransmitters have been expanded by the discovery of a number of chemical messengers that do not meet the criteria established for classical transmitters, but which clearly convey information from one neuron to another.

FUNCTIONAL ASPECTS OF MULTIPLE NEUROTRANSMITTERS

There are dozens if not hundreds of molecules that function as chemical messengers between neurons. Why do we need so many neurotransmitters? When transmitters were first being characterized it appeared that simple excitatory or inhibitory transmission would suffice, thus requiring two or at most a few transmitters. However, we now appreciate the complexity and nuance of interneuronal communication.

There are several factors that may contribute to the need for multiple chemical messengers (Deutch and Roth, 2012). The simplest explanation is that many axons terminate on a single postsynaptic neuron, which must be able to distinguish

between these multiple inputs. Although multiple inputs terminate on different parts of the postsynaptic neuron (such as the soma or dendrite), many of these inputs are so closely positioned that inputs using the same transmitter cannot be discriminated. Multiple transmitters allow the postsynaptic cell to distinguish differences in inputs by chemically coding the information, with the receptive neurons having distinct receptors and intracellular signaling pathways. This system also permits modulation of transmitter actions, changing a simple excitatory-inhibitory mode of communication to a situation where a single input determines the response of the neuron to a subsequent input.

A second reason for multiple transmitters may be related to the number of chemical messengers found in a single neuron. Thirty years ago, it was commonly thought that each neuron had but a single neurotransmitter; it is now clear that most if not all neurons have two or more chemical messengers (Deutch and Bean, 1995). Multiple transmitters in a single neuron permit the information transmitted by a neuron to a postsynaptic target to be encoded by different chemical messengers for different functional states. For example, the firing rates of a neuron differ over time, ranging from relatively slow firing rates to rapid bursts of firing. It may therefore be useful for a neuron to encode a high-frequency discharge by one transmitter and a lower-frequency discharge by another transmitter. Similarly, differences in firing pattern convey different information; for example, classical and peptide transmitters are differentially released by different patterns of discharge.

A third reason for multiple transmitters is that different types of transmitters are depleted at different rates. Classical transmitters are synthesized in the nerve terminal by enzymatic processing of a precursor; this process allows these transmitters to be released over extended periods of time while simultaneously being replenished at the terminal. In contrast, peptide transmitters are synthesized in the cell body and transported over long distances to the axon terminal. Peptides can therefore be depleted by repetitive firing of neurons before new stores of the peptide are synthesized and transported to the nerve terminal for use.

Yet another reason for multiple transmitters is that transmitters are released from different parts of a neuron. The prototypic site of release is the axon terminal. However, transmitters are also released from dendrites and can also be released from varicosities of an axon, not just the axon terminal. These different sites of release may be occupied by different transmitters.

The types of spatial arrangements between neurons may dictate yet another reason for multiple transmitters. We generally consider synapses to be the structural specializations for intercellular communication. However, transmitters may also be released from non-junctional appositions between two neurons. Multiple transmitters may allow the postsynaptic cell to distinguish between transmitters released from non-junctional appositions and areas of synaptic specializations.

A final factor that may contribute to the need for multiple transmitters is that postsynaptic responses to transmitters occur over different time periods. Such temporal differences

allow the postsynaptic cell to respond in a manner that takes into account antecedent activity in the presynaptic neuron. Thus, one transmitter can set the stage for the response of a particular cell to subsequent stimuli, which can occur on the order of seconds, or even minutes.

So many substances are now commonly accepted as neurotransmitters that one cannot discuss them all, much less new transmitter candidates. We will therefore review in some detail the principles of neurotransmission for one group of classical neurotransmitters. A representative peptide transmitter is then discussed, emphasizing similarities and differences between neuropeptide and classical transmitters. Finally, we briefly touch on unconventional transmitters, a growing group that includes such unexpected members as soluble gases (e.g., nitric oxide and carbon monoxide).

CLASSICAL TRANSMITTERS

Classical is a relative term in science, and particularly in neuroscience. Despite the use of the adjective, some of the classical neurotransmitters were unknown 50 years ago. Nonetheless, there is a wealth of information concerning virtually every step in the biosynthetic and catabolic processes of the classical transmitters. One characteristic of classical transmitters is that the final synthesis of classical transmitters occurs in the axon terminal: precursors of the transmitter are transported from the cell body to the axon (or, in some cases dendrite), where the transmitter is released to influence a follower cell. Another defining characteristic of classical transmitters is that they (or their metabolic products) are accumulated by the presynaptic cell via an active process; there is no energy-dependent, high affinity reuptake process for non-classical transmitters.

The catecholamines are a group of three related classical transmitters that are synthesized in certain central neurons, as well as the peripheral nervous system, where they can have hormonal functions. Because of the involvement of the catecholamines in several neuropsychiatric disorders, ranging from schizophrenia and depression to Parkinson's disease and dystonias, these transmitters have been the focus of extensive investigation. A detailed description of the life cycle of catecholamine transmitters provides an excellent example of the various steps involved in intercellular communication by classical transmitters.

CATECHOLAMINES

Catecholamines are organic compounds with a catechol nucleus (a benzene ring with two adjacent hydroxyl substitutions) and an amine group (Fig. 2.1). The term *catecholamine* is used more loosely to describe dopamine (DA; dihydroxyphenylethylamine) and its metabolic products norepinephrine and epinephrine. These three transmitters are generated by successive enzymatic modification of the amino acid *tyrosine*, each step requiring a different enzyme. The three catecholamines are found as transmitters in distinct dopamine-, norepinephrine-, and

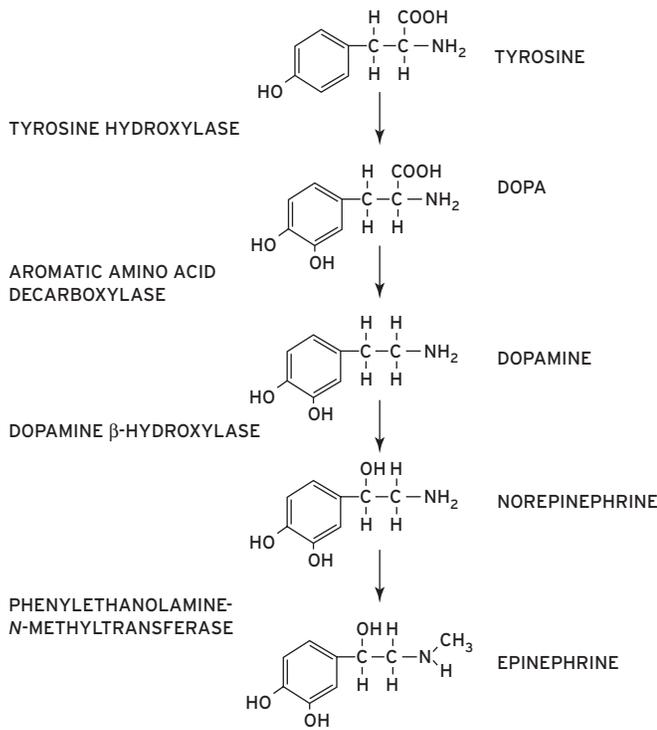

Figure 2.1 Synthetic pathway for catecholamines. From Hyman and Nestler (1993) from *The Molecular Foundations of Psychiatry*, (Copyright ©1993). American Psychiatric Publishing.

epinephrine-containing neurons because the biosynthetic enzymes that sequentially form these transmitters are localized to different cells.

CATECHOLAMINE SYNTHESIS

The amino acids *phenylalanine* and *tyrosine* are present in high concentration in plasma and the brain and are precursors for catecholamine synthesis. Under most conditions the starting point of catecholamine synthesis in the brain is tyrosine, which is derived from dietary phenylalanine by the hepatic enzyme *phenylalanine hydroxylase*. Decreased levels of this enzyme cause phenylketonuria, a disorder that if untreated (in part by limiting dietary intake of foods containing phenylalanine) results in severe intellectual deficits.

The amino acid *tyrosine* is accumulated by catecholamine neurons and then hydroxylated by the enzyme *tyrosine hydroxylase* (TH) to 3,4-dihydroxyphenylalanine (L-DOPA); this intermediary is immediately metabolized to DA by L-aromatic amino acid decarboxylase (AADC). In dopamine (DA)-containing neurons, this is the final synthetic step. However, neurons that use norepinephrine (NE) or epinephrine as transmitters also contain the enzyme *dopamine-β-hydroxylase* (DBH), which acts on DA to yield NE. Finally, brainstem neurons that use epinephrine as a transmitter, and adrenal medullary cells that release epinephrine, contain *phenylethanolamine-N-methyltransferase* (PNMT), which is responsible for the formation of epinephrine from norepinephrine (Fig. 2.1).

The entry of tyrosine into the brain occurs through a large neutral amino acid transporter; tyrosine competes with other

large neutral amino acids at this transporter. Under normal conditions, brain levels of tyrosine are high enough to saturate TH, and thus changes in precursor availability do not affect catecholamine synthesis. As a result, TH is considered the rate-limiting step in catecholamine synthesis. There are, however, certain exceptions to this rule, including in poorly controlled diabetes, in which the size of the large neutral amino acid pool is altered.

Tyrosine Hydroxylase

A single TH gene in humans gives rise to four TH messenger ribonucleic acids (mRNAs) through alternative splicing. In most non-human primates, two mRNA species are present; in rodents there is but a single transcript. The functional significance of multiple transcripts is unknown, although it has been speculated that there may be subtle differences in enzyme activity of the different protein species.

The amount of TH protein and the activity of the enzyme determine overall TH function. Enzyme activity is dependent on phosphorylation of the enzyme at four distinct serine residues by different protein kinases. This provides remarkably specific control over TH activity. In addition to regulation of the enzyme by phosphorylation, TH activity can be regulated by end product (e.g., dopamine) inhibition. Catecholamines inhibit the activity of TH through competition for tetrahydrobiopterin, a required cofactor for TH. Levels of reduced tetrahydrobiopterin are not saturated under basal conditions and thus play an important role in regulating TH activity. This is best illustrated by DOPA-responsive dystonia, which is due to mutations in the gene encoding GTP-cyclohydrolase I, the rate-limiting enzyme in the synthesis of tetrahydrobiopterin (Segawa, 2011).

The two means by which catecholamine neurons can cope with an increased demand for synthesis are by inducing TH protein or by activating existing enzyme (through phosphorylation). The degree to which catecholamine synthesis depends on *de novo* synthesis of enzyme protein or changes in enzymatic activity differs in various catecholamine neurons. Noradrenergic neurons of the locus coeruleus, a brainstem nucleus that is the source of much of the forebrain NE innervation, respond to increased demands for synthesis primarily by increasing TH gene expression, ultimately leading to an increase in TH protein levels. In contrast, in midbrain DA neurons changes in TH mRNA levels are rarely seen, with regulation of synthesis in these DA cells primarily determined by changes in the activity of TH through posttranslational processes (phosphorylation).

L-Aromatic Amino Acid Decarboxylase (AADC)

The product of tyrosine hydroxylation is L-DOPA, which is immediately decarboxylated to generate DA. This step requires the enzyme AADC (also referred to as *DOPA decarboxylase*). AADC has low substrate specificity: because the enzyme decarboxylates tryptophan as well as tyrosine, it is a key step in the synthesis of serotonin and catecholamines. The activity of AADC is so high that L-DOPA is almost instantaneously converted to DA.

A single AADC gene encodes multiple transcripts that are differentially expressed in the central nervous system

(CNS) and peripheral tissues. L-aromatic amino acid decarboxylase mRNA is enriched in both catecholamine- and indoleamine-containing neurons in the CNS but is also found at low levels in other cell types.

Dopamine poorly penetrates the poor blood-brain barrier. In contrast, the DA precursor L-DOPA readily enters the brain and has therefore become the mainstay of the treatment of Parkinson's disease, the proximate cause of which is striatal DA insufficiency. Administration of L-DOPA to parkinsonian patients quickly increases brain DA levels and improves motor deficits.

Dopamine- β -Hydroxylase (DBH)

Noradrenergic and adrenergic neurons, but not dopaminergic neurons, contain DBH, the enzyme that converts DA to norepinephrine. In noradrenergic neurons this is the final step of catecholamine synthesis. Two different human DBH mRNAs are generated from a single gene.

Dopamine- β -hydroxylase has relatively poor substrate specificity and can oxidize *in vitro* almost any phenylethylamine to its corresponding phenylethanolamine. Thus, in addition to the oxidation of DA to form NE, DBH promotes the conversion of tyramine to octopamine and α -methyl dopamine to α -methylnorepinephrine. This lack of substrate specificity has been exploited in the laboratory: several structurally analogous compounds can replace NE and function as "false transmitters," providing useful experimental tools. Contrary to the usual situation in which TH is the rate-limiting step in catecholamine synthesis, when the activity of locus coeruleus noradrenergic neurons is increased, DBH is thought to be saturated and becomes the rate-limiting step. DBH is localized to the vesicle, separating NE and its precursor dopamine into a vesicular, transmitter pool of NE and a cytosolic, non-transmitter pool for DA in noradrenergic neurons. If vesicular DBH is saturated, the result will be an accumulation of DA in the vesicle; when the vesicular contents are released by depolarization, both DA and NE are released. In this manner the noradrenergic vesicle becomes a Trojan horse for dopamine.

Phenylethanolamine-N-Methyltransferase (PNMT)

This enzyme methylates NE to form epinephrine. Central epinephrine neurons are located in two groups of brainstem cells; high levels of PNMT are also present in the adrenal medulla. PNMT has relatively poor substrate specificity and will transfer methyl groups to the nitrogen atom on a variety of β -hydroxylated amines. Nonspecific N-methyltransferases are also found in the lung and will methylate many indoleamines. The high levels of PNMT in the adrenal gland, coupled with relatively easy experimental access to the adrenal, have led to an extensive characterization of the enzyme in this gland, where enzyme activity and expression are tightly regulated by glucocorticoids and nerve growth factor.

Trace Amines and Trace Amine Receptors

A number of amines that are derived from catecholamine metabolism have been identified in the brain, including tyramine, octopamine, and β -phenethylamine. As their name

indicates, these compounds are present in trace amounts relative to the classical catecholamines, and a number of different receptors for which trace amines have high affinities have been identified (Sotnikova et al., 2009). These receptors are expressed in brain and gut and may in part be responsible for certain side effects of treatments with therapeutic drugs, such as certain monoamine oxidase inhibitors (see following), and may contribute to some actions of psychoactive drugs such as amphetamine and lysergic acid diethylamide (LSD), which are agonists at a trace amine receptor.

STORAGE OF CATECHOLAMINES: SYNAPTIC VESICLES AND VESICULAR TRANSPORTERS

Catecholamine transmitters are stored in small vesicles located near the synapse and poised for fusion with the neuronal membrane and subsequent exocytosis. In addition to serving as a storage depot for catecholamines, vesicles sequester catecholamines from cytosolic enzymes and from some toxins that enter the neuron.

The accumulation of catecholamines by vesicles depends on a vesicular monoamine transporter (VMAT). Two VMAT genes have been cloned: one is in the adrenal medulla, and the other, designated VMAT2, is found in catecholamine and serotonin neurons of the CNS. VMAT2 broadly accumulates monoamines, including catecholamines and indoleamines such as serotonin.

The VMATs are targets of some psychotropic drugs. Reserpine, a blocker of VMAT, has been used for decades to treat hypertension and psychosis. Studies of reserpine shed light on how this drug can reduce psychotic symptoms (by decreasing DA accumulation into vesicles and thereby decreasing DA availability) and hypertension (by disrupting catecholamine synthesis in the adrenal medulla and thereby decreasing circulating catecholamine levels).

REGULATION OF CATECHOLAMINE SYNTHESIS AND RELEASE BY AUTORECEPTORS

We have discussed how catecholamines are synthesized and some of the regulatory features that govern synthesis of these transmitters. Another way in which the synthesis of catecholamines can be regulated is by the catecholamine released from the neuron. Once released, the transmitter (e.g., dopamine) interacts with a receptor located on the catecholamine axon that binds the transmitter (e.g., a dopamine D₂ receptor). This nerve terminal "autoreceptor" is part of a feedback loop that maintains synaptic dopamine within a homeostatic range. This feedback can be a negative feedback, in which the released transmitter shuts down further transmitter release; drugs that are antagonists of the autoreceptor can promote transmitter release. There are several types of autoreceptors. In addition to autoreceptors that regulate transmitter release, there are autoreceptors that govern transmitter synthesis, and still another type that controls the firing rate of the neuron. The precise cellular distribution of these autoreceptors is linked to their function. For example, release- and synthesis-modulating autoreceptors are found on axon terminals of catecholamine neurons, while impulse-modulating autoreceptors that regulate the firing rate of catecholamine

neurons are localized to somatodendritic regions of the neuron. All three types of dopamine autoreceptors are thought to be D₂ receptors, one of the five types of dopamine receptors; this suggests that these D₂ receptors are coupled to different intracellular transduction cascades.

Release-modulating autoreceptors are found on all dopamine neurons, but synthesis-modulating autoreceptors are not. For example, both midbrain dopamine neurons that innervate the prefrontal cortex and certain hypothalamic dopamine neurons lack functional synthesis-modulating autoreceptors. Similarly, impulse-modulating autoreceptors are present on most but not all dopamine neurons. Such differences in the localization of autoreceptors to different types of neurons are thought to confer regional specificity on the function of dopamine neurons.

Autoreceptors for norepinephrine are also well characterized. Among these are noradrenergic autoreceptors that regulate release of NE, which are important targets for drugs used to treat cardiovascular and neuropsychiatric disorders. Norepinephrine autoreceptors in the brain are α₂-adrenergic receptors, the activation of which serves to inhibit norepinephrine release. In contrast, autoreceptors on peripheral nerves are β-adrenergic receptors and facilitate norepinephrine release.

INACTIVATION OF RELEASED CATECHOLAMINE NEUROTRANSMITTERS

Continuous (as opposed to discrete pulsatile) release of a transmitter does not provide target neurons with appropriate information about the dynamic state of the presynaptic neuron. Accordingly, there is a need for mechanisms to inactivate the released transmitter. The importance of this process can be easily appreciated by considering the consequences of unrestrained stimulation of channel-forming receptors through which calcium enters neurons: if intracellular Ca²⁺ levels increase too much, excitotoxic cell death results.

There are several specific mechanisms for terminating transmitter actions. Diffusion from the synapse is the most simple. However, in addition to being a slow mode of inactivation, diffusion is a poor means for terminating transmitter action because functional receptors are often present on the axon as well as in the immediate synaptic region. The primary mode of inactivation appears to be uptake of the released transmitter by a plasma membrane-associated transporter protein. Because these transporters are typically located on cells that release the transmitter, inactivation by means of transporter-mediated reuptake is efficient and often allows for recycling of the transmitter or metabolites to lower energy demands on the neuron. A second way for transmitter actions to be terminated is by catabolic enzymes located either extra- or intracellularly.

Enzymatic Inactivation of Catecholamines

Two enzymes sequentially metabolize catecholamines. Monoamine oxidases (MAO) deaminate catecholamines to yield aldehyde derivatives; these are further catabolized by dehydrogenases and reductases. Catechol-O-methyltransferase (COMT) methylates the meta-hydroxy group on catechols, and these methylated intermediaries are further oxidized by MAO. Enzymatic inactivation, particularly by COMT, is the primary

mode of terminating the actions of catecholamines circulating in the blood. In the brain, termination of catecholamine actions by reuptake mechanisms appears to be more important. Nevertheless, drugs that target the enzymatic inactivation of catecholamines have been very useful therapeutic strategies for several disorders, including depression.

Two MAO genes have been cloned, and two isoforms of the enzyme can be distinguished by substrate specificity. Both isoforms are present in the CNS and peripheral tissues. MAO_A displays high affinities for NE and serotonin, whereas MAO_B has a higher affinity for β-phenylethylamines. Drugs that inhibit MAO_A (*clorgyline*, *tranylcypromine*) are effective antidepressant drugs. However, these agents have serious side effects, including the development of hypertensive crisis: patients treated with MAO_A inhibitors who eat foods high in tyramine content (e.g., aged cheeses and Chianti, a particularly appetizing combination) do not effectively metabolize tyramine, which releases catecholamines from nerve endings and thereby dangerously increases blood pressure. These adverse effects associated with MAO_A inhibitors may be mediated in part by interactions with trace amine receptors.

Deprenyl is a specific inhibitor of MAO_B and is sometimes used in the treatment of Parkinson's disease (PD). The use of deprenyl in PD springs from studies of the neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), which causes a Parkinson's Disease (PD)-like syndrome. The tetrahydropyridine MPTP itself is not toxic, but its metabolite MPP⁺, which is generated by the actions of MAO_B, is highly toxic. Because the MAO_B inhibitor deprenyl blocks the formation of MPP⁺ from MPTP, pretreatment with deprenyl prevents MPTP-induced parkinsonism. This finding led to the suggestion that an environmental toxin similar to MPTP might cause parkinsonism, and studies of deprenyl in newly diagnosed PD patients ensued. Although initial analyses suggested that deprenyl slowed disease progression, subsequent analyses failed to sustain the early enthusiasm. It is now clear that deprenyl does not slow progression but may offer some symptomatic relief. This probably occurs by increasing DA levels secondary to the inhibition of MAO_B-mediated catabolism of DA. In addition, small amounts of amphetamine and methamphetamine, potent DA releasers, are generated by the metabolism of deprenyl and may contribute to symptomatic improvement in parkinsonian symptoms.

Catecholamine Reuptake: Membrane Transporter

The reuptake of transmitters released into the extracellular space via specific cell membrane proteins is thought to be the major mode of inactivation of classical transmitters. The accumulation of transmitters in the presynaptic neuron also permits intracellular degradative enzymes to act and further contribute to transmitter inactivation, particularly if the transmitter is not rapidly accumulated by vesicles.

Neuronal reuptake of catecholamines and other classical transmitters has several characteristics: the process is energy dependent, saturable, involves Na⁺ co-transport, and requires extracellular Cl⁻ (Kristensen et al., 2011). It is worthwhile to note that transporters can operate bidirectionally and under

certain conditions may paradoxically transport in the “wrong” direction, thereby “releasing” a transmitter.

Catecholamine transporters are found in catecholamine but not other neurons. There appears to be some catecholamine uptake by glial cells, but this is not a high-affinity reuptake process and the functional significance of this process remains obscure. However, there are high-affinity transporters for amino acid transmitters (such as γ -aminobutyric acid [GABA] and glutamate) that are localized to astrocytes and play a major role in regulating extracellular levels of these amino acid transmitters.

In mammals, two different catecholamine transporters, the dopamine (DAT) and norepinephrine (NET) transporters, have been identified. An amphibian epinephrine transporter has been cloned, but a mammalian homolog of this gene has not been identified. DAT and NET share significant sequence homology, and both exhibit relatively poor substrate specificity. In fact, NET has a higher affinity for DA than for NE.

Anatomical studies have revealed that DAT and NET are restricted to dopamine- and norepinephrine-containing cells, respectively. However, DAT is not present in measurable levels in all dopamine neurons. For example, the hypothalamic tuberoinfundibular neurons that release dopamine into the pituitary portal blood supply do not express detectable levels of DAT mRNA or protein. Because DA released from these neurons is rapidly carried away in the vasculature, there is probably no need for inactivation of DA by reuptake into tuberoinfundibular neurons.

Immunohistochemical studies have revealed that under basal conditions, DAT and other transmitter transporters are localized to the extrasynaptic region of the axon terminal (Pickel et al., 2002), suggesting that the transporter may be important in clearing DA that has diffused from the synaptic region. When one considers that DA receptors are also found adjacent to the synapse rather than at the synaptic junction (Pickel et al., 2002), extrasynaptic (so-called paracrine or volume) transmission may be of greater importance than previously realized for catecholamine transmission (Wickens and Arbuthnott, 2005).

Just as there is a tight process of regulation over enzyme activity, there are regulatory controls for neurotransmitter transporters. Chronic administration of catecholamine reuptake inhibitors decreases the number of transporter sites, consistent with a decrease in gene expression. In addition, the activity of catecholamine transporters appears to be regulated acutely by several mechanisms (Zahniser and Doolen, 2001). The recognition that transporter expression is dynamically regulated has broad implications for *in vivo* imaging studies of transporters (such as studies of DAT in PD) because drug treatments that patients receive may alter the apparent density of the transporter.

Studies of DAT knockout mice have revealed that a broad array of DA neuron functions is disrupted by loss of the transporter (Sotnikova et al., 2006). It is therefore not surprising that transporters are key targets of psychoactive drugs. Cocaine increases extracellular monoamine levels by blocking the transporters for DA, NE, and serotonin. The tricyclic antidepressants potentially inhibit NE and serotonin reuptake, with

significantly weaker effects on dopamine, and are one of the major means of treating certain types of depression. The newer serotonin-selective reuptake blockers, such as fluoxetine, are now the most widely prescribed antidepressant medications.

ANATOMY OF CATECHOLAMINE NEURONS

Neurons expressing dopamine, norepinephrine, and epinephrine are found in a wide variety of species, although there are some major differences in the anatomical organization of these neurons between species. For example, midbrain DA neurons are present in all vertebrates except bony fish (*teleosts*), and dopaminergic cells (although few in number) are present in flies and worms. There are some differences in the anatomy of the catecholaminergic neurons between primate and lower mammalian species, but these differences are mainly quantitative rather than qualitative, and the general organization of the catecholamine systems of primates and lower mammalian species is quite similar.

Dopamine neurons in the ventral midbrain cells project to several forebrain sites, including the striatum, limbic sites such as the amygdala, septum, and hippocampus, and to certain cortical sites (Fig. 2.2). The cortical DA innervation in primates is much broader than is seen in rodents. In addition to the midbrain DA neurons, several clusters of DA neurons are found in the diencephalon, including hypothalamic cells with long axons that innervate the spinal cord as well as intra-hypothalamic projections. Still another set of DA neurons is found in the olfactory bulb. The reader is referred to the review by Morelli and Bentivoglio (2005) for a more comprehensive discussion of the anatomy of DA neurons.

Norepinephrine-containing cells are located in the medulla and pons (Fig. 2.3). In the rostral pons, a small but important group of cells is found in the nucleus locus coeruleus. These neurons give rise to most of the noradrenergic innervation of

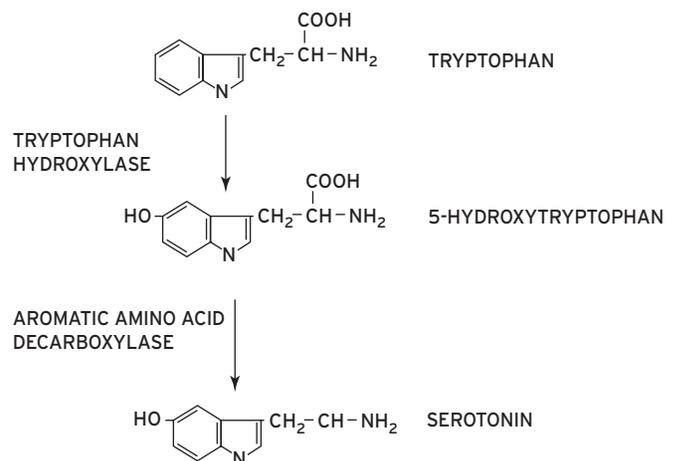

Figure 2.2 Dopaminergic projection systems in the brain. The major dopaminergic nuclei in the brain are the substantia nigra pars compacta (hatched), containing dopamine neurons that project to the striatum (also hatched); the ventral tegmental area (fine stipple), shown projecting to the frontal and cingulate cortex, nucleus accumbens, and other limbic structures (fine stipple); and the arcuate nucleus of the hypothalamus (coarse stipple), which provides a dopaminergic innervation of the pituitary. Figure 2.3 Noradrenergic projection systems in the brain. Shown are the major noradrenergic nuclei of the brain, the locus coeruleus (hatched) and the lateral tegmental nuclei (fine stipple). Epinephrine-containing nuclei are shown in black. The projections from the locus coeruleus (as described in the text) are markedly simplified. Projections from the other noradrenergic nuclei are not shown. From Hyman and Nestler (1993) permission from *The Molecular Foundations of Psychiatry*, (Copyright ©1993). American Psychiatric Publishing.

the forebrain, as well as of the brainstem and spinal cord. Other pontine and lower brainstem noradrenergic cells innervate certain nuclei in the hypothalamus and thalamus, and limbic areas such as the amygdala, septum, and hippocampus.

Epinephrine-containing cells are found in two nuclei in the medulla and provide descending projections as well as sending efferents to the pons that regulates the activity of the locus coeruleus NE-containing cells.

SEROTONIN

The major processes that regulate catecholamine synthesis and degradation are shared by all classical transmitters, including serotonin. Nonetheless, there are some relatively minor differences among the classical transmitters. The following discussion focuses on the differences between serotonin and catecholamine neurotransmitters.

SYNTHESIS OF SEROTONIN

The synthesis of serotonin (5-hydroxytryptamine) follows the basic scheme laid out for catecholamine transmitters: the uptake of a precursor amino acid (tryptophan) into a neuron, the sequential enzymatic formation of serotonin from tryptophan, the accumulation of serotonin by VMAT2 into vesicles, and, following release of the transmitter, inactivation by active reuptake of extracellular serotonin.

The precursor amino acid *tryptophan* enters the CNS via the large neutral amino acid transporter, where it competes with other amino acids (including phenylalanine and tyrosine). In serotonergic neurons, tryptophan is a substrate for tryptophan hydroxylase, which results in the formation of 5-hydroxytryptophan (5-HTP), the immediate serotonin precursor (Fig. 2.4). Tryptophan hydroxylase is not saturated, and

thus peripheral (including dietary) sources of tryptophan have a major influence on central serotonin synthesis.

There are two forms of tryptophan hydroxylase, one peripheral (TPH1) and the other central (TPH2). Situations requiring increased synthesis of serotonin are dealt with mainly by increasing the activity of the enzyme through phosphorylation; some long-term changes in demand may lead to increases in tryptophan hydroxylase gene expression.

5-Hydroxytryptophan is metabolized to serotonin by L-aromatic amino acid decarboxylase, the same enzyme that converts L-DOPA to dopamine. The serotonin formed can be metabolized to an acidic metabolite by MAO.

Although one usually thinks of serotonin as the end point of tryptophan pathways in the brain, there are two important exceptions to this rule. In the pineal gland serotonin is metabolized by serotonin-*N*-acetyltransferase to yield *N*-acetylserotonin, to which a methyl group is then added to form the hormone *melatonin*. Throughout the brain there is also a kynurenic acid shunt from tryptophan metabolism that results in the formation of several compounds, including quinolinic acid and kynurenic acid. Quinolinic acid is a potent agonist at *N*-methyl-D-aspartate (NMDA)-type glutamate receptors and causes seizures and neurotoxicity. In contrast, kynurenic acid is an NMDA antagonist. It has been suggested that the ratio of the two tryptophan derivatives may be of significance in conditions such as stroke, where cell death is mediated in part by NMDA receptors, as well as in schizophrenia (Wonodi and Schwarcz, 2010).

STORAGE AND REGULATION OF SEROTONIN RELEASE AND SYNTHESIS

Serotonin, like other classical transmitters, is stored intraneuronally in vesicles. The accumulation of 5-HT by vesicles depends on VMAT2, which also transports the catecholamines into vesicles. The other regulatory features of serotonin are essentially the same as seen in catecholamine transmitters, including the presence of serotonin autoreceptors that regulate serotonin release and synthesis, acting through functionally distinct somatodendritic and terminal autoreceptors. One

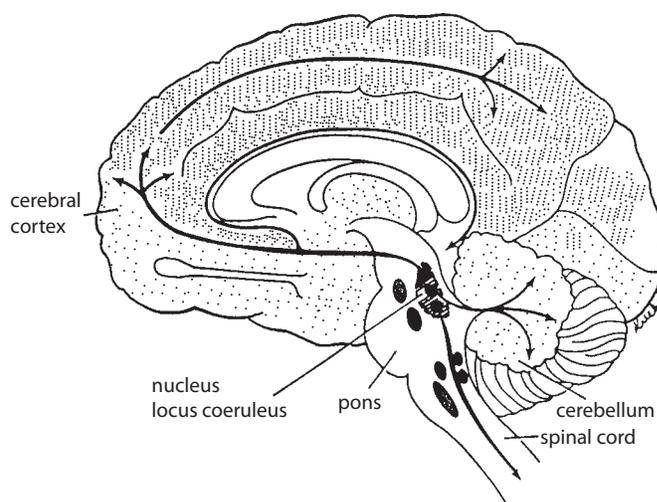

Figure 2.4 Synthetic pathway for serotonin. From Hyman and Nestler (1993) reprinted with permission from *The Molecular Foundations of Psychiatry*, (Copyright ©1993). American Psychiatric Publishing.

difference between serotonin and catecholamine neurons is that serotonin synthesis is not regulated by end-product inhibition *in vivo*. The release- and impulse-modulating autoreceptors in serotonin neurons are 5-HT₁ receptors. The 5-HT_{1A} receptor is an autoreceptor present on the somatodendritic region of the serotonin neurons, whereas the 5-HT_{1B} receptor is an autoreceptor located on serotonin nerve terminals. In addition, the 5-HT_{1A} receptor is also found on some non-serotonergic neurons. Changes in the number and coupling of 5-HT₁ receptors in response to chronic treatment with serotonin-selective reuptake inhibitor antidepressants is thought to be critical to the therapeutic actions of these drugs.

INACTIVATION OF RELEASED SEROTONIN

Reuptake of released serotonin by the serotonin transporter (SERT) is the major means of terminating serotonin's actions. The serotonin transporter belongs to the same molecular family as the catecholamine membrane transporters and has the same requirements for action. The SERT is also the target for the most commonly used antidepressants, the serotonin-selective reuptake inhibitors (Thompson et al., 2011). Like the catecholamines, serotonin can be inactivated enzymatically by MAO.

ANATOMY OF SEROTONIN-CONTAINING NEURONS

There are a number of distinct groups of serotonin neurons, most of which are located on the midline of the pons and medulla. (see Fig. 2.5). Pontine serotonin cells in the dorsal and median raphe nuclei are the major source of diencephalic and telencephalic sites; cells in the medulla provide important descending serotonin projections to the spinal cord.

AMINO ACID TRANSMITTERS

The excitatory and inhibitor amino acid transmitters glutamate and γ -aminobutyric acid (GABA) are the most abundant transmitters in the brain. The cell bodies of monoamine neurons

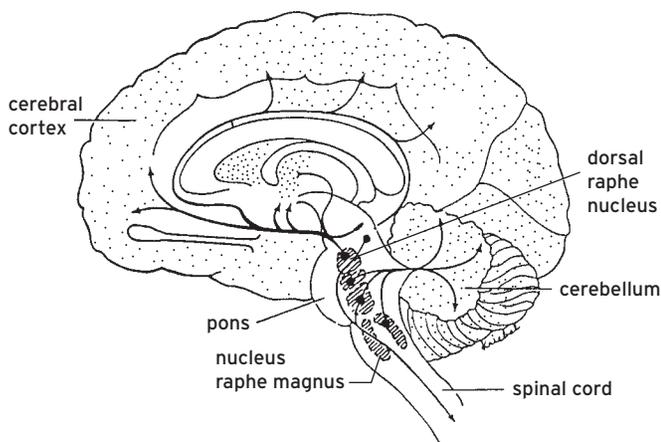

Figure 2.5 Serotonergic projection systems in the brain. The major serotonergic nuclei in the brain are the brainstem raphe nuclei (hatched). The nuclei are shown slightly enlarged, and their diffuse projections (as described in the text) are markedly simplified. are discretely localized in the brain, but glutamatergic and GABAergic neurons are found in virtually all areas of the brain. Although there are some significant differences between amino acid and monoamine transmitters, most of the major principles discussed in the section on catecholamine transmitters are applicable to amino acid transmitters. The amino acid transmitters are derived from intermediary glucose metabolism. The dual roles of GABA and glutamate as transmitters and metabolic intermediaries requires a means of segregating the transmitter and metabolic pools (Hassel and Dingledine, 2012; Olsen and Li, 2012). The other major difference between amino acid and monoamine transmitters is that the former are inactivated by uptake of the released transmitter through high-affinity transporters located on glial cells as well as by transporters found on neurons. This discussion focuses on those aspects of amino acid transmitters that differ from monoamine transmitters, as enumerated in the preceding. Although glycine is also an inhibitory transmitter, particularly in the spinal cord, GABA is discussed as the representative example of the inhibitory amino acid transmitter. Similarly, glutamate is discussed as the major excitatory transmitter, although other excitatory amino acids, including aspartate and sulfur-containing amino acids such as homocysteic acid, are also thought to be neurotransmitters.

AMINO ACID TRANSMITTER SYNTHESIS AND VESICULAR STORAGE

γ -aminobutyric acid is derived from glucose metabolism, with α -ketoglutarate from the Krebs (tricarboxylic acid) cycle being transaminated to glutamate by GABA α -oxoglutarate transaminase (GABA-T). The key step for the generation of the transmitter pool of GABA is the action of the enzyme *glutamic acid decarboxylase* (GAD), which converts glutamate to GABA. Glutamic acid decarboxylase is essentially restricted to neurons that use GABA as a transmitter and thus serves as a marker for GABAergic neurons.

Two isoforms of GAD are encoded by two different genes. The two GAD species (designated GAD₆₅ and GAD₆₇ on the basis of their mass) have somewhat different intracellular distributions and are differently regulated. Glutamic acid decarboxylase requires a pyridoxal phosphate cofactor for activity. The lower-mass enzyme, GAD₆₅, has a high affinity for the cofactor, but GAD₆₇ does not. The high affinity of GAD₆₅ for cofactor provides a way in which enzyme activity can be quickly and efficiently regulated. However, GAD₆₇ activity is not as readily regulated, although the amount of enzyme can be regulated at the transcriptional level.

The biosynthetic enzyme GAD is a cytosolic protein. However, GABA-T, which synthesizes the GABA precursor glutamate from α -ketoglutarate, is a mitochondrial enzyme. Thus, there appears to be a metabolic pool of GABA that is mitochondrial. The process by which glutamate destined for the transmitter pool is exported from the mitochondria is not fully understood.

Glutamate is the immediate precursor of the inhibitory transmitter GABA, but is also a major excitatory transmitter in different neurons. Neurons must therefore have some mechanisms to prevent GABA neurons from using glutamate as a transmitter. Glutamic acid decarboxylase is not found

in neurons that use glutamate as a transmitter, thus ensuring that GABAergic neurons use GABA but not glutamate as a transmitter. Moreover, vesicular transporters for GABA are localized exclusively to GABAergic neurons. In contrast to the monoamine vesicular transporters, which use a pH gradient to transport monoamines into the cell, the vesicular GABA transporter uses electrochemical and pH gradients to drive transport.

Similarly, in glutamatergic neurons one of several vesicular glutamate transporters (VGluTs) allows glutamate to be stored in vesicles for use as a transmitter (El Mestikawy et al., 2011). The VGluTs are used as markers of glutamatergic neurons. Despite these means of separating the transmitter pools of glutamate and GABA, and the general utility in having excitatory and inhibitory transmitters being found in different neurons, there are some examples of co-localization of excitatory and inhibitory amino acid transmitters in single neurons (Zander et al., 2010).

Glutamate can also be formed directly from glutamine, which is synthesized in glial cells. The glutamine that is formed in glia can be transported out of the glia and into nerve terminals and then locally converted by glutaminase into glutamate. Thus, glial cells may in part regulate glutamate synthesis, as well as determine extracellular levels of glutamate by means of membrane-associated transporters. This underscores the complex functions of glia, which are now recognized to play several critical roles in brain function in addition to the support role previously envisioned (Halassa and Haydon, 2010; Panatier et al., 2011), including key roles in neurotransmission.

REGULATION OF AMINO ACID TRANSMITTER RELEASE BY AUTORECEPTORS

Autoreceptor-mediated regulation of GABA neurons occurs through GABA_B receptors, which in contrast to postsynaptic ionotropic GABA_A receptors are coupled to G proteins. GABA_B receptors are also found on non-GABA cells, where they may regulate the release of glutamate and other transmitters. The release of glutamate from nerve terminals is also subject to autoreceptor regulation, a function subserved by G protein-coupled metabotropic glutamate receptors (mGluR). Three groups of mGluR receptors that include eight different receptors have been identified (Niswender and Conn, 2010); group II mGluRs are release-modulating autoreceptors. In addition to the well-characterized release-modulating mGluRs, electrophysiological studies have suggested the presence of a glutamate impulse-modulating autoreceptor. Various mGluRs are a target for the development of new drug treatments for a variety of neuropsychiatric disorders, including schizophrenia, Parkinson's disease, PTSD, and Fragile X syndrome.

INACTIVATION OF RELEASED GABA AND GLUTAMATE

The uptake of released GABA and glutamate is the primary means of terminating the actions of these transmitters. High-affinity GABA and glutamate uptake into both neurons and astrocytes occurs, the latter distinguishing these transmitters from the monoamines, which are not accumulated by high-affinity glial transporters.

In contrast to monoamine transporters, which include a single transporter for each of the monoamines (albeit with low substrate specificity), at least three transporters accumulate GABA (Kanner, 2006); other transporters present in the brain, such as a betaine transporter, can also accumulate GABA. The three types of membrane GABA transporters (GATs) do not readily correspond to different GAT isoforms in glia and neurons.

Glial and neuronal expression of membrane glutamate transporters also occurs, with at least four membrane glutamate transporters defined. These transporters display high affinities for glutamate, but differ in their affinities for other amino acids. Two glutamate transporters are primarily expressed in glia, with a third glutamate transporter being predominantly neuronal.

ANATOMY OF AMINO ACID TRANSMITTERS

GABA- and glutamate-containing neuronal elements can be found in almost every area of the brain. Nonetheless, certain discrete projections for excitatory and inhibitory neurons have been identified. For example, inhibitory GABAergic cells are usually local circuit neurons. However, some GABA neurons are projection neurons; among these are cells that project from the basal forebrain to the cortex and striatal GABAergic neurons that innervate the globus pallidus and substantia nigra. Among the many glutamatergic neurons are the pyramidal cells of the cortex, as well as a variety of long-axoned projection neurons in subcortical sites.

DIVERSITY OF AMINO ACID TRANSMITTERS

More so than other classical transmitters, GABA and glutamate as transmitters are marked by a complexity and diversity of function. There are multiple membrane transporters for GABA and glutamate, and multiple vesicular glutamate transporters. GABA and glutamate play transmitter and metabolic roles in neurons. There are a diverse group of receptors for GABA and glutamate, including ionotropic and metabotropic receptors. GABA and glutamate involve more than just neurons but critically bring into play glial cells.

We have focused this brief discussion on GABA and glutamate as amino acid transmitters, but there are other amino acids that are also transmitters or have been proposed to be neurotransmitters; these include, glycine, aspartate, and sulfur-containing amino acids. Among the most surprising of the amino acids transmitter candidates are D-amino acids (Wolosker et al., 2008). Conventional wisdom has held that L-enantiomers but not D-enantiomers of amino acids are active; D-amino acids were relegated to their functions in bacteria and invertebrates. However, D-serine and D-aspartate are present in relatively high concentrations in the human brain. D-serine is heterogeneously distributed, with the highest concentrations in regions with a high density of NMDA glutamate receptors. An enzyme, *serine racemase*, which converts L-serine to D-serine, has been found in glia but not neurons, suggesting that glia may synthesize and release D-serine. However, classical considerations of transmitters hold that neurons but not glia communicate via release of transmitters. This conundrum has been resolved by noting that certain

types of glia express α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)-type glutamate receptors and respond to glutamate stimulation by releasing D-serine onto NMDA-receptor-bearing neurons. Thus, in this case, glia serve as intermediate functional links between two neurons, and D-amino acids may be neurotransmitters, albeit unconventional ones (see following sections).

PEPTIDE TRANSMITTERS

Peptides, once viewed as pretenders to the royalty of neurotransmitters, have become firmly established as neurotransmitters over the past 30 years. The notion of peptide transmitters initially met with resistance because peptides did not meet some of the criteria developed for classical transmitters; some of these missing steps were subsequently shown to be due to methodological issues, including sensitivity of assay techniques.

There are two major differences between classical and peptide transmitters. The first is the intraneuronal site(s) of synthesis of the transmitter. Synthetic enzymes for classical transmitters are present in axon terminals as well as cell body regions, allowing a rapid response to increased demand for transmitter release from axon terminals. In contrast, peptide transmitters are typically synthesized in the cell body but not in axons. As such, increased demand for the peptide transmitter requires *de novo* protein synthesis and transport of the peptide to the terminal. The second major difference is that peptides are inactivated almost exclusively by enzymatic means; there are no high-affinity transporters that accumulate neuropeptides. Despite the failure of peptide transmitters to meet all of the classical criteria for transmitters, neuropeptides clearly convey information between neurons. Such information is not simply generalized information about the milieu, but is temporally and spatially coded information. Table 2.1 lists some of the many peptide transmitters in the brain.

The general principles of the peptide transmitters are discussed next. The discussion focuses on specific examples drawn from one widely distributed peptide, *neurotensin*.

SYNTHESIS AND STORAGE OF PEPTIDE TRANSMITTERS

Classical transmitters are typically synthesized by enzymatic processing of precursor(s) in the vicinity of the release site, usually the axon terminal. In contrast, peptide transmitters are formed from a prohormone precursor that is transcribed and translated in the cell body of the neuron, where it is then incorporated into vesicles. Thus, most peptide transmitters are formed from a single precursor from which active peptides are cleaved, in contrast to the successive enzymatic modifications of a precursor amino acid that give rise to most classical transmitters.

The general process can be easily understood by examining the case of the peptide transmitter neurotensin (NT). A large (170 amino acid) prohormone precursor of NT and a related

peptide, *neuromedin N* (NMN), are encoded by a single gene that is transcribed to yield two mRNAs. The two transcripts are present in equal abundance in most brain areas. Different molar ratios of NT and NMN are found in some tissues because of differential processing of the prohormone.

Classical neurotransmitters are usually packaged in small (<50 nm) synaptic vesicles, while neuropeptide transmitters are localized to large (<100 nm) dense-core vesicles. Peptides are often released at higher neuronal firing rates than classical transmitters. The mechanisms that govern the different processes responsible for vesicular release of peptides and classical transmitters is still being untangled (Bean et al., 1995), and may be cell type-specific (Ramamoorthy et al., 2011)

RELEASE OF PEPTIDES

Depolarization-elicited release of peptides from dense-core vesicular stores is calcium-dependent. The amount of peptide transmitter that is released varies as a function of the firing rate and firing pattern of the neuron. For example, studies of neurons that use both DA and NT as transmitters have found that higher firing frequencies are required to elicit release of the peptide. The temporal pattern of impulses arriving at the nerve terminal also determines release characteristics: the release of many peptides is most prominent under conditions of burst firing, where neurons fire in very rapid succession followed by a quiescent period (Bean et al., 1995).

INACTIVATION OF PEPTIDE TRANSMITTERS

Peptides are inactivated enzymatically: there do not appear to be conventional transporters that accumulate released peptides. The enzymes that metabolize peptides are specific for certain dipeptide sites along the peptide chain. Thus, the same enzymes can catabolize any peptide with the requisite dipeptide linkages. An example is a metallo-endopeptidase that inactivates the small opioid transmitters called *enkephalins*. Although this enzyme is often called *enkephalinase*, it also participates in the enzymatic processing of other peptides, including NT. Because the enzymes cleave and inactivate peptides work at sites across many peptides, most peptides have several major peptidases involved in the catabolism of the peptide. Three endopeptidases enzymatically inactivate NT. Enkephalinase cleaves NT at two sites, Pro10-Tyr11 and Tyr11-Ile12, to yield a decapeptide. Another peptidase acts at the Arg8-Arg9 site, and the third at the same Pro10-Tyr11 site as enkephalinase. Such processing can give rise to multiple metabolic products of the parent peptide.

The enzymatic inactivation of classical transmitters results in products that are not active at the transmitter's receptors. However, this is not necessarily the case for peptide transmitters, in which the products of enzymatic breakdown may retain activity at the receptor site. Indeed, some peptide fragments that are generated by the actions of peptidases may have a higher affinity for the peptide's receptor than the parent molecule.

NEWER PEPTIDE TRANSMITTERS

No additions have been made to the list of classical transmitters for some time, although new receptors for these transmitters have been discovered at a rapid rate. In contrast to the stable number of classical transmitters, the number of peptide transmitters continues to grow. The increased number of peptide transmitters is due in part to molecular biological strategies aimed at identifying novel genes. Many peptides have been identified in this manner, and of these, a considerable number have subsequently been shown to be neuroactive and meet criteria for a transmitter. One recent example stands out. Two groups simultaneously identified a novel gene encoding a prohormone that gave rise to two isoforms of a peptide, designated *hypocretin* (de Lecea et al., 1998) or *orexin* (Sakurai et al., 1998). These peptides are expressed only in a small number of lateral hypothalamic neurons. Despite the small number of hypocretin/orexin neurons, these cells send axons to cover almost the entire brain. Two G protein-coupled hypocretin/orexin receptors are widely but differentially distributed in the brain. One of the most interesting aspects of these cells is that among the functions ascribed to them is arousal (Boutrel et al., 2010). Degeneration of hypocretin/orexin neurons in humans is the cause of narcolepsy, a disorder marked by excessive daytime sleepiness, while in narcoleptic dogs there is a mutation in one of the hypocretin/orexin receptors. Since the discovery of the hypocretins/orexins, it has become apparent that this transmitter is critically involved in attention and cognition, reward and motivated behavior, and feeding behavior and metabolism.

UNCONVENTIONAL TRANSMITTERS

Technical approaches limit advances in any scientific endeavor, including neuroscience. For example, prior to the development of radioimmunoassays, it was difficult to detect peptides in the brain, and hence peptides were not considered serious transmitter candidates. The development of contemporary analytical methods, which are capable of reliably measuring substances at attomole levels, has opened the door to the identification of many new neurotransmitters.

The criteria necessary for establishment of a neuroactive substance as a neurotransmitter may need to be reconsidered. We previously discussed the idea that a very simple definition of *neurotransmitter* would be a neuroactive substance that allows information to flow from one neuron to another (Deutch and Roth, 2012). This definition avoids the issues of glial contribution to the milieu of the neuron, despite the fact that glia may convey important information and play an active role in the CNS (Halassa and Haydon, 2010). One problem with this definition is that it does not specify either the temporal or spatial characteristics of a transmitter, and thus could denote as a neurotransmitter a hormone, which typically acts over an extended time course across relatively large distances. Nor does this definition cover roles for transmitters that are only now starting to be uncovered, such as soluble gases and neurotrophic factors. And D-serine, which we already discussed,

can hardly be considered conventional, being synthesized in glia and posing as an intermediate between pre- and postsynaptic neurons, with even the synapse almost seeming to be an outdated concept.

In view of our inability to arrive at a satisfactory definition for transmitters, we suggest the term “unconventional transmitters.” Because the unconventional may soon become conventional, it is likely that our choice of terms will bring only temporary relief.

NITRIC OXIDE AND GAS NEUROTRANSMITTERS

Nitric oxide (NO) is perhaps best known as an air pollutant and would not immediately come to mind as a neurotransmitter candidate. Indeed, it is difficult to envision gases as neurotransmitters because a gas cannot be conventionally stored by neurons or released in an impulse-dependent manner. Nitric oxide is not stored and thus does not meet one of the key criteria for a neurotransmitter. Other gases, including carbon monoxide and hydrogen sulfide, also appear to have a transmitter function (Mustafa et al., 2009). Because NO is not stored in cells, it cannot be released by exocytosis. Nitric oxide also lacks an active process to terminate its action, and its “receptor” is the intracellular signaling protein guanylyl cyclase. Finally, NO appears to regulate the function of presynaptic terminals. As one lists these characteristics of NO, it becomes obvious that “unconventional” is a very conservative modifier to “transmitter” in the case of NO. Despite some hesitancy to embrace fully NO as a neurotransmitter, there are now ample data on the processes that control the synthesis, “release,” and termination of action of NO to consider gases as transmitters (Mustafa et al., 2009).

There is only one step in the synthesis of NO: the conversion of L-arginine by the enzyme nitric oxide synthase (NOS) to yield NO and citrulline. Three forms of NOS have been identified. *Macrophage-inducible NOS* (iNOS) is present in microglia, *endothelial NOS* (eNOS) is found in cells that line blood vessels, and *neuronal NOS* (nNOS) is indeed neuronal. All three NOS isoforms can be regulated, despite the use of the adjective *inducible* only for iNOS. Among the regulatory processes are phosphorylation (which decreases NOS activity) and hormonal control. In addition, levels of NOS can be modified by direct inhalation of NO as a feedback mechanism.

Nitric oxide is an uncharged molecule that diffuses freely across cell membranes. This allows NO to play a role in interneuronal communication. For example, NO may pass from one cell through an adjacent cell to influence a third neuron, which is not even a next-door neighbor of—much less synaptically coupled with—the original neuron. Indeed, recent data suggest that NO may act primarily as a retrograde messenger, modifying transmitter release and metabolism from presynaptic terminals. This situation has been most thoroughly explored in the hippocampus, where NADA-evoked NO release from pyramidal neurons increases glutamate release from presynaptic elements and may thereby influence long-term potentiation (and, by extension, learning and memory). Although one would suspect that a transmitter that acts by diffusion could not phasically regulate other cells, neuronal stimulation elicits NO release and therefore suggests phasic signaling capacity.

There is no active mechanism to terminate the effects of NO. However, the half-life of NO is only about 30 seconds, and thus this spontaneous decay to nitrite limits the duration of action of NO. In addition, NO can react with iron-containing compounds, such as hemoglobin, which effectively terminate the actions of NO.

ENDOCANNABINOIDS AND RETROGRADE NEUROTRANSMISSION

Marijuana has been used as a recreational drug and a therapeutic agent for thousands of years and remains a popular but largely illicit drug in the United States. The name *marijuana* is derived from the Mexican word *maraguanquo*, meaning “intoxicating plant.” The behavioral effects of marijuana vary widely across individuals, with some becoming giddy and euphoric, while others become sedated and depressed. Use of the drug may lead to distortion of sensory perceptions and time. Potential adverse effects following acute administration include impairment of short-term memory and impaired motor coordination and tracking during the performance of certain tasks such as driving. The psychoactive properties of marijuana suggest that there is a specific brain receptor for the drug. The cannabinoid receptor (CB₁) was cloned and it was demonstrated that this receptor and a related CB₂ receptor are G protein-coupled receptors, present in both the brain and other tissues. Both receptors are coupled to G_{i/o} and inhibit adenylyl cyclase. Initially it was thought that the CB₁ receptor is neuronal and CB₂ receptors are localized to peripheral sites. It is now clear that although CB₁ is the major cannabinoid receptor in brain, it is also found in the periphery, and there are CB₂ sites in brain.

The identification of cannabinoid receptors in turn led to the search for endogenous cannabinoid molecules (endocannabinoids, ECs). Progress has been rapid, and there is now a reasonably good understanding of the endogenous cannabinoid transmitters.

Endocannabinoids represent the first lipid transmitters. Because they are lipids they easily diffuse across membranes, and thus cannot be stored in vesicles. Instead, they are synthesized and released when needed from membrane-localized lipid precursors. Two major ECs have been identified, *N*-arachidonylethanolamide (anandamide) and 2-arachidonoylglycerol (2-AG). The EC synthetic pathways and the mechanisms through which ECs can be released on demand are fairly well characterized (Alger and Kim, 2011). The synthesis of 2-AG is fairly well characterized, and involves an increase in intracellular calcium stimulating phospholipase C to subsequently yield diacylglycerol, which is a substrate for a lipase that converts DAG to 2-AG. The synthesis of anandamide is more complex, with alternative pathways leading to its formation. The inactivation of ECs involves three proteins. 2-AG is primarily metabolized by monoacylglycerol lipase (MGL), while anandamide is metabolized by fatty acid hydrolyase (FAAH). There is also an energy- and sodium-dependent anandamide transporter that inactivates anandamide.

Endocannabinoids appear to act primarily as retrograde messengers at synapses. Upon appropriate stimulation of

neurons that result in intracellular changes (such as increase in intracellular calcium), ECs are “released” from membranes and interact with cannabinoid receptors on the presynaptic axon; the CB1 receptor is present on both excitatory (glutamatergic) and inhibitory (GABAergic) axons. The interaction of ECs with CB1 presynaptic receptors modulates subsequent release of the amino acid transmitter from the presynaptic axons. This EC retrograde signaling is intimately involved in specific forms of short- and long-term synaptic plasticity that subserve learning and memory (Chevalleyre et al., 2006).

In light of the psychoactive properties of cannabis, there is considerable interest in potential therapeutic actions of drugs that alter EC synthesis or inactivation. Because recreational marijuana use is often accompanied by “the munchies,” there have been trials of CB₁ antagonists in obesity; potential side effects essentially halted this line of drug development. CB antagonists have also been suggested to be of value in reducing cigarette smoking.

It has been widely speculated that cannabinoid receptors or ECs may be dysregulated in certain psychiatric disorders, particularly schizophrenia. Several indirect lines of evidence are consistent with a possible role of endogenous cannabinoids in the pathophysiology of schizophrenia. Early marijuana use is associated with an increased risk for a schizophrenic psychosis. Chronic marijuana use has been associated with cognitive deficits that progressively worsen with continued drug use and resemble to some degree the cognitive deficits of schizophrenia, and elevated cerebrospinal fluid levels of anandamide have been reported in patients with schizophrenia. There is an increase in the density of CB₁ receptors in the dorsolateral prefrontal cortex of patients with schizophrenia. Although some of these findings await independent verification, studies in laboratory animals are consistent with THC-induced cognitive deficits and transmitter changes. In particular, chronic administration of THC causes a decrease in DA turnover and ACh release in the prefrontal cortex that persists upon discontinuation of the drug treatment; during this drug-free period, attention and short-term memory deficits are present.

Both ECs and NO are retrograde signaling transmitters; there are other examples of retrograde messengers discussed next. It is not, in retrospect, surprising that there is both anterograde and retrograde transmission. We have already discussed certain mechanisms that permit the presynaptic axon to regulate its synthesis and release of transmitters (autoreceptors, end-product inhibition of synthesis). Retrograde signaling of information to modulate presynaptic release adds still another component to the tightly regulated orchestra of controls that homeostatically regulate neurotransmission.

NEUROTROPHIC FACTORS

Another group of molecules that appears to have retrograde neurotransmitter functions is the neurotrophins or growth factors. This diverse group of proteins is critical for the survival and differentiation of neurons (Huang and Reichardt, 2001). There are many different classes of neurotrophic factors, and within each class several members can be identified (Table 2.2). Although there are differences in the effects of members of a

^b Cytokines are categorized according to the receptor with which they interact; all couple ultimately to the JAK-STAT signaling pathway (see Chapter 4).

given class of growth factors, and differences in the receptors through which these growth factors exert their effects, there are broad similarities in the basic principles concerning synthesis, release, and termination of action of these growth factors (Huang and Reichardt, 2001).

Neurotrophic factors are unconventional in several ways, including their synthesis and release characteristics. In addition, the target neurons of the neurotrophic factors are often presynaptic to the cell in which the factor is found, consistent with neurotrophic factors providing trophic support for developing axons.

Current appreciation of the synthesis and regulation of neurotrophic factors has been gained primarily through molecular biology studies. Neurotrophic factors are often translated from multiple mRNAs. An example is brain-derived neurotrophic factor (BDNF), which contains five different exons that encode BDNF protein. Four of the five exons are controlled by separate promoters, the alternative use of which generates eight different BDNF mRNAs. Yet there appears to be only one mature BDNF protein! Because the different promoters are regulated through different means, an intricate cascade of events leads to mature BDNF production, with different transcripts varying in stability and yielding different amounts of protein.

Our knowledge of the posttranslational processing of neurotrophic factors is relatively poor compared to that of peptide transmitters. Perhaps the best-known situation is that of nerve growth factor (NGF), where the mature protein is cleaved from a prohormone, somewhat analogous to the situation seen in peptides. However, the NGF prohormone is quite different from neuropeptide prohormones: three subunits of the prohormone are present, one of which is catalytic and cleaves the prohormone to generate NGF. An interesting twist in the synthesis of neurotrophins is the necessity for dimerization of neurotrophins to form active species. It was originally thought that neurotrophins were exclusively present as homodimers *in vivo*, in contrast to *in vitro* studies that indicated heterodimer assembly. However, recent data suggest that heterodimers of BDNF and NGF can be formed in mammalian cells *in vivo*.

Neurotrophins and other proteins are secreted or released from neurons through two different pathways. The constitutive pathway for secretion is not driven by extracellular stimulation and is used to secrete membrane components, viral proteins, and extracellular matrix molecules; in other words, the constitutive pathway is not the pathway generally associated with neurotransmitters. Yet neurotrophic factors have typically been considered to be secreted by the constitutive pathway, in contrast to the release of more conventional classical and peptide transmitters (e.g., those shown in Table 2.1) through the regulated pathway. Prohormones have an N-terminal signal sequence, which targets the protein to the endoplasmic reticulum and then to the Golgi network, from where it is ultimately packaged into vesicles. Because many neurotrophic factors lack a signal sequence, the idea that growth factors are secreted by the constitutive pathway occurred by default. However, specific antibodies used for immunohistochemical studies have suggested that BDNF is present in chromogranin-containing secretory granules and thus can be secreted through the regulated pathway as well as the constitutive pathway.

The pathway through which neurotrophic factors are secreted is critical because of the question whether the release can be evoked by neuronal depolarization. It appears that under basal conditions BDNF and NGF are constitutively released from somatodendritic regions of the neuron, but that depolarization leads to regulated release, although it is unclear if this release is calcium-dependent.

Among the functions subserved by neurotrophic factors are those commonly ascribed to growth factors, including involvement in development, differentiation, and survival of neurons. However, there are other more “transmitter”-like functions. Neurotrophic factor expression and release from neurons, like transmitter expression and release, are regulated by afferent signals. For example, NGF and BDNF expression are increased by the excitatory transmitter glutamate and decreased by the inhibitory transmitter GABA. In addition, the regulation of BDNF by events such as seizures is regionally, spatially, and temporally distinct, with seizures leading to BDNF induction in different types of hippocampal neurons and with specific patterns of promoter activation.

Finally, a transmitter role for neurotrophic factors is suggested by their ability to regulate other neurons. Neurotrophic factors activate receptor proteins on target cells, which then initiate complex cascades of intracellular signaling pathways leading to their diverse biological effects. These effects include not only the more traditional growth factor responses but also the same types of changes that are seen in response to classical transmitters, such as regulation of ion channels (albeit on a different time scale). This underscores the notion that neurotrophic factors can serve as transmitters, just as more conventional transmitters (e.g., monoamines) can exert some trophic effects on target cells.

NEUROTRANSMITTERS AND THEIR EVOLVING ROLES

Our views of what constitutes a neurotransmitter are constantly changing. We have moved from being limited to classical transmitters such as acetylcholine to accepting peptides as transmitters, and have grown comfortable with gases and lipids, which are neither stored nor actively released. Having considered these changes in our views of neurotransmitters, it is not surprising to learn that interneuronal communication may be only one of multiple roles played by transmitters. For example, mRNAs that encode enzymes involved in transmitter synthesis, such as the ACh-synthesizing enzyme *choline acetyltransferase*, are found in lymphocytes. The ACh-inactivating enzyme *acetylcholinesterase* is also expressed in lymphocytes, as are certain acetylcholine receptors. The expression of these markers of transmitter systems is not restricted to lymphocytes but is seen across different tissues: choline acetyltransferase is even found in spermatazoa! When one considers that so many different aspects of acetylcholine synthesis and action are found in blood cells, it is reasonable to speculate that changes in these factors in peripheral cells may in some cases reflect central changes in these transmitters in neuropsychiatric disorders. This tantalizing notion has been repeatedly explored,

but no simple peripheral biomarker of central neuropsychiatric disorders has yet emerged from these studies.

There is inevitably strong resistance to change in scientific thinking, as Kuhn so compellingly argued. Just as inevitably, our conventional wisdom changes and gives rise to new dogma. The consideration of interneuronal messengers such as NO and the endocannabinoids as neurotransmitters is indicative that we have entered a new era with a growing degree of (new) dogmatism. However, our most cherished beliefs will be challenged soon by new data, which will cause us to revise (and ultimately overthrow) our current views. This should not be a cause for alarm, but perhaps celebration. As we have advanced in our understanding of the nature of neurotransmitters, so have we discovered new potential targets for the treatment of psychiatric disorders. While our current pharmacological treatment approaches will soon seem appallingly crude and ineffective, this can only emerge through an appreciation of transmitters and their receptor partners, as well as other near and distant relatives such as transporters and transduction mechanisms.

DISCLOSURES

Dr. Deutch serves on an Advisory Board for Eli Lilly and Co. He receives grant support from the National Institutes of Health. He is the chair of the Clinical and Scientific Advisory Board of the National Parkinson Foundation and a member of the Scientific Council of the Brain & Behavior Research Foundation. To the best of his knowledge he has no conflicts of interest, financial or otherwise, with regard to the subject matter of the chapter.

Dr. Roth receives grant support from the National Institutes of Health. To the best of his knowledge he has no conflicts of interest, financial or otherwise, with regard to the subject matter of the chapter.

3 | PRINCIPLES OF ELECTROPHYSIOLOGY

EVELYN K. LAMBE

Neurons communicate with each other through electrochemical signaling. Their electrical state is vital to their ability to respond to stimuli and to release neurotransmitters, the chemical signal that is the main form of communication between neurons. Although we have understood for a long time how neurons send signals, we are only beginning to understand how this signaling in different brain regions is affected by prior activity and by the presence of neuromodulators.

Electrophysiologists examine how neurons communicate with each other and how different conditions (genetic variability, stress, pharmacological manipulations) affect this signaling. *Electrophysiology* as a subject covers a broad range of techniques, but all give access to a higher level of resolution than most brain-imaging methods. To understand the meaning of electrophysiological data, it is critical to understand how neurons work and to know about the typical electrophysiological methods. This chapter begins with a review of neuronal physiology, discusses the typical tools electrophysiologists use, and then gives examples of how electrophysiological approaches are relevant to understanding the neurobiology and treatment of mental illness.

HOW NEURONS WORK

Neurons are encased in phospholipid membranes in which proteins are embedded. The proteins of greatest relevance to electrophysiology are *ion channels* and *receptors*. The latter group falls into two types that are discussed in detail later in this chapter: receptors that are ligand-gated ion channels and receptors that couple to G proteins. The membrane is impermeable to charged particles unless they travel passively through ion channels or are actively moved by another group of proteins called *ion pumps*. Together, ion pumps and ion channels lead to the creation of concentration and electrical gradients across the membrane. We now discuss mechanisms by which these gradients are created and how they serve the neuron's ability to communicate.

RESTING POTENTIAL

To understand the baseline or resting condition of a neuron, one must appreciate how ions are distributed. The solution surrounding neurons, called *extracellular fluid*, is essentially like seawater. There is a high level of sodium ions and a low level of potassium ions in this external solution. Neurons spend a lot of

energy pumping sodium ions out of, and potassium ions into, their intracellular space. As depicted in Figure 3.1, neurons thus have low internal sodium ion and high internal potassium ion concentrations. In addition to these positively charged sodium and potassium ions, neurons also contain negatively charged ions, most of which are membrane-impermeable anions (abbreviated as A^- on figures) such as sulfate ions. At rest, the membrane is permeable to potassium ions because of “leak” potassium channels; by contrast, there is very low permeability to sodium ions.

The array of channels that are open at a given time determines the membrane potential. Since the sodium-potassium pump has raised the internal potassium ion concentration above that found in the extracellular solution, potassium ions flow down their concentration gradient, leaving the cell through the leak potassium channels. As illustrated in Figure 3.2, this potassium ion movement leads to a local buildup of positive charge on the outside of the cell membrane near the potassium channels, and a local buildup of negative charge on the inside of the membrane. This electrical gradient opposes the concentration gradient. Rather than flowing through their ion channel from a place of high concentration to one of low concentration, the intracellular potassium ions are attracted to the buildup of negatively charged ions on the inside of the membrane and repelled by the local buildup of positively charged ions on the outside. So, the net flow of potassium ions stops. This steady state is called the *equilibrium potential* for potassium ions, or the *reversal potential* if determined experimentally. Since neurons have many more leak channels for potassium than for other ions, the equilibrium potential for potassium contributes disproportionately to the neuronal *resting potential*. The word *potential* refers to the difference in charge. At rest, the neuron is hyperpolarized; the inside of the membrane is more negative than the outside of the membrane. While the leak potassium channels are integral to setting a hyperpolarized resting potential, the exact resting potential is a function of the permeability of that neuron to potassium, sodium, and chloride ions. A typical membrane potential for a cortical pyramidal neuron at rest is -75 mV.

It is important to remember that this resting state is a dynamic process. Ion channels that are open have ions flowing through all the time; at rest, there is only no net flow. Under most conditions, the flow of ions through ion channels has negligible effects (less than 0.01%) on the total concentrations of ions inside and outside the cell. The energy-driven pumps are the main players at setting the intracellular concentration of ions, and the volume of extracellular fluid can be presumed

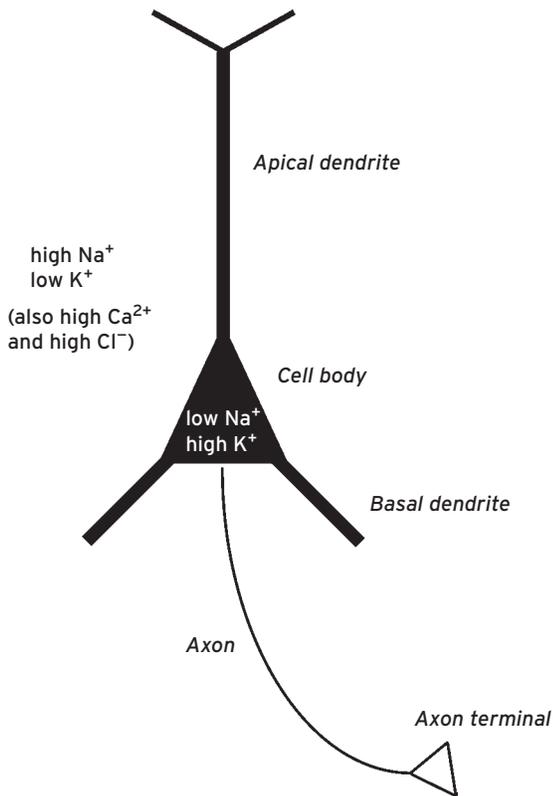

Figure 3.1 Schematic of a neuron showing concentration differences for various ions across the cellular membrane. The cytoplasm of the neuron is high in potassium ions (K^+) and low in sodium ions (Na^+), whereas the extracellular solution is high in sodium ions and low in potassium ions. Chloride (Cl^-) and calcium (Ca^{2+}) ions also occur at higher concentrations in the extracellular space compared to the intracellular space. Neurons receive inputs to their dendrites and send out information in the form of action potentials through their axons.

to be infinite compared to that of the neuron. The ion channels lead to charge separations across the membrane, as illustrated in part C of Figure 3.2.

Calcium is another positively charged ion that is found at a higher concentration in the extracellular fluid than in the cytoplasm (mostly because the neuron spends energy sequestering calcium in intracellular storage compartments). At rest, the cell membrane has very low permeability to calcium ions. Calcium can enter the neuron through a variety of channels, some opened by neurotransmitters (these particular channels are usually also permeable to other cations such as sodium and potassium) and some opened by changes in membrane potential. Calcium ions are very important for many aspects of neuronal signaling and are discussed further in the next two sections.

HOW NEURONS COMMUNICATE: SPIKES

The negative resting potential, together with the concentration gradient of sodium across the cell membrane, allows the neuron the ability to communicate rapidly. At the resting potential, sodium ions don't have open ion channels to travel through because channels that are permeable to sodium are either ligand gated (e.g., by glutamate) or are voltage gated (i.e., the neuron has to become less negative before these channels

will open). Activation of glutamate receptors opens channels that allow sodium and calcium to flow along their concentration gradients into the cell, which makes the neuron less negative transiently—known as an *excitatory postsynaptic potential* or EPSP. If a given cell is sufficiently depolarized by the summation of several EPSPs arriving close together in time, the voltage-gated sodium channels will open. This level of depolarization is called *threshold* because once a few voltage-gated sodium channels open, sodium ions rush in down their concentration gradient, leading to more depolarization, which opens more voltage-gated sodium channels, and so on. Threshold is

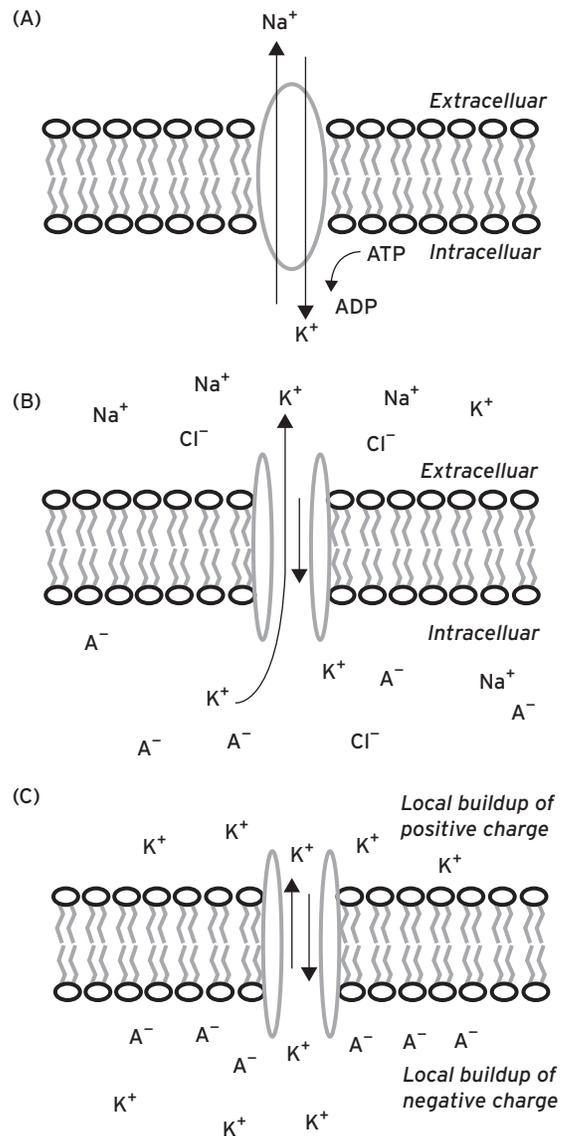

Figure 3.2 Schematic of a portion of the phospholipid membrane. (A) Depiction of the sodium-potassium pump. This protein uses energy to create concentration gradients by pumping sodium ions (Na^+) out of the neuron and potassium ions (K^+) into the neuron. (B) The leak potassium channels are open at rest. Through these channels, potassium diffuses out of the neuron along its concentration gradient. This diffusion creates a local electrical gradient that opposes the concentration gradient. (C) A schematic of the separation of charge across the membrane created by diffusion through leak potassium channels. This separation of charge contributes to the resting potential, in which the inside of the cell membrane is more negative than the outside.

thus the start of a positive-feedback “all-or-nothing process” that is called the *action potential*, as illustrated in Figure 3.3.

In an action potential, sodium rushes in through voltage-gated sodium channels, and this makes the membrane go from being negative relative to the local extracellular environment to being positive (remember: this is about local changes in electrical charge, not major changes in total intracellular or extracellular ion concentrations). As the cell membrane becomes more positive, however, two changes happen that tend to restore the neuron to its resting potential. First, voltage-gated potassium channels begin to open. The outward flow of potassium ions down their concentration gradient

tends to bring the membrane potential to a more negative level. Second, voltage-gated sodium channels begin to inactivate. When they are inactivated, they are open but blocked. For this block to be relieved and the channels to close, the membrane potential must again become hyperpolarized. So with a hyperpolarizing force and the loss of the depolarizing force, the cell membrane becomes even more negative than the resting potential (calcium-activated potassium channels play an important role in this phenomenon called *afterhyperpolarization*, also shown in Fig. 3.3) and then returns to the resting potential as the voltage-gated potassium channels slowly close.

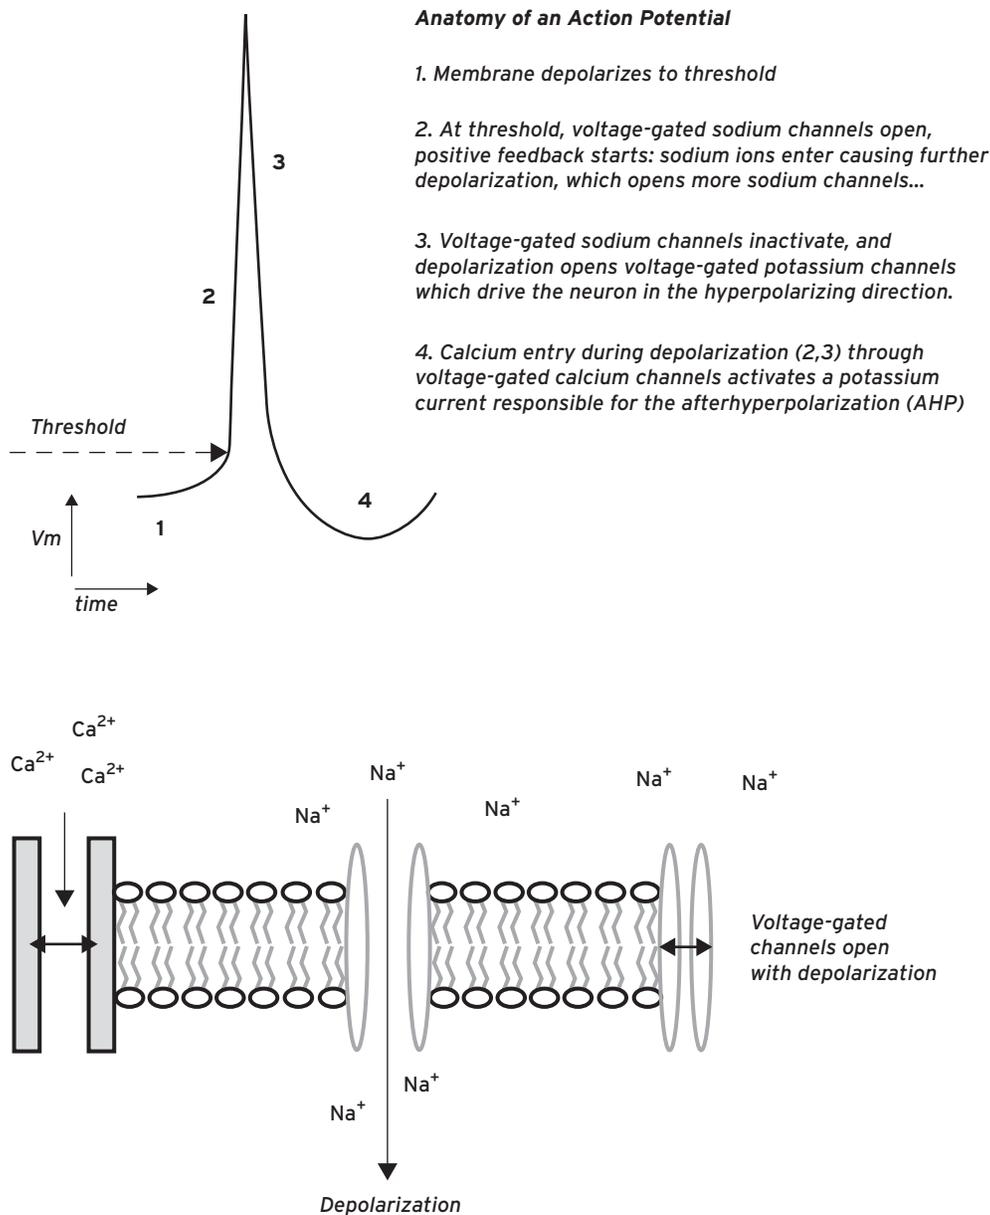

Figure 3.3 Action potentials are all-or-nothing events. When the membrane is depolarized to the threshold point, either by inputs from other neurons or through intrinsic mechanisms, voltage-gated sodium channels open, letting sodium ions (Na^+) flow down their concentration gradient into the cell, further depolarizing the cell and opening more voltage-gated sodium channels. This depolarization also opens voltage-gated calcium channels and voltage-gated potassium channels. The latter are important for repolarizing the membrane potential. There is often an afterhyperpolarization, where the neuron overshoots its typical resting potential, as a result of additional potassium channel activation beyond the usual complement of leak potassium channels. Calcium ions (Ca^{2+}), which entered while the neuron was depolarized, can contribute to the afterhyperpolarization by activating yet another set of potassium channels.

Voltage-gated sodium channel activation and inactivation explain much about how action potentials are generated and travel. Summation of several depolarizations or EPSPs arriving close together in time is usually required to trigger an action potential. A spike then depolarizes the entire neuron as the wave of depolarization opens more and more voltage-gated sodium channels. The axon, the output branch of the neuron, has evolved to enable particularly fast conduction. This thin branch is coated in myelin, which is similar in principle to the insulation that is used to increase the efficiency of electrical wires. Because the wave of depolarization is not substantially decreased between the gaps in myelin, it essentially “jumps” between the gaps or nodes (which have clusters of voltage-gated sodium channels). The action potential keeps traveling along neuronal structures toward their ends because sodium channel inactivation prevents sodium influx in a portion of the cell where the spike has already passed through. This phenomenon also limits how closely together spikes can be fired; this is known as the *refractory period*.

RELEASE OF NEUROTRANSMITTER

When the action potential reaches the end of the axon, it reaches a structure specialized for chemical transmission. Axon terminals have vesicles of neurotransmitter that are docked and ready to be released. Most axon terminals are the

presynaptic structure of a synapse. Figure 3.4 shows a glutamatergic synapse. *Synapses* are an anatomical specialization for chemical neurotransmission, involving a presynaptic portion that releases the neurotransmitter and a postsynaptic portion that has a high density of relevant receptors and ion channels. The trigger for release of neurotransmitter is the influx of calcium through voltage-gated calcium channels in the axon terminal. Although there are such channels in many parts of the neuron, only in the axon terminal does calcium influx trigger neurotransmitter release. Once released, the neurotransmitter diffuses across the synapse to receptors on the postsynaptic cell. For example, if the transmitter is glutamate, it brings about an EPSP in the postsynaptic cell, as previously described.

EFFECT OF NEUROTRANSMITTERS ON POSTSYNAPTIC NEURONS: FAST, IONOTROPIC RECEPTORS

The major way neurons communicate with each other is through chemical transmission, by releasing neurotransmitters from their axon terminals onto the dendrites of target neurons where they bind to specialized receptors. It is important to appreciate how the resting potential of a given cell is affected by the neurons that communicate with it. When an excitatory neuron sends a signal down its axon to the postsynaptic neuron, it can excite the cell (make it less negative). When an inhibitory

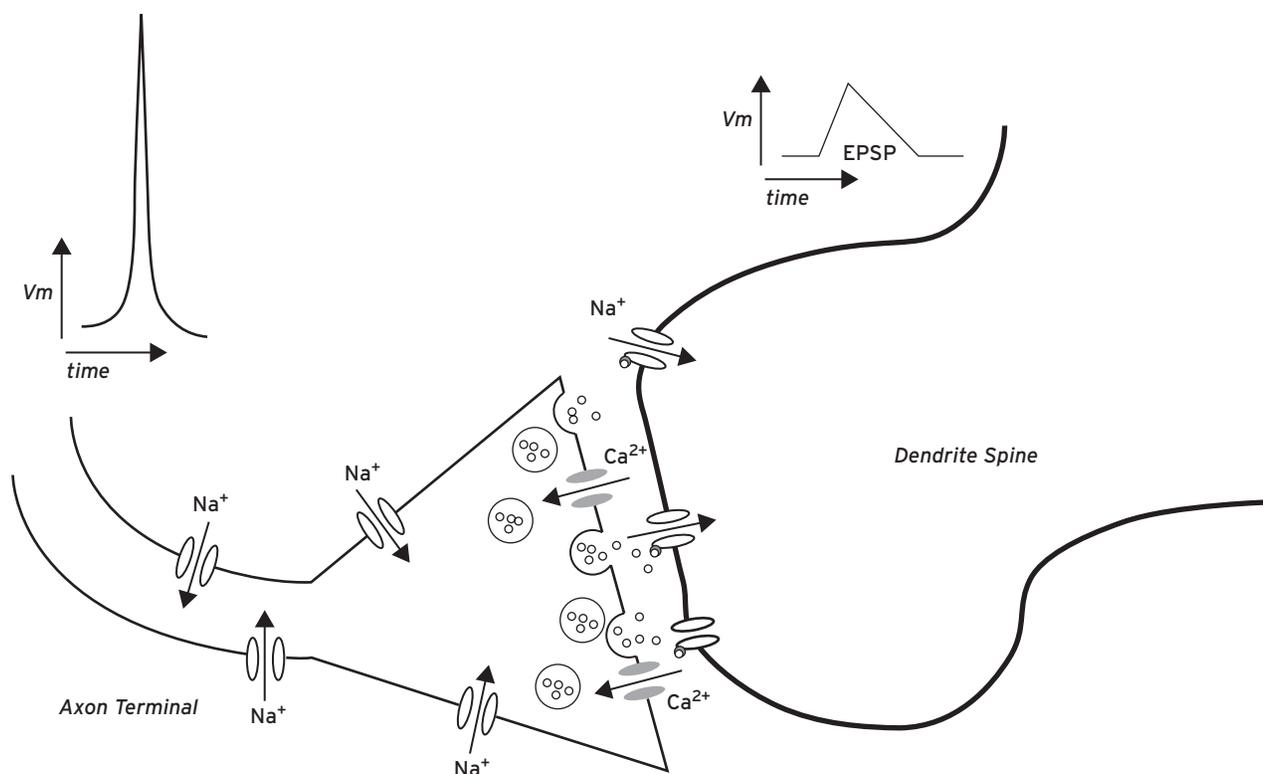

Figure 3.4 When an action potential reaches the end of an axon, the flood of calcium ions (Ca^{2+}) into the terminal through voltage-gated calcium channels results in the fusion of vesicles with the cell membrane and the release of neurotransmitter. Molecules of neurotransmitter diffuse across the synaptic cleft and bind to receptors on the postsynaptic membrane. The binding of the neurotransmitter glutamate to AMPA receptors opens these ligand-gated ion channels to allow sodium (Na^+) and potassium (K^+) to pass through. This mixed cation current (mainly sodium ions diffusing into the neuron) is depolarizing and results in an excitatory postsynaptic potential (EPSP). If this EPSP depolarizes the postsynaptic neuron to threshold, perhaps through summation with another EPSP close together in time and space, it could cause an action potential in this postsynaptic neuron.

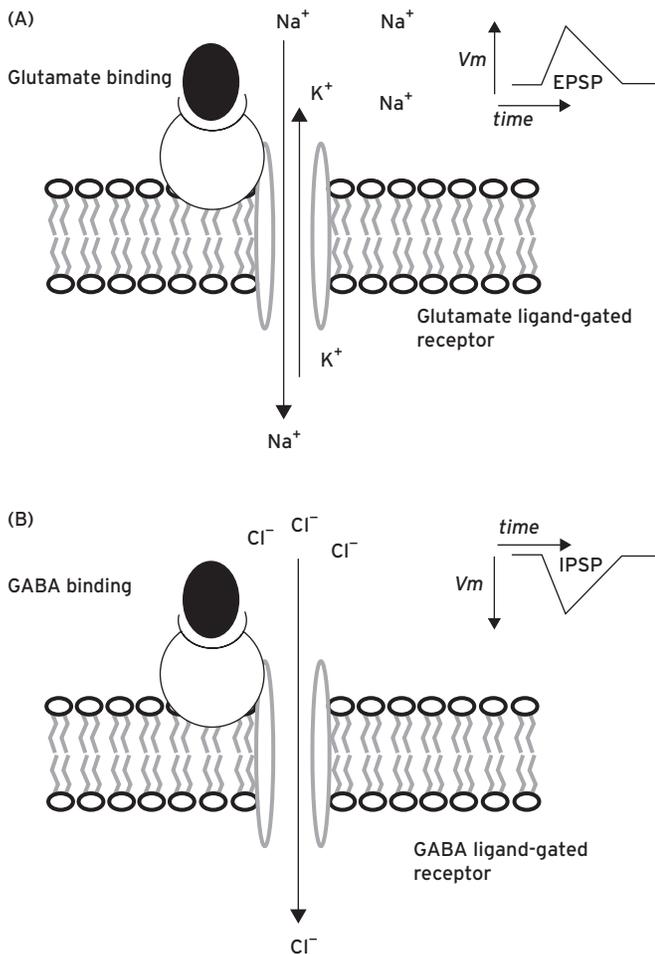

Figure 3.5 Schematic of postsynaptic effects. (A) If glutamate is released and binds to postsynaptic α -amino-3-hydroxy-5-methyl-4-isoxasolepropionic acid (AMPA) receptors, it will open and allow a mixed cation current to depolarize the neuron, producing a subthreshold wave of depolarization called an excitatory postsynaptic potential (EPSP). (B) By contrast, if γ -aminobutyric acid (GABA) binds to a postsynaptic GABA_A receptor, it will open to allow chloride ions (Cl⁻) to flow down their concentration gradient into the cell. This current hyperpolarizes the neuron in a wave of negative potential called an inhibitory postsynaptic potential (IPSP).

cell sends a signal to this neuron, it can inhibit the cell (make it more negative). In both cases, this is accomplished by neurotransmitters binding to a receptor that is directly coupled to an ion channel (referred to as fast neurotransmission). The two major fast neurotransmitters are *glutamate* and *γ -aminobutyric acid (GABA)*. Neurons are typically excited by glutamate binding and inhibited by GABA binding. As shown in Figure 3.5, activation of glutamate receptors creates an EPSP by opening channels that allow sodium and calcium ions to flow along their concentration gradients into the cell, which makes the neuron less negative transiently. By contrast, GABA binding opens a channel that allows negatively charged chloride ions to flow along their concentration gradient into the neuron, which makes it more negative transiently—known as an *inhibitory postsynaptic potential (IPSP)*. Waves of potential spread passively along dendrites. If many inputs to a neuron are active within a narrow time window, these waves summate (or cancel in the case of concurrent excitatory and inhibitory potentials). In the special case when several excitatory neurons release glutamate onto a neuron nearly simultaneously, the EPSPs or waves of positive potential can raise the membrane potential to the level that can open voltage-gated sodium channels and trigger an action potential.

The ligand-gated channels represent the most direct form of coupling between a receptor and effector where both components are part of the same protein complex. This group of channels is described further in Table 3.1. Binding of the agonist results in a conformational change of the channel protein complex, resulting in a rapid and marked increase in the permeability of the channel to the ion or ions for which it is selective. For example, when glutamate binds to an α -amino-3-hydroxy-5-methyl-4-isoxasolepropionic acid (AMPA) receptor as shown in Figure 3.5, it opens a channel that is permeable to sodium and potassium ions (as well as calcium ions to a limited degree). Some ligand-gated channels also have a component of voltage gating. For example, glutamate is an agonist for the *N*-methyl-D-aspartate (NMDA) receptor as well; however, glutamate binding alone will not open the NMDA channel at hyperpolarized voltages. When the membrane is hyperpolarized, a magnesium ion blocks the channel from the extracellular side. The membrane must be depolarized to free

TABLE 3.1. Ligand-gated ion channels

NEUROTRANSMITTER	RECEPTOR SUBTYPE	ION CHANNEL PERMEABILITY	PHYSIOLOGICAL RESPONSE
Acetylcholine	Nicotinic	Na ⁺ , K ⁺ , Ca ²⁺	Fast excitation
Glutamate	AMPA	Na ⁺ , K ⁺ (Ca ²⁺)	Fast excitation
	Kainite	Na ⁺ , K ⁺ (Ca ²⁺)	Fast excitation
	NMDA	Na ⁺ , K ⁺ , Ca ²⁺	Slow excitation
Glycine	GlyR α/β	Cl ⁻	Fast inhibition
GABA	GABA _A	Cl ⁻	Fast inhibition
Serotonin	5-HT ₃	Na ⁺ , K ⁺ , Ca ²⁺	Fast excitation

AMPA: α -amino-3-hydroxy-5-methyl-4-isoxasolepropionic acid; GABA: γ -aminobutyric acid; NMDA: *N*-methyl-D-aspartate.

the magnesium ion and allow sodium, potassium, and calcium ions to pass through the NMDA channel into the neuron. In essence, this means that presynaptic axons must release sufficient glutamate onto the neuron not only to bind to NMDA receptors but also to depolarize that region of the cell (through activation of AMPA receptors and influx of sodium). So the NMDA receptor is thought to act as a coincidence detector, and its permeability to calcium ions allows for long-term changes in the cell through mobilization of second messenger systems.

EFFECT OF NEUROTRANSMITTERS ON POSTSYNAPTIC NEURONS: G PROTEIN-COUPLED RECEPTORS

In addition to glutamate and GABA, there are many other transmitters. So far, we have only discussed ligand-gated channels also known as *ionotropic receptors* (those where the receptor directly opens an ion channel). However, there are also *metabotropic receptors*. The latter can affect cellular processes quickly or over a longer time period through activation of second messenger systems. Glutamate, GABA, serotonin, and acetylcholine have both ionotropic and metabotropic receptors. Other neurotransmitters, such as dopamine and norepinephrine, appear to have only metabotropic receptors. In fact, most neurotransmitter receptors found in the brain are not an intrinsic component of ion channels but are coupled to ion channels through *G proteins* whose functional properties are intimately related to their ability to bind guanosine-5' triphosphate (GTP). These metabotropic receptors can up- or downregulate the excitability of neurons in the short term and over a longer time period. Many examples of metabotropic G protein-coupled receptors in the brain and their functional effects are described Table 3.2.

G proteins are heterotrimers of α , β , and γ subunits, with the α subunit determining which of several major classes the G protein belongs and allowing us to predict its direct and indirect effects on ion channels. The direct effects involve interactions of the G protein subunits with ion channels. For example, the $\beta\gamma$ subunits of activated $G\alpha_i$ proteins dissociate and activate the inwardly rectifying potassium channels (Kir3 or GIRKs), ion channels that inhibit or hyperpolarize neurons. The indirect effects of G protein-coupled receptors, by contrast, affect ion channels through involving the modulation of second messenger cascades. The specific type of second messenger depends on the type of G protein α subunit. In this regard, the three major types of G proteins are $G\alpha_s$ (which stimulates the production of the second messenger, cyclic adenosine monophosphate [cAMP]), $G\alpha_i/G\alpha_o$ (which inhibit the production of the second messenger cAMP), and $G\alpha_q$ (which stimulates the second messenger phosphoinositol pathway). Table 3.2 identifies the second messenger cascades modulated by many G protein-coupled receptors in the brain. Such cascades can additionally have long-term effects on neuronal physiology through covalent modification of ion channels, as well as through changes in gene expression of receptors and channels. Through these indirect mechanisms, G proteins can modulate the fast, ionotropic transmission described in Table 3.1 and the previous section.

THE BASIC TOOLS OF THE ELECTROPHYSIOLOGIST

Electrophysiology is the study of the electrical properties of neurons, and the investigation of how these properties change under different conditions. Such recordings can be performed *in vivo*, in brain slice, or in isolated cells (either from dissociated brain slices or primary culture of neurons or another cell type). Each of these types of recordings has benefits and limitations in terms of the types of questions that can be addressed.

In vivo electrophysiologists record neuronal activity in certain regions of the brain to answer the question of how small groups of neurons respond during the performance of a task or when another brain area is stimulated. Data about individual neurons are extracted mathematically from the recordings of electrical activity at the place where the electrode was positioned. These experiments are extremely difficult logistically and are limited in terms of controlling different variables.

Questions about local circuitry can be better explored with slice physiology. This technique relies on the fact that it is possible under special conditions to keep a slice of brain alive and healthy for many hours. The investigator records from individual neurons and can examine how this neuron's electrical activity is affected by different conditions. Yet here too, there can be logistical difficulties accounting for so many variables.

Some investigators want to understand how one type of ion channel behaves under different conditions. To answer this sort of question, there are electrophysiologists who record from a small section of membrane from either a neuron or a cell from a line that has been molecularly altered such that it contains one channel or receptor of interest.

The brain is so complicated that any one level of electrophysiology will not answer all our questions. But the interplay of answers from labs using different techniques gives us unparalleled information about how neurons communicate with each other.

IN VIVO RECORDING

The spiking activity of individual neurons can be studied *in vivo* with extracellular recording via a microelectrode in the brain. This form of recording is referred to as *extracellular* because the electrode picks up signals from outside a cell. Recording in awake animals, termed *chronic unit recording*, allows for correlations between neuronal activity and behavioral state. If the animal is doing a task, patterns of neuronal activity correlated with correct performance can be contrasted with activity correlated with making a mistake. Patterns of activity can be correlated with broader behavioral states such as the different stages of sleep. Chronic unit recording is also performed sometimes in people with intractable epilepsy to better localize seizure foci before surgery. Extracellular recording is generally used to measure changes in firing activity. Some investigators will apply small quantities of a drug that affects a certain type of receptor, to see how either stimulating or blocking this receptor will change the firing pattern of a neuron or group of neurons. This is known as *microiontophoresis*.

TABLE 3.2. G Protein–coupled receptors

NEUROTRANSMITTER	RECEPTOR SUBTYPE	G PROTEIN	SECOND MESSENGER	ION CHANNEL	PHYSIOLOGICAL RESPONSE
Acetylcholine	M ₁ , M ₅	G _q /G ₁₁	↑ IP ₃ & DAG	↓ K ⁺ currents	excitation
	M ₂ , M ₃ , M ₄	G _i /G _o	↓ cAMP	↑ Kir3 ^a , ↓ Ca ²⁺	inhibition
Cholecystokinin	CCK ₁ , CCK ₂	G _q /G ₁₁	↑ IP ₃ & DAG		excitation
Dopamine	D ₁ , D ₅	G _s /G _{olf}	↑ cAMP		variable
	D ₂ , D ₃ , D ₄	G _i /G _o	↓ cAMP	↑ Kir3, ↓ Ca ²⁺	inhibition
GABA	GABA _B	G _i /G _o	↓ cAMP	↑ Kir3, ↓ Ca ²⁺	inhibition
Glutamate	mGlu group 1	G _q /G ₁₁	↑ IP ₃ & DAG	↓ K ⁺ currents	excitation
	mGlu groups 2 & 3	G _i /G _o	↓ cAMP	↑ Kir3, ↓ Ca ²⁺	inhibition
Hypocretin/Orexin	Hcrt1, Hcrt2	G _q /G ₁₁	↑ IP ₃ & DAG	↓ K ⁺ currents, ↑ cationic	excitation
Neuropeptide Y	Y ₁ , Y ₂ , Y ₄ , Y ₅	G _i /G _o	↓ cAMP	↑ Kir3, ↓ Ca ²⁺	inhibition
Norepinephrine	α ₁	G _q /G ₁₁	↑ IP ₃ & DAG	↓ K ⁺ currents	excitation
	α ₂	G _i /G _o	↓ cAMP	↑ Kir3, ↓ Ca ²⁺	inhibition
	β ₁ , β ₂	G _s	↑ cAMP		variable
Opiate	μ, δ, κ	G _i /G _o	↓ cAMP	↑ Kir3, ↓ Ca ²⁺	inhibition
Serotonin (5-HT)	5-HT ₁ family	G _i /G _o	↓ cAMP	↑ Kir3, ↓ Ca ²⁺	inhibition
	5-HT ₂ family	G _q /G ₁₁	↑ IP ₃ & DAG	↑ K ⁺ currents	excitation
	5-HT _{5A}	G _i		↑ Kir3	inhibition
	5-HT _{4,6,7}	G _s	↑ cAMP		variable
Somatostatin	SST ₁₋₅	G _i /G _o	↓ cAMP	↑ Kir3, ↓ Ca ²⁺	inhibition
Tachykinins	NK ₁₋₃	G _q /G ₁₁	↑ IP ₃ & DAG	↓ K ⁺ currents, ↑ cationic	excitation
VIP	VIP ₁ , VIP ₂	G _s	↑ cAMP	↑ cationic	excitation

^a Kir3 is also known as GIRK (G protein–activated inwardly rectifying potassium current).

cAMP: cyclic adenosine monophosphate; DAG: diacylglycerol; GABA: γ-aminobutyric acid; 5HT: 5-hydroxytryptamine; IP₃: inositol triphosphate; VIP: vasoactive intestinal peptide.

Neurons can be further studied *in vivo* with multiphoton imaging. The longer wavelengths of light used for this imaging can penetrate deeply into thick, scattering brain tissue. As a result, multiphoton microscopy can be used to visualize fluorescent molecules hundreds of microns deep in the cortex. Usually the fluorescent dyes or calcium indicators have been infused with a pipette or were genetically expressed. Transgenic animals expressing green fluorescent protein (GFP) in a Golgi-like pattern in a population of neurons can be used to assess developmental or environmental changes in dendritic branches and spines.

SLICE RECORDING

Recording from individual neurons in brain slice is used to measure changes in membrane potential affected by the

behavior of different ion channels. The slice is kept alive in a chamber under conditions that mimic those *in vivo* as closely as possible. The state of the art is to use an infrared camera that allows the visualization of the neurons in the slice so the experimenter can select a healthy neuron and guide the pipette up to the selected neuron under carefully controlled conditions, as illustrated in Figure 3.6. When the pipette is brought into contact with the neuron, a small amount of suction is applied. This induces the formation of a strong seal between the glass of the pipette and the cell membrane. At this point, further suction is applied and the small patch of membrane is opened. The pipette then has complete physical and electrical access to the neuron; this is known as *whole-cell patch recording*.

Slice physiologists can then look at changes in membrane potential or firing in response to certain treatments, such as application of a drug in the bath or more locally through

Figure 3.6 Visualization of a pyramidal neuron in a slice of cerebral cortex using infrared-differential interference contrast optics. The pipette, shown to the right, will be brought into contact with the neuron. After formation of a gigaohm seal, a small amount of suction will be applied to allow recording in the whole-cell configuration.

another pipette. When reading about slice physiology experiments, it is interesting to note whether the recordings were made in current clamp or voltage clamp. In the former, either depolarizing or hyperpolarizing current is injected and the effect on the membrane potential is assessed. This is similar to mimicking the effects of synaptic input. In voltage clamp, by contrast, the experimenter controls the membrane potential and measures the amount of current needed to maintain this “holding” potential. This is particularly useful for assessing the effects of some treatment on different voltage-gated ion channels because membrane potential is the key variable for this type of channel gating. Synaptic potentials are best measured in voltage clamp (they are measured as opposing currents needed to hold the membrane at the set potential) because they are relatively small and brief events that would be obscured by capacitive transients.

The complete physical access permitted in whole-cell recording allows the neuron to be filled with a fluorescent dye so that it can be visualized as shown in Figure 3.7. There are indicators available that change their level of fluorescence depending on the concentration of calcium. These calcium indicators allow us to “watch” the effects of calcium channels being opened by an action potential as it back-propagates through the dendritic arbor. The wave of depolarization opens voltage-gated calcium channels, increasing the concentration of calcium in spines and dendrites as shown in Figure 3.8.

BEYOND SLICE

There are many reasons why experimenters would like to reduce the complexity of the preparation they record in. For example, they might want to minimize inputs to the neuron they record from, to record from a small piece of membrane, or to record from a cell that has been genetically altered. Various possibilities for simplifying the system exist. These include mechanically dissociating a slice, creating a primary culture of the slice (though it is not possible to have neurons replicate themselves the way

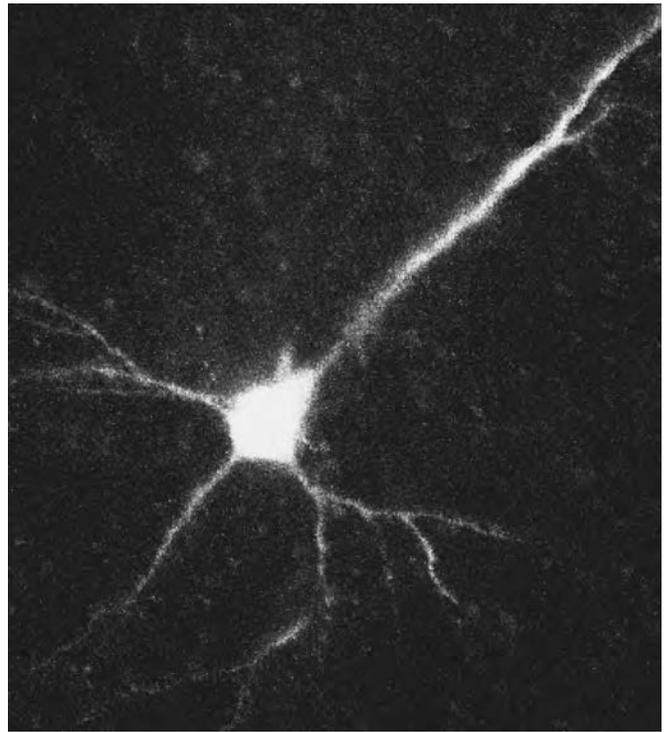

Figure 3.7 A cortical pyramidal neuron previously filled with a fluorescent indicator through whole cell patch clamp. The membrane reseals after the patch pipette is pulled away.

other cell types will under cell culture conditions, it is feasible to create conditions where neurons from a brain slice will live for weeks rather than the hours they usually survive under typical slice conditions), or working with “neuronal-like” cell lines (cells originally from a tumor that will replicate themselves). The last are frequently transformed genetically so that they express certain receptors or ion channels that an electrophysiologist wishes to further characterize. For example, transfecting a cell line with different subunits of a particular channel in varying proportions permits one to investigate the kinetic properties of channels with different combinations of subunits. One way one could approach this question would be with single channel recording. Generally, one patches onto a cell, much the same way one would patch onto a neuron in slice. Then the electrode is pulled away. Depending on the technique, this can enable one to record from a small piece of membrane in several possible configurations. The single-channel approach allows the detailed examination of the kinetics of channel gating by different modulators and, in combination with genetically altered amino acids in channel subunits, the ability to understand which amino acids are critical for ion permeability through the pore or which endow vulnerability to various ion channel toxins.

ION CHANNELS AND MENTAL ILLNESS

Mental illness is a compelling example of a subtle dysfunction of neuronal communication that has dramatic consequences for how a person perceives and responds to the world. Our understanding of what triggers and perpetuates these illnesses is still

in its infancy. We are only beginning to understand the genetic causes of specific mental illness and how these affect ion channels and brain physiology. Much of the brain functions normally, but certain processes unique to each mental illness go awry. Human imaging studies that assess brain activity levels suggest that the balance between excitation and inhibition in particular regions of the brain is abnormal in these disorders. For example, people with major depression have abnormally elevated activity in a specific brain region of the prefrontal cortex, the subcallosal cingulate gyrus, as well as in the amygdala (Hamani et al., 2011; Drevets et al., 2008). Interestingly, there is unexpectedly high comorbidity between major depression and seizure disorders (Kanner et al., 2008), which is consistent with altered excitation and inhibition in the brain in psychiatric disorders.

Recent studies have linked mental illnesses with genetic variability in the function of specific ion channels. For example, a single nucleotide polymorphism in the coding region of a nicotinic receptor subunit, *CHRNA5*, results in reduced function of the channel (Bierut et al., 2008; Kuryatov et al., 2011) and is strongly associated with increased vulnerability to nicotine addiction (Bierut et al., 2010). Rodent studies suggest that the reduction of the nicotinic receptor nonselective cation current resulting from this polymorphism will have behavioral consequences including a loss of sensitivity to the adverse effects of the drug nicotine (Tuesta et al., 2011) and a decrease in attentional performance (Bailey et al., 2010). Interestingly, this variation in the *CHRNA5* gene has been found in half of people with schizophrenia (Hong et al., 2011), a group of people with a high prevalence of nicotine addiction (Myles et al., 2012) and deficits in attention (Hahn et al., 2012).

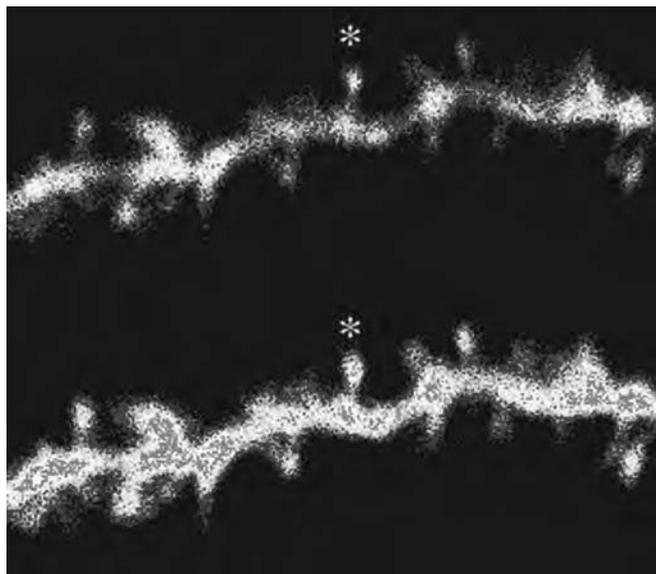

Figure 3.8 Multiphoton images of spines on a dendritic branch. The fluophore is Oregon Green BAPTA-1, a calcium indicator that becomes more intensely fluorescent when the level of calcium in the neuron increases. The upper image is this portion of the branch under baseline conditions of slice physiology. The lower image shows when the neuron is induced to fire repeated action potentials with injection of positive current. Action potentials open voltage-gated calcium channels along the dendrites and in the spines. One spine is marked by an asterisk to facilitate comparisons between low and high conditions of calcium influx. The influx of calcium raises the intensity of the indicator.

Genetic variants can affect the *expression levels* of the protein encoded by the gene. For example, polymorphisms in noncoding regions of the gene *NRG1* are associated with schizophrenia (Harrison and Law, 2006) and act in a gene-dose dependent manner to increase levels of the protein neuregulin 1 (Law et al., 2006), which interferes with the upregulation of NMDA glutamate receptor signaling (Pitcher et al., 2011). In essence, the genetic difference acts to reduce NMDA receptor mediated non-selective cation currents. Eliciting NMDA hypofunction pharmacologically, by comparison, is well known to provoke psychosis in otherwise healthy adults (see section on Psychotomimetics).

Genetic variation in a voltage-gated calcium channel gene, *CACNA1C*, has recently been found to be overrepresented in patients with several different mental illnesses, including patients with schizophrenia, bipolar disorder, and major depression (Bhat et al., 2012). It appears that at least one of the risk-associated single nucleotide polymorphisms increases the expression (Bigos et al., 2010) of this CaV1.2 channel that mediates an L-type or “long-lasting” calcium current. These channels open when the neuron is depolarized during a train of action potentials and allow calcium ions to rush down their concentration gradient into the neuron. This elevation in intracellular calcium ions is critical for changes in intracellular pathway activity, gene transcription, and synaptic plasticity (Bhat et al., 2012). Several studies have linked the polymorphisms in this particular calcium channel to widespread changes in the activation of brain networks necessary for executive function (Bhat et al., 2012).

ELECTROPHYSIOLOGY OF PSYCHOTROPIC DRUG ACTION

In the treatment of psychiatric illnesses such as depression and schizophrenia, certain drugs have been shown to be able to ameliorate some of the symptoms, although often with serious side effects. Most medicines for psychiatric illness have been found serendipitously and not by design. Despite understanding certain properties of these drugs (e.g., their acute ability to block a certain type of receptor), we do not fully appreciate how these properties change activity of brain systems over time in terms of bringing about improved function and in terms of causing side effects. In this section, several classes of psychoactive drugs are explored from the perspective of basic electrophysiology. In each case, a brief example is given of how we have come to better understand the initial or chronic action of such drugs using electrophysiological techniques. Because it is not feasible to study the neurophysiology of mental illness directly, where relevant, we also briefly describe possible animal models that may be helpful in the study of neuronal physiology relevant to mental illness.

ANXIOLYTICS

Several drugs to relieve anxiety—such as benzodiazepines, barbiturates, and even alcohol—work by enhancing inhibitory neurotransmission through the GABA system. They are the rare psychoactive drugs in which the acute action is also

the therapeutic one; their therapeutic effects are directly correlated to the current blood level of the drug in the person taking it. Anxiolytics work by potentiating the GABA_A receptor. As described in a previous section, the GABA_A receptor is an ionotropic receptor that opens a chloride channel, tending to make the neuron less excitable, partly through hyperpolarization, and therefore less likely to be brought to spike threshold by an excitatory stimulus.

Benzodiazepines bind to a site on the GABA_A receptor that increases the probability that GABA binding will open the chloride channel. They increase the chance that chloride can flow down its concentration gradient and hyperpolarize the neuron. In short, benzodiazepines potentiate the effect of synaptically released GABA. Barbiturates take this action one step further by increasing the duration of individual channel openings. Because GABA is the major inhibitory neurotransmitter in the brain, the anticonvulsant and sleep-inducing properties of these drugs are not surprising. Side effects such as withdrawal insomnia and withdrawal convulsions can be serious. Currently, dose level and metabolic clearance of the drug are the variables that are manipulated to try to maximize the therapeutic effect while minimizing side effects.

It is not well understood which regions of the brain are particularly involved in the antianxiety action of these drugs. Yet it appears that GABA_A receptors are actually a heterogeneous population made up of different combinations of subunits. Certain combinations appear to be limited to regions of the brain, such as the amygdala and the limbic circuit, that are particularly involved in generating anxiety disorders. This may allow for the modification of the drugs to create compounds affecting the GABA system that are able to discriminate between anxiolytic, anticonvulsant, and sleep-inducing effects.

Another approach to anxiety disorders is through manipulating neuromodulatory systems such as serotonin or norepinephrine. One reason to focus on these systems is not necessarily because they are thought to be involved in the etiology of the illness, but because they are more limited in their actions. They modulate glutamate and GABA transmission, which means through neuromodulators one can manipulate glutamate and GABA transmission indirectly. Such indirect manipulation has less potential for extreme side effects (precipitating seizures or unconsciousness) than drugs that affect the glutamate or GABA systems directly.

PSYCHOTOMIMETICS

Psychotomimetics or hallucinogens are not used to treat mental illness; in fact, they can exacerbate schizophrenia and other types of psychosis. However, they give us an interesting window into the neurobiology of hallucinations and sensory perturbations. The effects of hallucinogens on an array of complex integrative processes such as cognition, perception, and mood suggest the involvement of the cerebral cortex. There are two major classes of psychotomimetics: psychedelics and NMDA antagonists. Both have been considered relevant animal models of psychosis.

The psychotomimetic effect of psychedelic hallucinogens depends on their stimulation of serotonin 5-HT_{2A} receptors. Slice physiology experiments in cerebral cortex have shown that selective stimulation of 5-HT_{2A} receptors decreases the threshold for recurrent network activity and enhances its duration far beyond that normally seen (Lambe and Aghajanian, 2007; Benekareddy et al., 2010). This effect of selective 5-HT_{2A} stimulation in cortex might be responsible for the sensory perturbations that people experience after taking psychedelic hallucinogens. Network activity has been suggested to provide a “context” in which information is interpreted and decisions are made. It has been hypothesized that aberrations in the modulation of network activity may account for the perceptual and cognitive abnormalities in schizophrenia. Normal modulation of network activity may work to enhance cortical efficiency by changing the signal-to-noise ratio.

The results of brain imaging studies by Vollenweider and colleagues tend to support this hypothesis (Vollenweider and Geyer, 2001; Vollenweider et al., 1997). They show that psilocybin, another 5-HT_{2A} receptor agonist, tends to activate the frontal cortex, and this activation correlates with the onset of sensory perturbations. Serotonin, the endogenous agonist of this receptor, does not cause this phenomenon. Most likely, this is due to its opposing actions through other receptors, such as the 5-HT_{1A} receptor. Whereas the 5-HT_{2A} receptor tends to inactivate potassium conductances and make neurons more excitable, 5-HT_{1A} receptor tends to activate potassium currents and make neurons less excitable. These opposing actions appear to have ramifications for psychoactive drugs such as the selective serotonin reuptake inhibitors (SSRIs) that tend to increase serotonin at synapses in the brain.

NMDA antagonists such as phencyclidine (PCP) and ketamine are dissociative anesthetics. In short, at high concentrations they are anesthetic and at lower concentrations they produce psychosis in adults (these psychiatric side effects do not occur in children, and ketamine is routinely used in pediatric anesthesia). Phencyclidine intoxication causes effects in otherwise healthy people that mimic positive and negative symptoms of schizophrenia, and it exacerbates psychotic symptoms in people with schizophrenia. Phencyclidine and ketamine are known to act as noncompetitive antagonists of the NMDA receptor, a subtype of glutamate receptor discussed previously. These antagonists bind to the open pore NMDA receptors and block the flow of cations through the channels. However, they do not block the AMPA subtype of glutamate receptors. It appears that blocking glutamate transmission through NMDA receptors increases glutamate release and excessively stimulates AMPA receptors in certain regions of the brain, including the prefrontal cortex. Although this increased stimulation of glutamate receptors in prefrontal cortex appears to differ from that induced by psychedelic hallucinogens, suppressing excessive glutamate release ameliorates many of the adverse behavioral effects in both cases.

ANTIDEPRESSANTS

The most commonly prescribed antidepressants, the SSRIs, increase serotonin in the brain by blocking the mechanism

that actively removes serotonin from synapse. Over a period of chronic administration, this tends to desensitize the autoreceptors on serotonergic neurons, such that the feedback mechanism that normally limits the release of serotonin requires much higher levels of serotonin to be activated. It has been suggested that one possible explanation why some people may be vulnerable to developing depression is that their 5-HT_{1A} autoreceptors might be hypersensitive, which would tend to clamp down on the release of serotonin into the cortex. The time lag required for desensitization of the autoreceptors might explain why a therapeutic improvement is not observed until 2–3 weeks after onset of drug treatment. Single-cell recordings suggest that repeated daily administration of antidepressants enhances the effects of 5-HT in the forebrain with a time course that parallels the therapeutic effects of antidepressants (Mongeau et al., 1997).

Low doses of NMDA antagonists have rapid antidepressant effects (Berman et al., 2000). Recent electrophysiological work suggests the cellular mechanism involves a rapid upregulation of dendritic spines in prefrontal cortex (Li et al., 2010). This morphological change is opposite of the changes elicited by chronic stress and is compromised in transgenic mice with the human coding polymorphism (Val66Met) that results in a reduction of depolarization-induced BDNF release (Liu et al., 2012).

Stress can be used to produce animal models of depression. Preclinical and clinical studies have demonstrated that stress and depression result in cell atrophy and loss in limbic and cortical brain regions (Duman and Monteggia, 2006). These effects can be reversed with such diverse antidepressant treatments as SSRIs, electroconvulsive shock, and exercise. Interestingly, a number of gene products that mediate neurotrophin and growth factor signaling are reduced in depressed patients and in stressed animals. Antidepressant treatments, by contrast, elevate the expression of multiple genes involved in neurotrophin signaling pathways. Together, these findings implicate neurotrophic factors in the etiology and treatment of depression. Some electrophysiology studies of the neurotrophic hypothesis of depression have examined the properties of new neurons generated in the dentate through adult neurogenesis (van Praag et al., 2002) and their contributions to synaptic plasticity in the hippocampus (Ge et al., 2007). Other electrophysiology studies have used transgenic mice with alterations of neurotrophic factors or receptors to assess the effects of long-term changes in these systems on brain physiology (Rios et al., 2006).

ANTIPSYCHOTICS

Like most psychoactive drugs, antipsychotic drugs were discovered serendipitously. Although chlorpromazine, the original antipsychotic, had actions at many receptors, its ability to act as an antagonist at the dopamine D₂ receptor turned out to be critical. Although there are many antipsychotic drugs today, almost every single one has some ability to downregulate the activation of D₂ receptors by endogenous dopamine, either by direct antagonism or by partial agonism (Kapur and Remington, 2001). Positron emission tomography (PET) imaging studies have used radiolabeled versions of these drugs

to assess the degree and length of binding. For the typical antipsychotic, reduction of “positive” symptoms (for example, *psychosis, hallucinations, delusions*) requires the antipsychotic drug to have bound to ~65% of D₂ receptors. However, there is a very narrow window of binding before motor side effects, called *extrapyramidal symptoms*, set in at binding higher than 70%. A major development in psychiatry has been the emergence of an antipsychotic drug, *clozapine*, that does not cause these motor side effects. It is often referred to as an atypical antipsychotic in contrast to previous “typical” antipsychotics such as chlorpromazine and haloperidol. Of perhaps even greater significance is the fact that clozapine, unlike typical antipsychotics, treats negative symptoms of schizophrenia (for example, *flat affect, anhedonia, withdrawal*).

The emergence of clozapine has focused more recent research on differences between typical antipsychotics and clozapine. The latter has a very complicated profile of action that includes effects at dopamine, norepinephrine, serotonin, acetylcholine, and histamine receptors. Clozapine is a significantly more potent 5-HT_{2A} antagonist and a significantly less potent D₂ antagonist compared to the typical antipsychotics. This pattern, together with the large body of work on the psychotomimetic effects of 5-HT_{2A} agonists, awakened interest in the therapeutic effects of a pure 5-HT_{2A} antagonist. However, this drug did not succeed in clinical trials. It may be clozapine’s more moderate action at D₂ receptors, rather than its ability to block pure 5-HT_{2A} receptors, which is responsible for its ability to improve negative symptoms as well as its reduced propensity to induce motor side effects.

One hypothesis that has been proposed to explain the clinical efficacy of antipsychotic drugs relates to the “depolarization block” of midbrain dopamine neurons projecting to the prefrontal cortex (Bunney, 1992). The blockade of autoreceptors on dopaminergic neurons leads to chronic depolarization of these neurons, which prevents the relief from sodium channel inactivation. Electrophysiological experiments revealed that one difference between clozapine and typical antipsychotics is that chronic administration of clozapine results in depolarization block only of the midbrain dopaminergic cells that project to the medial prefrontal cortex, whereas chronic administration of typical antipsychotics results in depolarization block of the neostriatum as well as the medial prefrontal cortex. This former is thought to account for the extrapyramidal symptoms associated with typical antipsychotics.

There have been several animal models postulated for schizophrenia. The psychotomimetic drug model of the disease has proved informative about what types of neurotransmission are involved in acute psychosis. The amphetamine model has proved useful for understanding the paranoid state. However, given the evidence for neurodevelopmental abnormalities in schizophrenia, several groups of researchers have tried to model this illness in rodents through lesions early in development (Lipska and Weinberger, 2000). One such model, involving lesions to the ventral-hippocampus, has been shown to result in the postpubertal onset of dopaminergic abnormalities (Goto and O’Donnell, 2002; O’Donnell, 2012) similar to what is hypothesized to occur in schizophrenia. These animal models allow the *in vitro* and *in vivo* electrophysiological examination

of how an early brain lesion alters interactions between the dopaminergic and glutamatergic systems in adulthood.

OVERVIEW AND FUTURE DIRECTIONS

This chapter explored how basic electrophysiology can be used to clarify how neurons communicate with each other and how different drugs affect this signaling. Appreciating how a neuron maintains its electrical state and its ability to release neurotransmitters onto other cells is critical to appreciating the many subtle ways that thought can be influenced by genetic variations in ion channels. Understanding the electrophysiological mechanisms by which neurotransmitter receptors can modulate the activity of neurons is essential to appreciate the immediate and long-term consequences of psychoactive drugs. Recent progress in the molecular genetics of psychiatric illness, together with the capacity to model relevant human single nucleotide polymorphisms in transgenic mice, promises to provide new opportunities for targeting electrophysiological studies toward uncovering the role of susceptibility genes in these illnesses.

4 | PRINCIPLES OF SIGNAL TRANSDUCTION

JEAN-ANTOINE GIRAULT AND PAUL GREENGARD

SIGNAL TRANSDUCTION

All cells react to changes in their environment and to clues that may be important for their survival and/or function. This is true for unicellular as well as multicellular organisms. Unicellular organisms react to light, to chemical gradients of nutrients, and to specific molecules released by other cells from the same species. In multicellular organisms, the harmonious functioning of billions of cells, assembled in tissues as sophisticated as the human brain, requires a highly complex network of intercellular signaling involving molecules known as *hormones*, *neurotransmitters*, *cytokines*, *growth factors*, and so forth. Yet the molecular mechanisms by which these signals are perceived and interpreted by individual cells are quite similar to those used by much simpler unicellular beings. Indeed, work over the past years has demonstrated an amazing degree of conservation of many of these molecular mechanisms among brewer's yeast (*Saccharomyces cerevisiae*), nematode worms (*Caenorhabditis elegans*), fruit flies (*Drosophila melanogaster*), and mammals, including humans. In addition, specialized cells, such as the cones or the rods in the retina, or the olfactory epithelial cells, have retained the ability to perceive changes in the physical or chemical environment. These specialized cells translate information from the external world into changes in neuronal activity that can be communicated to the rest of the organism.

The term *signal transduction* is used to describe the cascades of biochemical reactions by which cells translate various extracellular signals into appropriate responses, whether the primary extracellular signal comes from other cells or from the external world. Signal transduction involves a number of key players and reactions that we examine successively. The initial reaction involves a “receptor,” the protein that interacts with the extracellular signal and triggers its effects. Subsequently, a series of reactions of varying degrees of complexity ensues, resulting in a vast array of physiological responses. In many instances, the coupling between receptors and effector pathways requires an intermediate agent, a guanosine 5'-triphosphate (GTP) binding protein or *G protein*, which acts as a molecular switch, and the generation of a second messenger. Second messengers are small molecules that are generated within cells in response to extracellular signals (the latter correspond to “first messengers”). One particular class of signaling molecules comprises small molecules that can readily cross biological membranes and act as intercellular messengers and second messengers. Such molecules include fatty acids such as arachidonic acid, and the gas nitric oxide. The major covalent modification of

proteins involved in signal transduction is phosphorylation. This modification has been shown to result in changes of innumerable biological properties of nerve cells, such as activation of biosynthetic enzymes, activation of transcription factors, regulation of the permeability of ion channels, regulation of neurotransmitter release, and alteration of the sensitivity to neurotransmitters.

GENERAL PROPERTIES OF SIGNAL TRANSDUCTION PATHWAYS

Signal transduction pathways have a number of important properties in common that are interesting to consider before describing these pathways in detail.

First, many signaling cascades have a tremendous capability of signal amplification. This explains why, in some instances, cells are able to detect only a single photon—in the case of retina photoreceptor cells—or a few molecules in their environment. A second property is specificity. Cells are able to discriminate between a virtually unlimited number of extracellular molecules and to react to very few of them. Moreover, different signals acting on the same cells will have different effects. This is true in spite of the fact that receptor proteins belong to a limited number of classes and that many of the components of the signaling cascades are rather ubiquitous. Thus, during development, a characteristic set of genes, the products of which are involved in signal transduction, is selected in each cell type, providing it with the capability to react in an appropriate way to specific signals. A third important characteristic of signal transduction pathways is their pleiotropy. Thus, a single extracellular signal can generate multiple responses in the cell. For instance, a single neurotransmitter can trigger the opening of some ion channels and the closing of others, the activation of multiple enzymes, the modification of cytoskeletal organization, and the stimulation of the expression of specific genes.

Another property of signal transduction pathways is that they allow the integration of several simultaneous or successive signals. The cascades of reactions triggered by each signal interact with the others at many levels, sometimes reinforcing each other, sometimes canceling each other. As a result, the final output in terms of cellular response is a subtle combination of what would have been induced by each extracellular signal separately and may indeed be quite different from responses to individual signals. Some signals may, for instance, have little effect by themselves yet inhibit or potentiate considerably the

response to other signals. In the nervous system this property is called *neuromodulation*. These properties of integration and transformation of multiple signaling pathways are often quite complex, and computer modeling is necessary to help predict their output.

Finally, the response to extracellular signals can have long-lasting effects on cells and modify their subsequent response to the same or other signals. One obvious example involves gene expression: One hormone, for instance, will induce the expression of a gene necessary for the response to a neurotransmitter. In fact, there are many different ways by which such long-lasting changes in cellular responses can be implemented. They represent the molecular basis for “cellular” learning and memory, a capacity that all cells possess to some extent. Thus at any given time the response of a cell to external signals depends on its previous history. Such mechanisms have a special importance in neurons in which they represent the cellular basis for synaptic plasticity, which is thought to underlie “psychological” learning and memory (Chapter 5).

THE IMPORTANCE OF ELUCIDATING SIGNAL TRANSDUCTION PATHWAYS

Deciphering the complex networks of reactions that constitute signal transduction pathways is important for understanding the physiology of cells and multicellular organisms, including the human brain. Moreover, such understanding is certainly critical for elucidating the mechanisms of diseases that are still elusive, and eventually treating them. It is easy to understand that dysfunctions of signal transduction pathways will have profound and deleterious consequences on the properties of cells. This point is well illustrated by the fact that cancers result from the dysfunction of signaling pathways that regulate cell growth and division. Similarly, many naturally occurring toxins exert their effects by interrupting or diverting normal intracellular signaling pathways. Recent work has identified mutations in genes which code for signaling proteins as the cause of mental retardation and syndromic autism spectrum disorders. It seems likely that, as our knowledge of signal transduction in neurons progresses, we will discover that alterations of signal transduction pathways play an important role in a number of neurological or psychiatric diseases. In addition, the multiple enzymes involved in these pathways represent potential targets for therapeutic drugs. Lithium is one example of a drug that is already used in psychiatry and is thought to exert its effect by acting on signal transduction mechanisms (see following). The study of complete genome sequences, including those of brewers’ yeast (*Saccharomyces cerevisiae*), a plant (*Arabidopsis thaliana*), a round worm (*Caenorhabditis elegans*), fruit fly (*Drosophila melanogaster*), and human (*Homo sapiens*), allows an estimation of the number of genes devoted to signal transduction in various eukaryotic organisms (Table 4.1). Comparison of signaling networks in organisms of various complexities provides useful information about their organizing and functioning principles. Exhaustive identification of the components of such networks in humans pinpoints potential candidates for genetic alterations that may underlie

neurological or psychiatric disease, or more likely enhance the susceptibility to such diseases. It also provides novel targets for designing new pharmacological tools aimed at modifying specific signaling pathways either to correct natural deficits or to counteract the consequences of their alterations, regardless of the cause of these alterations.

RECEPTORS: HOW CELLS DETECT EXTRACELLULAR SIGNALS

Cells can detect chemical as well as physical signals from their environment. We concentrate on chemical signals that are the more relevant for understanding brain physiology. The first step in signal transduction is the interaction of the extracellular signaling molecule with a receptor. A receptor is a protein that is able to bind the signaling molecule with high affinity and specificity, and to trigger a biological response in reaction to this binding. Extracellular signaling molecules include neurotransmitters, hormones, growth factors, and related substances and can be divided into two broad categories: those that do not penetrate the cells and act at the level of the plasma membrane and those that readily penetrate the cells and act on intracellular targets. It should be emphasized that these two mechanisms of action are not always exclusive and that compounds such as steroid hormones appear to have membrane receptors in addition to their well-characterized intracellular receptors.

SIGNALS THAT ACT AT THE LEVEL OF THE PLASMA MEMBRANE

Receptors that have been characterized at the level of the plasma membrane can be divided into several classes depending on their organization and properties. Representatives of each of these classes of receptors are present in neurons, where they play diverse roles.

NEUROTRANSMITTER-GATED ION CHANNELS

Biological membranes are impermeable to small ions including Na^+ , K^+ , Ca^{2+} , and Cl^- (Chapter 3). The concentrations of these ions are very different in the intracellular and extracellular compartments, due to the existence of active transport mechanisms. Ion channels are proteins that form pores within the membranes and allow the selective flow of specific ions to which they are permeable. The magnitude and direction of ion flow depend on two forces: the concentration gradient and the electrical potential difference between the two sides of the membrane. Opening or closing of one class of channels allows or blocks flow of ions to which this class of channels is permeable. This, in turn, regulates the electrical potential across the membrane. At rest, the intracellular side of the membrane is electronegative as compared to the extracellular side (usually -60 to -80 mV).

The opening of several ion channels is directly regulated by neurotransmitters. Such channels are called *neurotransmitter-gated channels* or *ionotropic receptors* (Box 4.1). The neurotransmitter binds to the ion channel and triggers

TABLE 4.1. Estimated numbers of proteins involved in signal transduction

The numbers of some proteins important for signal transduction are given for human (*Homo sapiens*), fly (*Drosophila melanogaster*), round worm (*Caenorhabditis elegans*), yeast (*Saccharomyces cerevisiae*), and mustard weed (*Arabidopsis thaliana*). Since the sequencing and analysis of the genomes of these organisms is not fully complete, these numbers represent only lower limits. Data are based on the publications by the International Human Genome Sequencing Consortium (Nature, 2001 409:860–921) indicated by an asterisk (*) and by Celera Genomics and associates (Science, 2001 291:1304–1351) indicated by °.

its opening by inducing a change in its conformation. Since no intermediate biochemical reaction is involved, the effects of neurotransmitters on ligand-gated channels are very fast. This type of receptor underlies most of the fast synaptic excitatory or inhibitory transmission in brain. In addition, the response of ionotropic receptors to neurotransmitters can be regulated by several extracellular or intracellular signals, providing a fine tuning of their properties (see the examples of glutamate *N*-methyl-*D*-aspartate [NMDA] receptor and γ -aminobutyric acid [GABA-A] receptor, Box 4.1). Such modulatory sites are targets for molecules of great pharmacological importance, including benzodiazepines and barbiturates, which increase the response to GABA (Box 4.1).

G PROTEIN-COUPLED RECEPTORS

A large number of receptors work in close association with heterotrimeric GTP-binding proteins or G proteins that are composed of three subunits (α , β , and γ ; Box 4.2; see also Box 4.7). Although these receptors belong to several different gene families, they have a major structural feature in common,

which has been conserved throughout evolution: *the polypeptide chain of these receptors crosses the plasma membrane seven times*. Therefore, these receptors are called *7-transmembrane domain receptors* or *serpentine receptors*. When these receptors bind their specific ligand, they undergo a conformational change that has consequences for the associated G protein (Box 4.2), leading to the dissociation of a GTP-bound α subunit and β/γ complex, each of which is able to interact with various targets including ion channels and enzymes (Box 4.7). Interestingly, these G protein-coupled receptors (often referred to as GPCRs) are also involved in the detection of clues from the environment: receptors for odors, pheromones, and light belong to this category.

RECEPTORS THAT ARE THEMSELVES ENZYMES

Some receptors are transmembrane proteins that are composed of an extracellular domain that binds the extracellular signaling molecule, a single transmembrane domain, and an intracellular domain that possesses an enzymatic activity. Binding of

BOX 4.1 NEUROTRANSMITTER-GATED ION CHANNELS

The neurotransmitter receptors responsible for fast synaptic transmission are ligand-gated ion channels. They comprise several subunits arranged in such a way as to form a central pore through which ions can cross the plasma membrane. Binding of the neurotransmitter triggers the opening of this pore. Neurotransmitter-gated ion channels are specific for one or several ions, the nature of which is responsible for their excitatory or inhibitory effects.

Receptors for excitatory neurotransmitters such as acetylcholine (nicotinic subtype), or glutamate (subtypes named after chemicals not present in the brain but which activate them specifically, *alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid* [AMPA] and *kainate*), let Na^+ ions flow into the neuron, and K^+ ions flow out [see (A)]. At resting potential, the Na^+ influx predominates and is responsible for the depolarizing, excitatory effects of these neurotransmitters. The open state of neurotransmitter-gated ion channels is usually unstable. They switch spontaneously to a desensitized state, in which the ion channel is closed, although the neurotransmitter is still bound with high affinity. Desensitization is thought to be a protective mechanism against overstimulation.

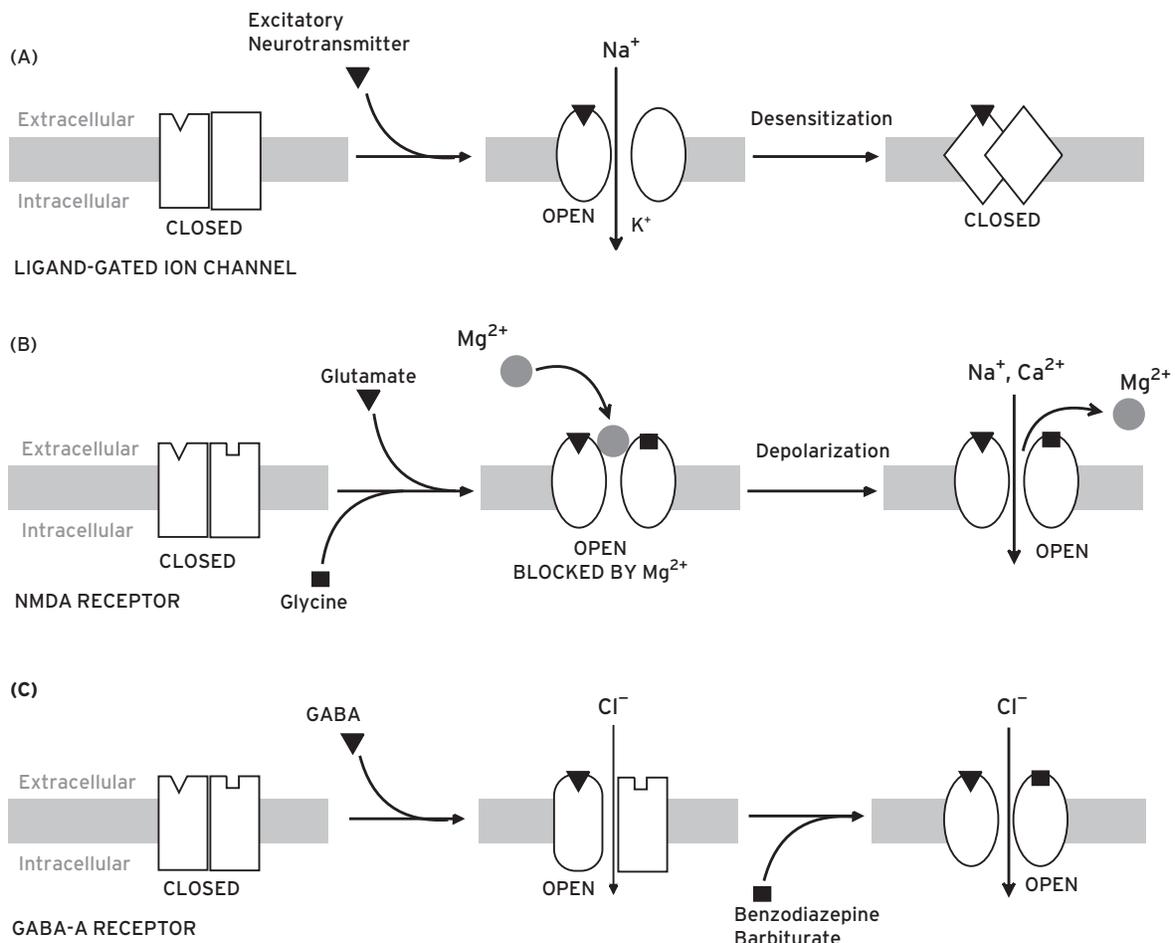

NMDA receptors are a subtype of glutamate receptors, named after their specific synthetic agonist (*N-methyl-D-aspartate*), that have a number of unique properties [see (B)]. First, glycine must also be bound to these receptors for them to open in response to glutamate. Second, at resting membrane potential, when NMDA receptors open, they are

obstructed by Mg^{2+} ions. This block is relieved only when the membrane is depolarized simultaneously by another mechanism (e.g., stimulation of nearby glutamate receptors of the AMPA subtype). Finally, in addition to Na^+ and K^+ , NMDA receptors are highly permeable to Ca^{2+} . The resulting Ca^{2+} influx is responsible for the role of NMDA receptors in synaptic plasticity and also for its deleterious, excitotoxic effects in pathological conditions.

Receptors for GABA [GABA-A subtype, see (C)] and glycine (not shown) are selectively permeable to Cl^- ions. In most instances, the resulting Cl^- influx is responsible for the inhibitory effects of these neurotransmitters. GABA-A receptors account for most of the inhibitory receptors in the central nervous system, whereas glycine receptors are restricted to the brainstem and spinal cord. GABA-A receptors are modulated by two classes of drugs that have important clinical applications. Benzodiazepines (e.g., diazepam) or barbiturates (e.g., phenobarbital), although they cannot open the GABA-A ion channel by themselves, increase the response to GABA. The existence and the nature of endogenous ligands for the benzodiazepine and barbiturate modulatory sites on GABA-A receptors are still a matter of dispute.

Other abbreviations: GABA: γ -aminobutyric acid.

BOX 4.2 G PROTEIN-COUPLED RECEPTORS

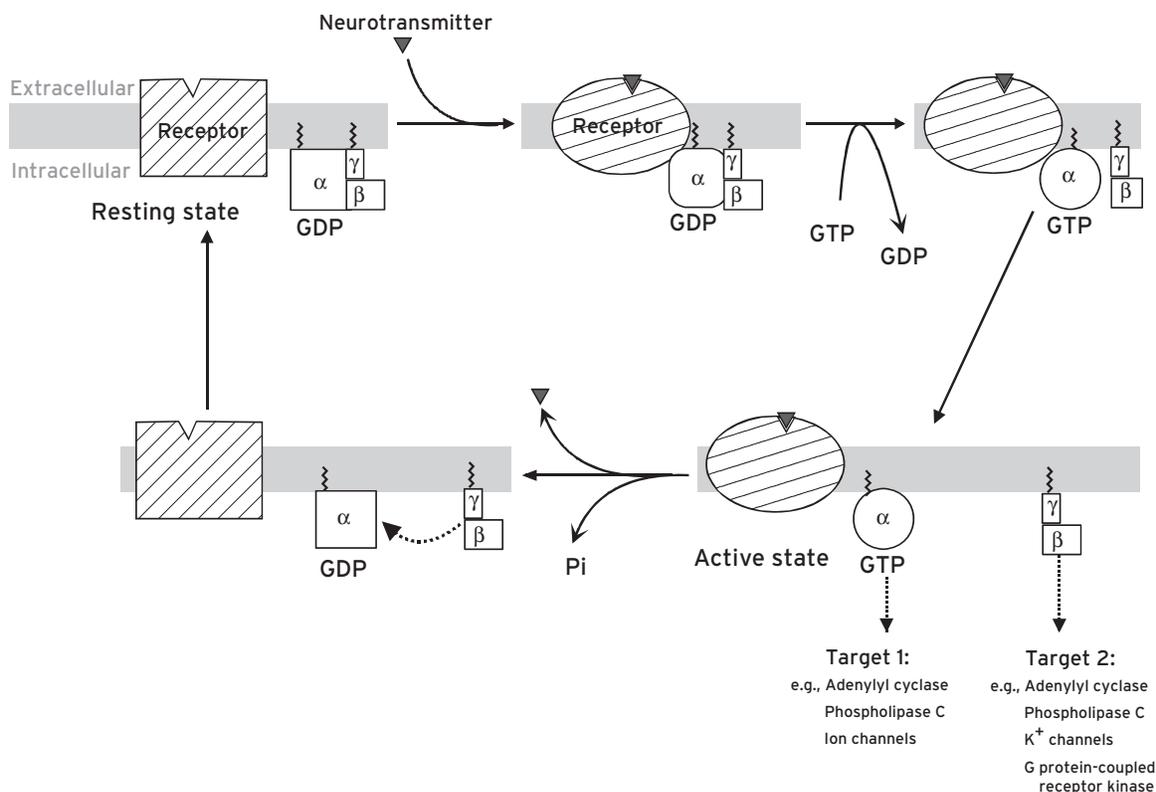

A large number of neurotransmitter receptors belong to the category of seven transmembrane domain *G protein-coupled receptors* (GPCRs), which also includes receptors for hormones, light, odorants, pheromones, and Ca^{2+} . These receptors are associated with heterotrimeric G proteins (see Box 4.7). Heterotrimeric G proteins comprise three subunits: α , β , and γ , which are not transmembrane proteins but are associated with the membrane by covalently bound fatty acid molecules. In the resting state, GDP is bound to the α subunit, which is closely attached to the β/γ complex. When the neurotransmitter binds to the receptor, the conformation of the receptor changes, inducing a change in the conformation of the α subunit, which expels GDP and replaces it by GTP. GTP-bound α subunit is no longer capable of interacting with the receptor or β/γ . Instead, GTP-bound α and β/γ diffuse away from each other and from the receptor, while still attached to the membrane, and interact with specific targets. After a short time GTP is hydrolyzed to GDP, and GDP-bound α reassociates with β/γ . At about the same time, the neurotransmitter leaves its

receptor, which returns to its resting state and reassociates with α -GDP and β/γ .

There are several different types of α , β , and γ subunits, encoded by different genes. The nature of the α subunit that associates with a given receptor determines the actions that can be triggered by this receptor. β/γ subunits have their own effects on similar targets that can be in the same direction as that of their cognate α subunit, or, sometimes, in the opposite direction. β/γ subunits have additional specific properties, such as recruiting to the membrane a protein kinase (*G protein-coupled receptor kinase* or GRK), which phosphorylates the receptor and prevents its further interaction with G proteins. This represents an important mechanism of desensitization of G protein-coupled receptors.

Other abbreviations: G protein: guanine nucleotide binding protein; GDP: guanosine 5'-diphosphate; GTP: guanosine 5'-triphosphate; Pi: inorganic phosphate.

Further reading: Bockaert and Pin, 1999; DeWire et al., 2007; Gainetdinov et al., 2004; Kobilka, 2011; May et al., 2007; Moore et al., 2007; Rosenbaum et al., 2009.

the ligand to the extracellular domain dramatically alters the activity of the intracellular enzymatic domain. This activation often results from the dimerization of the receptor.

The best-known receptors in this category are tyrosine kinase receptors for polypeptide growth factors, including nerve growth factor (NGF) and related neurotrophins (Box 4.3). Their ligands are polypeptides that are often soluble but can also be attached to the membrane of other cells. The

intracellular domain of this type of receptor is a protein kinase, which is able to phosphorylate itself and other proteins on tyrosines (see Box 4.14). Phosphorylation on tyrosine triggers cascades of reactions that are detailed in Box 4.3. These reactions involve recruitment of specific proteins through domains such as the SH2 (Src-homology 2) domain that bind to their target peptide sequence only when the tyrosine it contains is phosphorylated (Box 4.4). Thus, a variety of intracellular

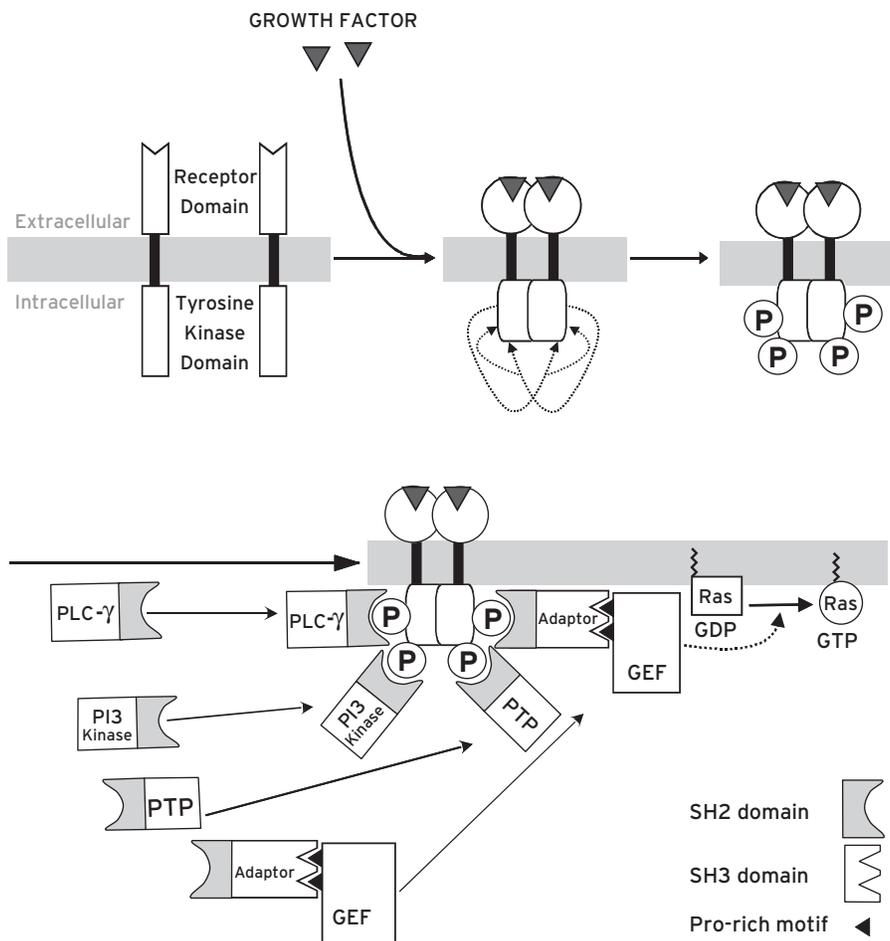

BOX 4.3 PROTEIN TYROSINE KINASE RECEPTORS

Receptors for many polypeptide growth factors, including nerve growth factor and related neurotrophins, are transmembrane tyrosine kinases. These receptors are composed of a single peptide chain whose extracellular domain can bind the growth factor, whereas the intracytoplasmic domain is a protein tyrosine kinase (see Box 4.14). In the absence of growth factor, the tyrosine kinase is inactive. In the presence of growth factor, two identical receptors interact with each other (*homodimerization*), and this results in the activation of the tyrosine kinase domains. They phosphorylate several tyrosine residues located in each other's sequence (*autophosphorylation*). Autophosphorylation on tyrosine provides docking sites for a number of proteins that possess SH2 domains (see Box 4.4), resulting in the phosphorylation-dependent clustering of several important proteins around the growth factor receptor. These proteins, many of which also become phosphorylated on tyrosine, include phospholipase C γ (PLC γ) that hydrolyzes phosphatidylinositol 4,5 biphosphate into diacylglycerol and inositol 1,4,5 trisphosphate (IP $_3$, see Boxes 4.10 and 4.12),

phosphatidylinositol 3 kinase (PI3 kinase) that phosphorylates phosphatidylinositol at position 3 and activates its own signal transduction pathway (see Box 4.18), phosphotyrosine phosphatases (PTP), adaptor molecules, and others. Adaptor molecules are proteins that possess, in addition to an SH2 domain, SH3 domains (see Box 4.4). By these SH3 domains the adaptors are bound to proline-rich regions of guanine nucleotide exchange factors (GEFs; see Box 4.7). GEFs are enzymes that catalyze the exchange of GDP for GTP on small G proteins of the Ras family. Their recruitment to the membrane, mediated by the adaptor, brings them in contact with Ras, which they put in its GTP-bound, active form (see Boxes 4.7 and 4.8). The precise nature of the SH2-containing enzymes or adaptor molecules that are recruited varies from one growth factor receptor to another; however, the principles of signaling are the same in all cases.

Other abbreviations: G protein: guanine nucleotide binding protein; GDP: guanosine 5'-diphosphate; GTP: guanosine 5'-triphosphate; P: phosphate group; SH2: Src-homology domain 2; SH3: Src-homology domain 3.

Further reading: Kalb, 2005; Lemmon and Schlessinger, 2010; Papin et al., 2005; Schlessinger, 2002.

signaling pathways are activated (see following Boxes 4.8, 4.10, and 4.18).

A variation on the same theme is represented by receptors that do not possess an enzymatic activity by themselves but that associate with tyrosine kinases. For example, receptors for some neurotrophic factors, such as glial derived neurotrophic factor (GDNF), are extracellular proteins attached to the membrane by a lipid anchor (*glycosyl-phosphatidyl inositol*). Due to their localization, they cannot transduce the signal directly to the interior of the cell. They do it by virtue of their association to a transmembrane protein whose intracellular domain is a tyrosine kinase (c-Ret in the case of GDNF receptor). An important class of receptor comprises transmembrane proteins that have the capability to associate with intracytoplasmic tyrosine kinase. This class includes receptors for key messengers in the immune response (e.g., cytokines, interferon), hormones (e.g., growth hormone, prolactin, leptin), and polypeptides that have growth factor activity (e.g., erythropoietin, ciliary derived neurotrophic factor). The intracellular segment of these receptors binds a tyrosine kinase of the JAK family (*Janus kinase*; see Box 4.5). Other types of receptors, including the receptors for the antigen of lymphocytes, have a similar, although more complicated, organization. In this case the enzyme is a member of the Src family of tyrosine kinases. Similarly, integrins, which are receptors for extracellular matrix proteins, associate on their intracellular side with a tyrosine kinase called *FAK* (focal adhesion kinase).

Several other families of receptors are transmembrane proteins that possess other types of enzymatic activities. One group corresponds to receptors for transforming growth factor beta (TGF β), activin, and inhibin, the intracellular domain of which possesses a protein serine/threonine kinase activity. Another group of receptors, including the receptor for atrial natriuretic factor (ANF), have an intracellular domain that is a guanylyl cyclase, an enzyme that generates the second messenger cyclic guanosine 3',5'-monophosphate (cGMP). Other receptors, such as those for Fas and tumor necrosis factor α (TNF α), which are able to trigger programmed cell death (apoptosis), associate with various intracellular proteins that, among other things, activate proteolytic enzymes.

EXTRACELLULAR SIGNALS THAT PENETRATE CELLS

Most of the molecules that act on membrane receptors cannot cross the plasma membrane because of their charge, which makes them highly hydrophilic, or their size. However, some signaling molecules are readily able to cross the lipid bilayer of the plasma membrane because of their hydrophobic nature and/or their small size. These molecules include steroid hormones and the related vitamin D derivatives, thyroid hormones, and retinoic acid. Steroid hormones bind to intracellular receptors that, in addition to the hormone binding domain, contain a deoxyribonucleic acid (DNA) binding domain, and a domain capable of stimulating messenger ribonucleic acids (mRNA) transcription of specific genes (Box 4.6). In the absence of hormone, the receptor is in an inactive conformation, unable to enhance

BOX 4.4 SH2 AND SH3 DOMAINS

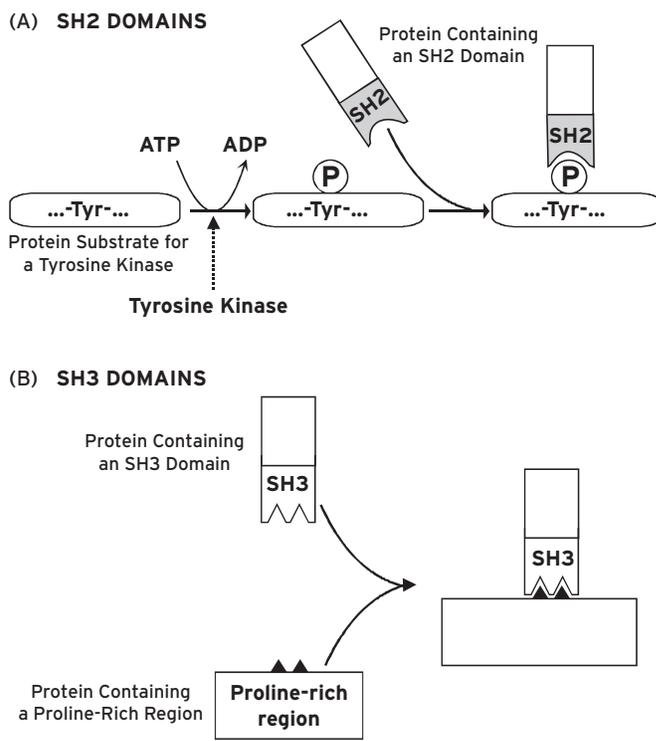

SH2 (Src-homology domain 2) and SH3 (Src-homology domain 3) were first identified in the cytoplasmic tyrosine kinase Src. They have now been recognized in a large number of proteins, many of which are involved in signal transduction.

SH2 domains bind to peptide sequences within proteins that contain a phosphorylated tyrosine. In the absence of phosphorylation, there is no binding. In addition, SH2 domains recognize a few amino acids located on the carboxy-terminal side of the phosphorylated tyrosine, thus providing specificity to this type of interaction: each SH2 domain binds preferentially to specific protein regions phosphorylated on tyrosine.

SH3 domains bind to proline-rich regions that adopt a characteristic conformation. Each SH3 domain reacts preferentially with particular proline-rich sequences, providing specificity to this type of interaction. SH3-mediated interactions are constitutive and do not depend on phosphorylation. In fact, SH3 and proline-rich regions are one example of a large number of pairs of protein domains that are able to interact with each other with high affinity and specificity. These protein-protein interactions are important in signal transduction and in other neuronal functions, such as the clustering of receptors at the postsynaptic sites.

Other abbreviations: P: phosphate group; Tyr: tyrosine.

BOX 4.5 JAK-STAT-COUPLED RECEPTORS

A large number of receptors for polypeptide messengers (e.g., cytokines, interferon, growth hormone, prolactin, leptin, erythropoietin, ciliary derived neurotrophic factor) utilize a tyrosine phosphorylation signaling mechanism. In contrast to the growth factor receptors depicted in Box 4.3, the cytoplasmic domain of these receptors does not possess tyrosine kinase activity. However, this domain is associated with a cytoplasmic tyrosine kinase belonging to the JAK subfamily (these kinases have two tyrosine kinase domains, only one of which is catalytically active, and are called *Janus tyrosine kinase* after the two-faced Roman god). When the receptor binds its ligand, it dimerizes and becomes phosphorylated by the associated JAK tyrosine kinases. Remarkably, activation of this class of receptor can regulate gene expression via a single family of intermediary proteins called *STAT* (signal transducer and activator of transcription). One important consequence of the phosphorylation of the receptor is the recruitment of *STAT*, which possesses an SH2 domain (Box 4.4). When *STAT* molecules are bound to the phosphorylated receptor by their SH2 domain, they become phosphorylated by the JAKs. This allows a switch in the interaction of the SH2 domain of the two molecules of *STAT* that, instead of binding to the receptor, bind to each other. The resulting dimer detaches from the receptor and enters the nucleus, where it binds to the promoter region of specific genes and, in combination with several other proteins, induces their transcription (Chapter 6).

Other abbreviations: P: phosphate group; SH2: Src-homology domain 2.

Further reading: Imada and Leonard, 2000; O'Shea et al., 2005; Seidel et al., 2000; Yamaoka et al., 2004.

transcription, and, usually, sequestered in the cytoplasm. In the presence of steroid hormone, the receptor switches to an active form, which translocates to the nucleus, where it binds to the promoter region of specific genes and activates their transcription. Retinoic acid and thyroid hormones have similar modes of action.

G PROTEINS: MOLECULAR SWITCHES IN SIGNAL TRANSDUCTION

G proteins are proteins that possess a specific domain capable of binding GTP or guanosine 5'-diphosphate (GDP). In general, the GDP-bound form is inactive and the GTP-bound form is active (Box 4.7). G proteins act as molecular switches that can be turned on by replacement of GDP by GTP, or turned off by hydrolysis of GTP to GDP. They belong to two classes: small G proteins that contain little more than the GDP/GTP binding domain, and large heterotrimeric G proteins in which the GDP/GTP interacting subunit α is associated with two other subunits, β and γ (Box 4.7). Small G proteins are involved in many cellular functions (see Table 4.2 in Box 4.7). The role of the small G protein *Ras* in triggering a cascade of phosphorylation reactions in response to growth factors' action on receptor tyrosine kinases is depicted in Box 4.8. Heterotrimeric G proteins are important in the action of seven transmembrane domain receptors (Box 4.2) and are also coupled to multiple effectors (Box 4.7).

SECOND MESSENGERS

CYCLIC NUCLEOTIDES

Cyclic adenosine 3'-5'-monophosphate (cAMP) was the initial second messenger to be identified. It is generated by a class of enzymes called *adenylyl cyclases* that form cAMP using adenosine 5'-triphosphate (ATP) as a precursor. The major action of cAMP is to activate the protein kinase called *cAMP-dependent protein kinase*. The metabolism and actions of cAMP are detailed in Box 4.9. cGMP is also a second messenger. It is formed by guanylyl cyclases that belong to two groups: as mentioned earlier, some are transmembrane receptors for polypeptides such as ANF; others are soluble enzymes activated by nitric oxide (see the following Box 4.13). cGMP has several targets in mammalian cells, one of which is cGMP-dependent protein kinase.

PHOSPHOLIPID METABOLITES

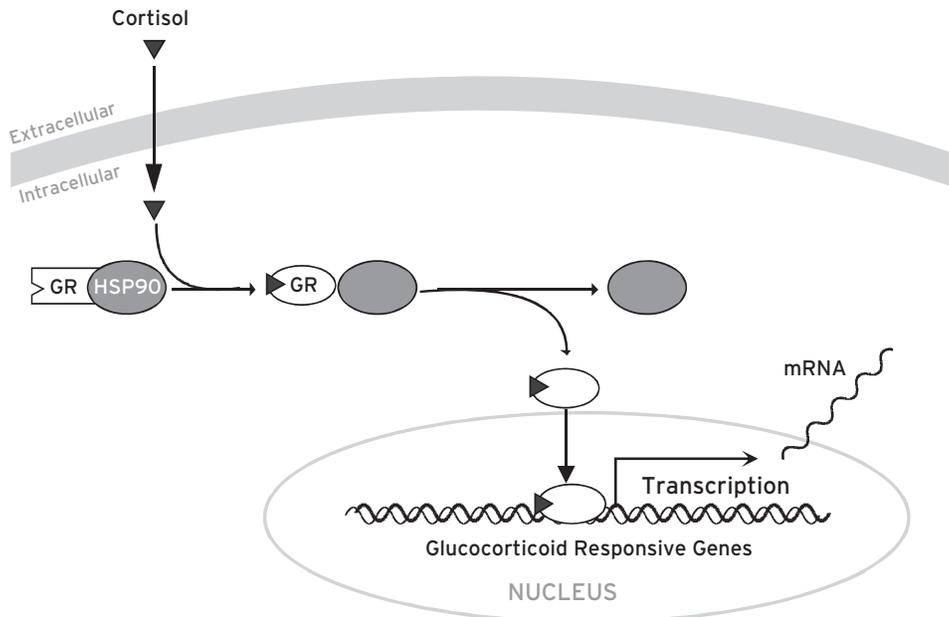

In addition to their importance in the structure of membranes, phospholipids are precursors for many signaling molecules. The structures of some glycerophospholipids are depicted in Box 4.10. These phospholipids generate signaling molecules under the control of different classes of phospholipases, each of which cleaves the precursor at a specific position (Box 4.10). In addition to glycerophospholipids, other membrane lipids such as sphingomyelin have been found to be involved in

BOX 4.6 RECEPTORS FOR STEROID HORMONES

In contrast to other intercellular messengers such as neurotransmitters, peptide hormones, or growth factors, steroid hormones are capable of readily penetrating the target cells. This is due to their lipophilic nature that allows them to cross the plasma membrane. The glucocorticoid receptor (GR) is a protein located in the cytoplasm, where it is sequestered by association with several proteins, including one called *heat shock protein 90* (HSP90). When the GR has bound cortisol, it undergoes a conformational change that releases it from the associated proteins. The hormone-bound receptor then diffuses into the

nucleus, where, as a dimer, it binds to specific DNA sequences in the promoter region of glucocorticoid-responsive genes. The hormone-bound receptor stimulates the transcription of these genes. Other steroid hormones have similar mechanisms of action, except that in some instances their receptor is always located within the nucleus but becomes capable of activating transcription only in the presence of the hormone. Thyroid hormones, vitamin D metabolites, and retinoic acid (a compound important for the regulation of development) have similar mechanisms of action.

Further reading: Dilworth and Chambon, 2001; Mark et al., 2006; Weatherman et al., 1999.

signal transduction. A breakdown product of sphingomyelin, ceramide, may play a role of second messenger. It should be noted that breakdown of membrane phospholipids does not only generate metabolites that contain fatty acids and are relatively hydrophobic, but also water-soluble molecules that are second messengers. An important molecule in that category is inositol-trisphosphate (IP₃), a second messenger released from a membrane phospholipid (phosphatidylinositol-4,5bisphosphate) following the action of phospholipase C (PLC, Boxes 4.10 and 4.11). IP₃ triggers the release of Ca²⁺ from intracellular stores (see Box 4.12).

Ca²⁺

Normal concentrations of Ca²⁺ in the cytosol are very low, due to the impermeability of membranes to this ion and the efficiency of the mechanisms of extrusion (Box 4.12). Ca²⁺ can flow into the cytosol either from the outside through neurotransmitter- or voltage-operated Ca²⁺ channels, or from internal stores (i.e., the endoplasmic reticulum) through Ca²⁺ channels called *inositol-trisphosphate* (IP₃) receptors and *ryanodine receptors* (see Box 4.12). Ca²⁺ has many biological effects that are brought about by its binding to a number

of enzymes and their subsequent activation (see Table 4.3 in Box 4.12). Ca²⁺ binds directly to some of these enzymes that contain specific Ca²⁺-binding domains. In many cases, however, Ca²⁺ interacts first with a small protein, *calmodulin*. The Ca²⁺/calmodulin complex binds to many proteins, including signaling enzymes, and alters their properties. An important class of such enzymes is the Ca²⁺/calmodulin-dependent protein kinases.

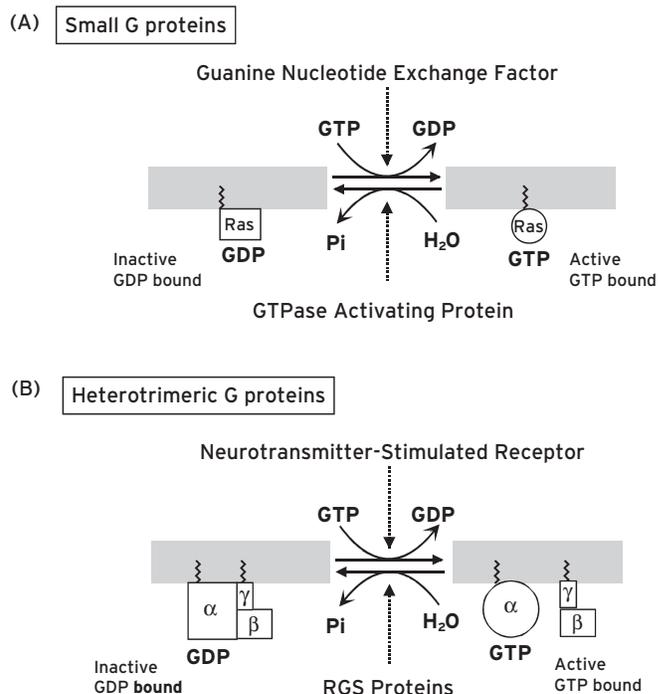

Depolarization of neurons triggers the opening of voltage-gated Ca²⁺ channels, leading to an increase in intracellular Ca²⁺. In nerve terminals, this is the signal responsible for neurotransmitter release. Ca²⁺ influx also provides a mechanism by which nerve cell stimuli, such as the action potential, can be transduced into biochemical signals important for the regulation of neurotransmitter synthesis, gene expression, and many other responses in neurons. Ca²⁺ is an essential trigger of the biochemical reactions that result in long-term depression and long-term potentiation of synaptic efficacy. These forms of synaptic plasticity are thought to be important cellular bases of learning and memory. In addition to its paramount role in neuronal physiology, Ca²⁺ is a key player in the induction of neuronal death in pathological circumstances. For instance,

BOX 4.7 G PROTEINS

G proteins can bind GDP or GTP. They act as molecular switches that are active in the GTP-bound form and inactive in the GDP-bound form. Although G proteins are not transmembrane proteins, they are attached to the membrane by various lipid molecules covalently bound to the protein and inserted into the membrane. Examples of G proteins are listed in Table 4.2.

Small G proteins are simple molecular switches. In the resting state they are bound to GDP and are inactive. The exchange of GDP for GTP is catalyzed by a guanine nucleotide exchange factor (GEF). In the case of Ras, the GEF is brought into play by its adaptor-mediated attachment to phosphorylated growth factor receptors (Box 4.3). In its GTP-bound form, Ras is active and triggers a cascade of phosphorylation reactions (Box 4.8). The inactivation of Ras requires a specific type of protein, called GAP (GTPase activating protein). GAP allows Ras to hydrolyze GTP and to return to the inactive, GDP-bound state.

Although the principle of their function is similar to that of small G proteins, large G proteins are more complicated. These heterotrimeric G proteins are composed of three subunits (α , β , and γ). The α subunit is the one that binds GDP and GTP. The exchange of GDP for GTP is triggered by seven transmembrane domain receptors, when they are bound to their ligand, a neurotransmitter or hormone (Box 4.2). Then, α -GTP and β/γ can diffuse freely at the level of the membrane and act on various targets (Box 4.2). The α subunit has the ability to hydrolyze GTP and to return spontaneously to the inactive GDP-bound form, behaving as a time device. Alpha subunits are the targets of bacterial toxins: α_s is irreversibly activated by cholera toxin, whereas α_i and α_o are irreversibly inhibited by the toxin of *Bordetella pertussis*, the agent of whooping cough.

Recently, GAPs for some α subunits have been identified. They are called RGS (regulator of G protein signaling) and facilitate the return to the inactive GDP-bound form of the G protein.

Other abbreviations: G protein: guanine nucleotide binding protein; GDP: guanosine 5'-diphosphate; GTP: guanosine 5'-triphosphate; Pi: inorganic phosphate.

TABLE 4.2. Examples of GTP-binding proteins

GTP-BINDING PROTEIN CLASS	NAME	FUNCTION
Small G proteins	Ras	Responds to growth factors, activates Raf/MAP kinase pathway
	Rho	Regulates actin filaments
	Rab	Regulates vesicle trafficking, including synaptic vesicles
Heterotrimeric G proteins		
α subunit (binds GTP)	α_s, α_{Of}	Activate adenylyl cyclase
	α_i	Inhibits adenylyl cyclase, activates K^+ channels
	α_t	Stimulates cGMP phosphodiesterase (retina)
	$\alpha_q, \alpha_{11, 14-16}$	Stimulate phospholipase C
	α_o	Inhibits Ca^{2+} channels
	$\alpha_{12, 13}$	Activate Na^+/H^+ exchanger
β/γ (does not bind GTP directly, but associates to α subunits)	$\beta_{1-5}, \gamma_{1-8}$	Activate or inhibit adenylyl cyclase and phospholipase C, activate K^+ channels, MAP kinase pathway, recruit β -adrenoceptor kinase

CGMP: cyclic guanosine 3'-5'-monophosphate; GTP: guanosine 5'-triphosphate; MAP kinase: mitogen-activated protein kinase.

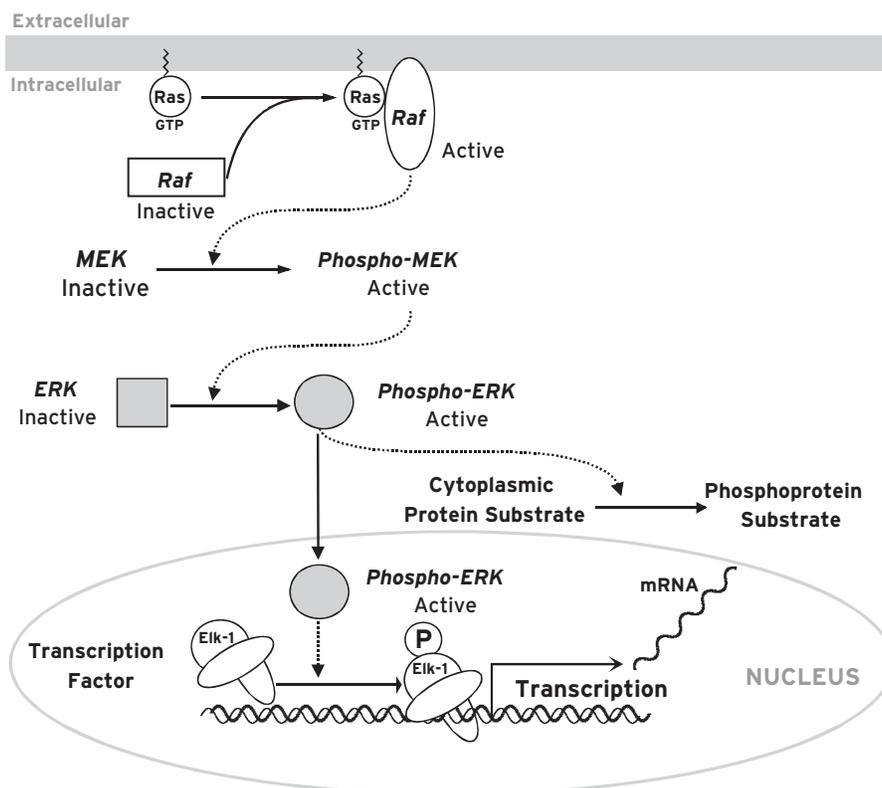

BOX 4.8 THE RAS/MAP KINASE PATHWAY

Stimulation of growth factor receptors results in the conversion of Ras to its active GTP-bound form (Boxes 4.3 and 4.7). Ras exerts its effects by triggering a protein kinase cascade that results, among other things, in the increased transcription of specific genes. The first step is the recruitment to the membrane, by Ras-GTP, of a protein kinase called *Raf*, which, thus, becomes activated (there are several isoforms of *Raf*: A-*Raf*-1, B-*Raf*, and c*Raf*-1). *Raf* phosphorylates a second protein kinase called *MEK* (MAP kinase/ERK kinase). Phosphorylation of *MEK* activates it, making it capable of phosphorylating *ERK* (extracellular signal-regulated kinase) also called *MAP kinase* (mitogen-activated protein kinase). *MEK* is an unusual protein kinase that is able to phosphorylate *ERK* on threonine and tyrosine residues. This double phosphorylation activates *ERK*

that can phosphorylate cytoplasmic substrates such as phospholipase A2 (Box 4.10) or enter the nucleus. In the nucleus, *ERK* phosphorylates transcription factors, including *Elk*-1, a component of the ternary complex factor, thus increasing the transcription of specific genes. This cascade of biochemical reactions is important in the regulation of cell growth and differentiation. In fact, it represents one example of a highly conserved set of kinase cascades that are involved in signal transduction in all eukaryotic cells. For example, two other pathways leading to the activation of MAPKs termed *JNK* and *p38-MAPK* are organized in a very similar manner.

Other abbreviations: *ERK*: extracellular signal regulated kinase; *GTP*: guanosine 5'-triphosphate; *JNK*: *c-Jun N*-terminal kinase; *P*: phosphate group.

during hypoxia extracellular glutamate levels increase, leading to an abnormal stimulation of glutamate NMDA receptors. This, in combination with the partial depolarization of neuronal membranes and impairment of Ca^{2+} extrusion mechanisms (due to an energy deficiency), leads to a prolonged increase in cytosolic Ca^{2+} concentrations. Ca^{2+} triggers several cascades of reactions that can lead to neuronal death. Such reactions are the subject of intense investigations, with the hope that their pharmacological inhibition will improve survival and recovery in stroke and other neurological diseases.

DIFFUSIBLE MOLECULES ACTING AS INTERCELLULAR AND INTRACELLULAR MESSENGERS

ARACHIDONIC ACID AND ITS METABOLITES

Arachidonic acid is a 20-carbon fatty acid with four double bonds. It is released from precursor phospholipids by phospholipase A2 (Box 4.10). It can act in the cells in which it has been produced, for instance, by stimulating protein kinase C. Arachidonic acid can also diffuse to neighboring cells or nerve terminals and act as a local intercellular messenger. In addition,

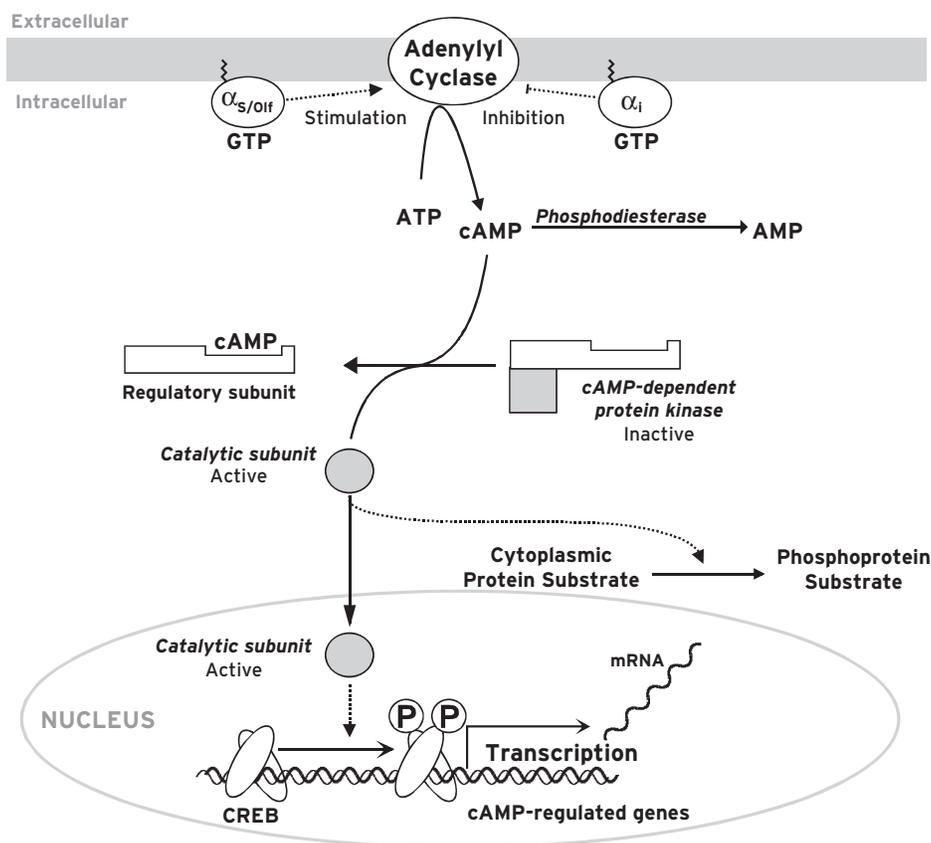

BOX 4.9 cAMP

Cyclic adenosine 3'-5'-monophosphate (cAMP) is formed from ATP by a class of transmembrane enzymes, *adenylyl cyclases*. Adenylyl cyclases are activated by two related subtypes of α subunits of heterotrimeric G proteins: α_s (stimulatory) and α_{olf} (olfactory, which is found in olfactory epithelium and some brain neurons such as striatal neurons). Adenylyl cyclases are inhibited by α_i (inhibitory). In addition, some adenylyl cyclases can be stimulated or inhibited by β/γ subunits of heterotrimeric G proteins, or Ca^{2+} combined with calmodulin. cAMP is inactivated by hydrolysis into AMP by phosphodiesterases, a family of enzymes that are inhibited by theophylline and related methylxanthines. cAMP has very few targets in vertebrates, including a cAMP-gated ion channel that is most prominently found in olfactory neurons, cAMP-regulated guanine nucleotide exchange factors (GEF; see Box 4.7), and the cAMP-dependent protein kinase that is present in all cells. cAMP-dependent protein kinase is a tetramer composed of two catalytic subunits and two regulatory subunits (only one of each is shown on the figure). When cAMP binds to the regulatory subunits (two molecules of

cAMP bind to each regulatory subunit), they dissociate from the catalytic subunits that, once free, are active as protein kinases. The catalytic subunit phosphorylates numerous specific substrates including ion channels, receptors, and enzymes synthesizing neurotransmitters. In addition, the catalytic subunit can enter the nucleus, where it phosphorylates transcription factors. One well-characterized transcription factor phosphorylated in response to cAMP is CREB (cAMP-response element binding protein). CREB forms a dimer that binds to a specific DNA sequence in the promoter region of cAMP-responsive genes, called CRE (cyclic AMP-response element). However, CREB is unable to promote transcription when it is not phosphorylated, whereas phospho-CREB strongly stimulates transcription. Genes regulated by CREB include immediate early genes *c-Fos* and *c-Jun* (Box 4.16). It should be noted that CREB is also activated by Ca^{2+} /calmodulin dependent protein kinases and by protein kinases downstream from MAP kinases (see Table 4.3, Box 4.11).

Other abbreviations: ATP: adenosine 5'-triphosphate.

Further reading: Arnsten et al., 2005; Michel and Scott, 2002; Smith et al., 1999.

it is a precursor for a large family of signaling molecules called *eicosanoids* (*eicosi* is the Greek radical for 20, referring to the length of the carbon chain). Such molecules include prostaglandins, thromboxanes, and hydroperoxymetabolites. A particular class of interesting derivatives of arachidonic acid is composed of endogenous ligands for brain cannabinoid receptors, referred

to as *endocannabinoids*. Cannabinoid receptors are the targets of Δ^9 -tetrahydrocannabinol, the main active substance in cannabis (hashish and marijuana). Endocannabinoids include arachidonylethanolamine, also called *anandamide* (from *ananda*, the Sanskrit word for "bliss"), and 2-arachidonoylglycerol, which are released from specific phospholipid precursors in a

BOX 4.10 PHOSPHOLIPID METABOLITES

The basic backbone of major phospholipids is made up of glycerol that is esterified on positions 1 and 2 by fatty acids and on position 3 by a phosphate group, forming phosphatidic acid. The two fatty acids are inserted into the membrane to which they attach the phospholipid. A water-soluble molecule is linked to the phosphate, giving rise to various types of phospholipids such as phosphatidyl-choline, phosphatidyl-ethanolamine, or phosphatidyl-inositol. Enzymes called *phospholipases* are capable of hydrolyzing specific chemical bonds within these phospholipids, as indicated by solid arrows in the figure.

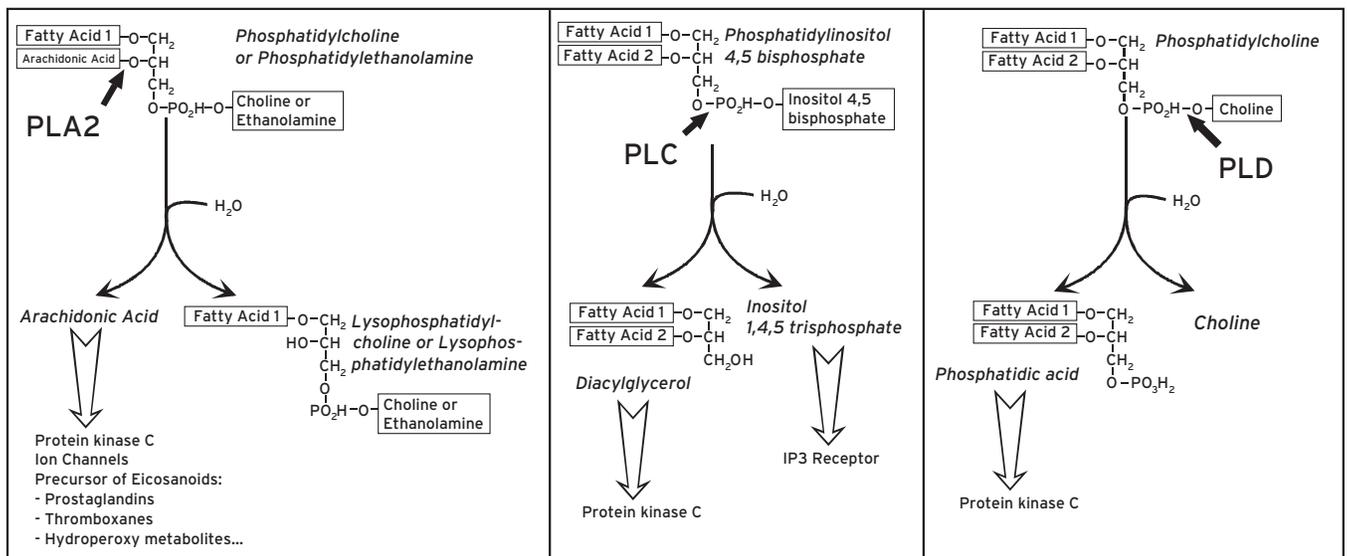

Phospholipase A2 (PLA2) releases the fatty acid located in position 2 of the glycerol backbone. PLA2 acts preferentially on phosphatidyl-choline or phosphatidyl-ethanolamine, in which the fatty acid in position 2 is arachidonic acid, releasing a lysophospholipid and free arachidonic acid. Arachidonic acid is moderately hydrophobic and can diffuse within the cell in which it has been formed, or to neighboring cells. It has several intrinsic biological activities by itself and is also a precursor for many active molecules called *eicosanoids*, including prostaglandins, thromboxanes, and hydroperoxymetabolites. PLA2 is activated by many extracellular signals including neurotransmitters, although the mechanism of its regulation is still incompletely understood.

Phospholipase C (PLC) hydrolyzes the bond between the phosphate group and the glycerol backbone. PLC acts preferentially on phosphatidylinositol 4,5 bisphosphate and generates diacylglycerol and inositol 1,4,5 trisphosphate (IP₃; see Box 4.11). Diacylglycerol stays in the membrane and participates in the activation of protein kinase C. IP₃ is very water-soluble and diffuses in the cytosol. It binds to a receptor located on the endoplasmic reticulum and triggers the release of Ca²⁺ from internal stores (Box 4.11). Among many other actions, Ca²⁺ participates in the activation of protein kinase C. PLC is activated by many neurotransmitters that act on G protein-coupled, seven transmembrane domain receptors. PLC is stimulated by α_q-GTP and α₁₁-GTP as well as by some β/γ complexes (Boxes 4.2 and 4.7).

Phospholipase D (PLD) acts preferentially on phosphatidylcholine and hydrolyzes the bond between the phosphate group and the water-soluble molecule that esterifies it. Thus, it releases phosphatidic acid and choline. It is not known if choline has a role in signal transduction. On the other hand, phosphatidic acid stimulates protein kinase C subtypes. Although PLD is activated by several extracellular signals, including neurotransmitters, the mechanism of its activation is still incompletely understood.

Other abbreviations: G protein: guanine nucleotide binding protein.

Further reading: Cockcroft, 2006; Farooqui et al., 2006.

Ca²⁺-dependent manner. Endocannabinoids, which do not easily cross cell membranes, are intercellular messengers, rather than second messengers, and are implicated in important aspects of neuromodulation, such as retrograde signaling from postsynaptic to presynaptic sites.

NITRIC OXIDE

Nitric oxide (NO) is a gas molecule that has important biological functions. On the one hand, it is a highly reactive chemical

species that is used by macrophages to destroy exogenous substances. On the other hand, it is a chemical messenger, which can diffuse freely, over a short range, through cellular membranes. Nitric oxide was originally discovered as a vasodilator substance generated by endothelial cells that acts on smooth muscle cells of blood vessels. In neurons, *NO synthase*, the enzyme that generates NO, is activated by Ca²⁺ (Box 4.13). A well-characterized effect of NO is to increase cGMP by activation of soluble guanylyl cyclase. Because of its diffusible nature, NO is a retrograde messenger in the nervous system, diffusing

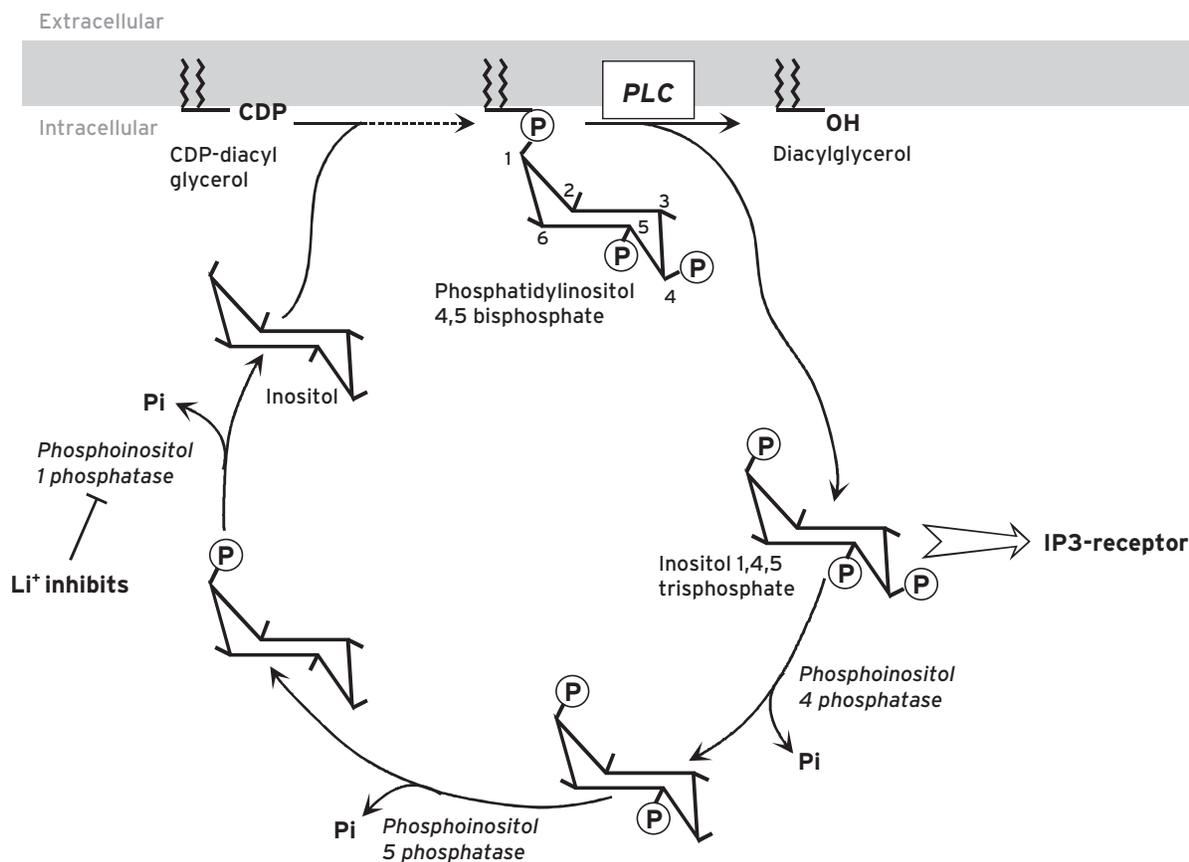

BOX 4.11 INOSITOL-TRISPHOSPHATE

Inositol 1,4,5 trisphosphate (IP₃) is an important second messenger. It is generated by the enzyme phospholipase C (PLC) that hydrolyzes a membrane phospholipid, *phosphatidylinositol 4,5 bisphosphate* (see Box 4.10). PLC is activated by neurotransmitters that act on G protein-coupled, seven transmembrane domain receptors (Box 4.2). PLC generates diacylglycerol and IP₃. IP₃ is very water soluble and diffuses in the cytosol. It binds to a receptor located on the endoplasmic reticulum and thereby triggers the release of Ca²⁺ from internal stores (see Box 4.12). Inositol 1,4,5 trisphosphate is inactivated by several phosphoinositid phosphatases that remove successively the phosphate molecules from the inositol backbone. These phosphatases can act in various sequences, not necessarily that depicted in the figure. The phosphatase that

removes the phosphate in position 1 of the inositol backbone is inhibited by lithium (Li⁺). Inositol can be reincorporated into membrane phospholipids by its coupling to an activated form of diacylglycerol (CDP-diacylglycerol) and phosphorylated on positions 4 and 5 by specific kinases to regenerate phosphatidylinositol 4,5 bisphosphate (broken arrow in the figure). Chronic treatment with lithium may decrease the amount of inositol that can be incorporated into neuronal phospholipids and thus dampen the effects of neurotransmitters that activate PLC. This property of lithium may participate in its mood stabilizing effects.

Other abbreviations: CDP: cytosine 5'-diphosphate; G protein: guanine nucleotide binding protein; Pi: inorganic phosphate.

from the postsynaptic to the presynaptic side of synapses, and thus plays a role in synaptic plasticity (Chapter 5).

PROTEIN PHOSPHORYLATION

Protein phosphorylation is a reversible covalent chemical modification of proteins that plays a central role in signal transduction (Box 4.14). The vast majority of known signal transduction pathways involve the activation of one or several protein kinases, the enzymes that phosphorylate substrate proteins (see

examples of protein kinases in Table 4.4 in Box 4.14). In most instances, it is by altering the state of phosphorylation of key intracellular proteins that intercellular messengers including neurotransmitters, hormones, growth factors, and others ultimately exert most of their effects. The amino acids whose side chains are phosphorylated in the context of signal transduction in multicellular animals (metazoans) are predominantly *serine*, *threonine*, and *tyrosine*. Most protein kinases belong to a very large and ancient gene family. They include serine/threonine kinases, tyrosine kinases, and a few dual specificity protein kinases (Table 4.1).

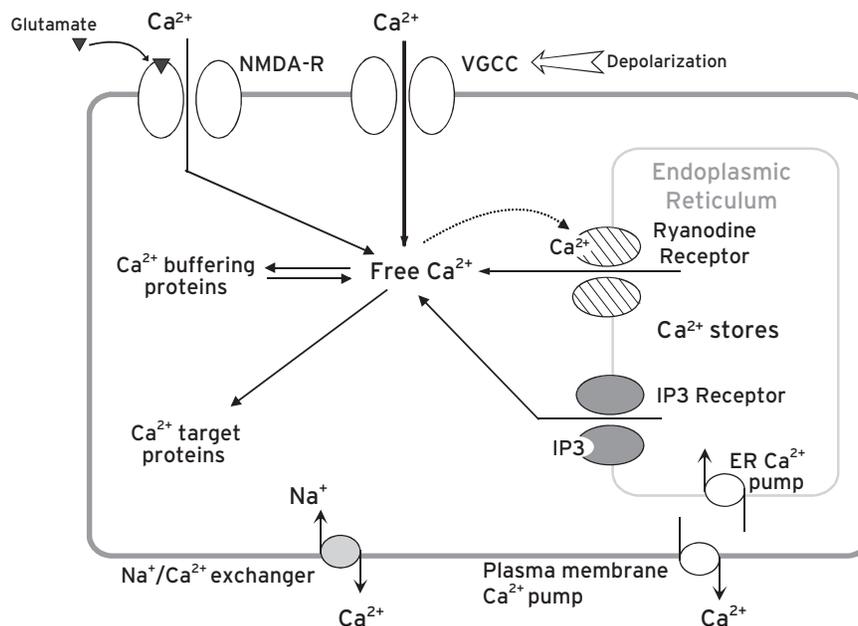

BOX 4.12 Ca^{2+}

Ca^{2+} is a divalent cation whose concentrations are relatively high in the extracellular space (around 1.2 mM) and more than 10,000 times lower within the cytosol (around 100 nM). Some intracellular organelles, however, namely *mitochondria* and *endoplasmic reticulum*, contain high concentrations of Ca^{2+} . In resting conditions the plasma membrane is impermeable to Ca^{2+} . Ca^{2+} can penetrate neurons through specific channels, which include voltage-gated Ca^{2+} channels (VGCC) and glutamate receptors of the NMDA subtype. When these channels are open, in response to depolarization in the case of VGCC or in the presence of glutamate in the case of N-methyl-D-aspartate (NMDA) receptor (see Box 4.1), Ca^{2+} flows readily into the cytosol following its concentration gradient and the electrical potential. Ca^{2+} can also be released into the cytosol from internal stores that are mostly located in the endoplasmic reticulum. Two types of Ca^{2+} channels are responsible for the release of Ca^{2+} from internal stores. One is the inositol 1,4,5 trisphosphate (IP_3) receptor whose opening is triggered by IP_3 , a second messenger generated by phospholipase C (Boxes 4.10 and 4.11). The other is the ryanodine receptor, named after *ryanodine*, a drug that triggers its opening, although it is not a physiological ligand. In fact, opening of ryanodine receptors is elicited by Ca^{2+} itself by a mechanism called *Ca²⁺-induced Ca²⁺ release*, which can give rise to propagation of waves of Ca^{2+} release along the endoplasmic reticulum. In the cytosol, Ca^{2+} is mostly bound to specific binding proteins. Some of them appear to play a role primarily as buffering proteins, preventing excessive rises in cytosolic free Ca^{2+} . Other proteins are the actual targets of Ca^{2+} , which account for its potent biological effects. Among the best characterized targets are calmodulin and calmodulin-related proteins. When they are bound to Ca^{2+} , calmodulin and the related proteins undergo a conformational change that enables them

TABLE 4.3. Examples of target proteins for cytosolic free Ca^{2+}

Ca^{2+} -BINDING DOMAIN	TARGET PROTEIN	FUNCTION
Calmodulin	Ca^{2+} /calmodulin kinases I, II, IV	Protein kinases that increase phosphorylation of multiple proteins
	Elongation factor 2 (EF2) kinase	Protein kinase that phosphorylates EF2 and inhibits protein synthesis
	Calcineurin (Phosphatase 2B)	Protein phosphatase that decreases phosphorylation of specific proteins
	Adenylyl cyclase	Increases cAMP
	Phosphodiesterase	Decreases cAMP
	NO synthase	Triggers NO production
Calmodulin-like	Calpains	Proteases that cut specific proteins
C2 domains	Protein kinase C	Increases phosphorylation of multiple proteins
	Phospholipase A2	Releases arachidonic acid
	Synaptotagmin	Regulates neurotransmitter release

to interact with, and activate, a number of enzymes (Table 4.3). Ca^{2+} can also bind to another type of protein domain called C2 that is found in several different proteins (Table 4.3). Free Ca^{2+} in the cytosol is maintained at very low levels by several

(continued)

BOX 4.12 CONTINUED

highly active processes, which include Ca^{2+} pumps and Ca^{2+} exchangers. Ca^{2+} pumps have a high affinity but a low capacity for Ca^{2+} and are used for fine-tuning Ca^{2+} levels. They are located on the plasma membrane and the membrane of the endoplasmic reticulum, and their energy is provided by ATP hydrolysis. $\text{Na}^+/\text{Ca}^{2+}$ exchangers, whose driving force is

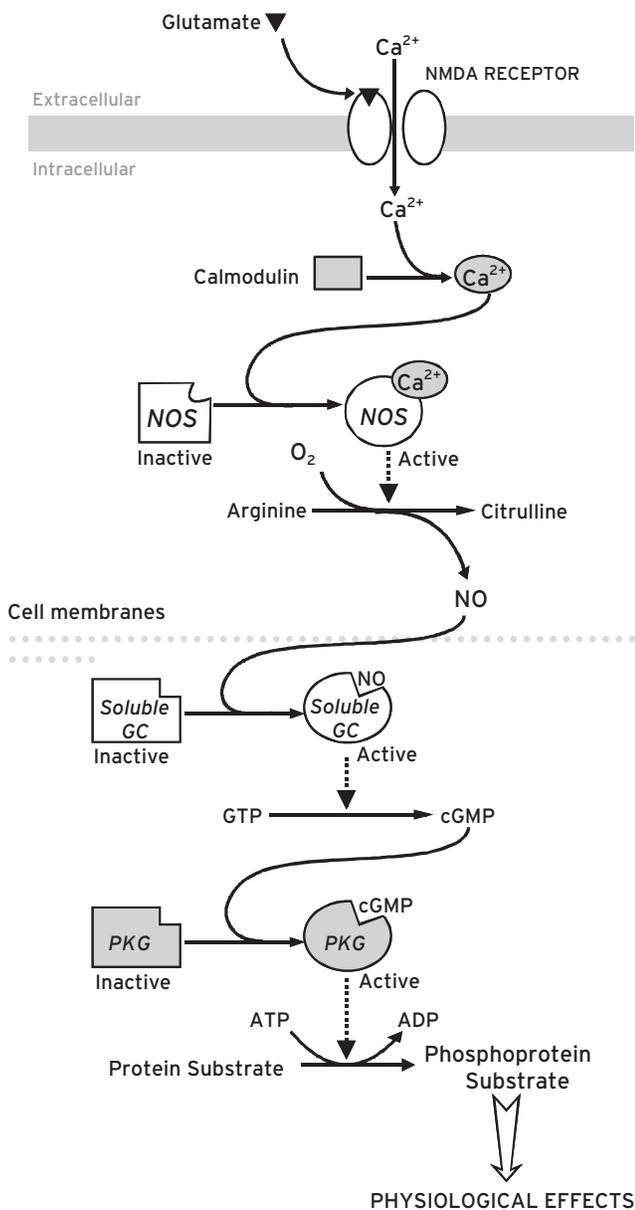

provided by the Na^+ gradient, have a large capacity, but a low affinity for Ca^{2+} .

Other abbreviations: C2: second constant domain within protein kinase C sequence; cAMP: cyclic adenosine 3'-5'-monophosphate; ER: endoplasmic reticulum; NMDA-R: N-methyl-D-aspartate subtype of glutamate receptor.

Further reading: Berridge et al., 2000; Berridge, 2009; Collin et al., 2005; Mikoshiba and Hattori, 2000; Pietrobon, 2005.

BOX 4.13 NITRIC OXIDE

Nitric oxide (NO) is a gas that is highly diffusible and chemically reactive. In the nervous system it is used as a locally active intra- or intercellular messenger. The enzyme responsible for the formation of NO is NO synthase (NOS). It is activated by Ca^{2+} associated to calmodulin. In neurons, opening of glutamate receptors of the N-methyl-D-aspartate (NMDA)

subtype is a major source of Ca^{2+} influx (Box 4.1) that can lead to the activation of NOS. NOS is a complex enzyme that uses molecular oxygen, O_2 , to generate NO by transforming arginine into citrulline. NO can cross membranes readily and diffuse to neighboring cells or nerve endings. Thus, the rest of the cascade depicted in the figure can take place in a cell different from that in which NO was generated, as symbolized by the dotted pair of lines in the figure. A major target of NO is soluble guanylyl cyclase. This enzyme is activated by NO and uses guanosine 5'-triphosphate (GTP) to form cyclic guanosine 3',5'- monophosphate (cGMP), a second messenger that remains within the cell in which it is produced. cGMP exerts its effects by activating several enzymes, one of which is cGMP-dependent protein kinase. Phosphorylation of specific proteins by cGMP-dependent protein kinase accounts for some of the physiological effects of NO.

Other abbreviations: GC: guanylyl cyclase; NMDA-R: N-methyl-D-aspartate subtype of glutamate receptor; PKG: cGMP-dependent protein kinase.

Further reading: Iino, 2006; Snyder et al., 1998.

The presence of a bulky and negatively charged phosphate group on the side chain of these amino acids can change dramatically the properties of the protein, leading to the activation or inhibition of enzymes, opening or closing of ion channels, modulation of neurotransmitter receptors, activation of transcription factors, and so forth (examples of neuronal proteins regulated by phosphorylation are listed in Table 4.6 in Box 4.14). Thus, phosphorylation reactions play an effector role when the substrate proteins are critical components for the behavior of cells (see Box 4.14). In addition, protein phosphorylation is involved in cascades of signal transduction in two other ways. First, phosphorylation of amino acid residues can promote the recruitment of proteins important for signal transduction, as exemplified by interaction of protein regions phosphorylated on tyrosine with Src-homology-2 (SH2) domains (Boxes 4.3–4.5). Second, many signaling pathways involve protein kinase cascades in which a first kinase activates a second kinase, which activates a third one, and so on. Functions of such kinase cascades (see Box 4.8 for an example and also Box 4.18) are to provide amplification and, in some cases, to turn graded inputs into switch-like all-or-none responses (bistable systems).

The state of phosphorylation of a protein is determined by its relative rates of phosphorylation and dephosphorylation. The enzymes that remove phosphate groups from proteins are called *phosphoprotein phosphatases* (Box 4.14, Table 4.5) and

BOX 4.14 PROTEIN PHOSPHORYLATION

Phosphorylation is carried out by protein kinases, which, in the presence of Mg^{2+} , transfer a phosphoryl group from ATP to serine, threonine, or tyrosine residues. Because these kinases often recognize the amino acid sequence surrounding the serine, threonine, or tyrosine to be phosphorylated, protein kinases have a high degree of substrate specificity. Protein kinases form a very large group of related enzymes, each of which has its own localization, regulation, and substrate specificity (Table 4.4). Some protein kinases are either receptors for extracellular signals (Box 4.3) or are associated with such receptors (Box 4.5). Several protein kinases are activated directly by second messengers and account for most of the effects of these second messengers. These include cAMP- and cGMP-dependent protein kinases (Boxes 4.9 and 4.13), protein kinases activated by Ca^{2+} associated to calmodulin (Box 4.11), and protein kinase C, which is activated by Ca^{2+} , diacylglycerol, and/or several other lipid derivatives (Box 4.10). Some protein kinases are themselves regulated by phosphorylation and participate in kinase cascades (see Box 4.8).

The reverse reaction, the removal of the phosphate group, is catalyzed by phosphoprotein phosphatases. This class of enzymes, if not quite as large as that of protein kinases, includes many members belonging to several gene families (Table 4.5). Different types of phosphatases are responsible for the removal of phosphate groups from serine and threonine side chains and from tyrosine side chains. A very large number of important neuronal proteins are regulated by phosphorylation/dephosphorylation (Table 4.6).

Other abbreviations: ATP: adenosine 5'-triphosphate; cAMP: cyclic adenosine 3'-5'-monophosphate; cGMP: cyclic guanosine 3'-5'-monophosphate.

Further reading: Greengard, 2001; Johnson and Hunter, 2005; Mansuy and Shenolikar, 2006; Papin et al., 2005.

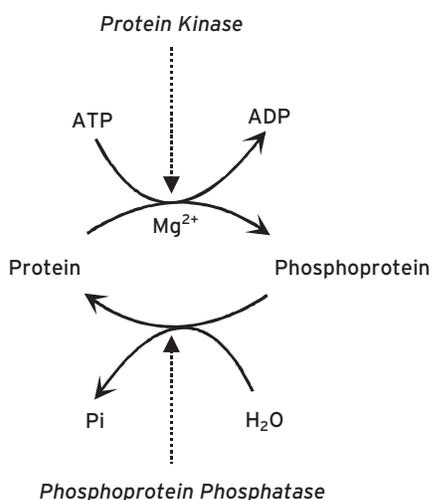

TABLE 4.4. Examples of protein kinases

PHOSPHORYLATED AMINO ACID	ACTIVATION MECHANISM	PROTEIN KINASE
Serine and/or threonine	cAMP	cAMP-dependent protein kinase
	cGMP	cGMP-dependent protein kinase
	Ca^{2+} -calmodulin	Ca^{2+} /calmodulin kinases I, II, IV
		Elongation factor 2 kinase
	Ca^{2+} , DAG, arachidonic acid	Protein kinase C
	Interaction with Ras-GTP	Raf
	Recruitment to the membrane by phosphoinositides	Akt (or PKB)
	Phosphorylation	MAP kinases (ERK, JNK, p38-MAP kinase)
	Phosphorylation, dephosphorylation, cyclin binding	Cyclin-dependent kinases
Tyrosine	Extracellular ligand binding	Receptors for insulin or growth factors
	Interaction with a receptor	JAK, Src family kinases
Threonine and tyrosine	Phosphorylation	MAP kinase (or MEK)

may be as important in signal transduction as protein kinases. The regulation of protein phosphatases is, in general, not as well understood as that of protein kinases. There are nevertheless well-documented examples of protein phosphatases whose activity is regulated by neurotransmitters, as illustrated in Box 4.15.

SIGNALING BY PROTEOLYSIS

In contrast to non-covalent protein-protein interactions and to protein phosphorylation, which are reversible, proteolysis is irreversible. In addition to its obvious role in the degradation of proteins, proteolysis is involved in intracellular signaling cascades. For example, signals that lead to programmed cell death, or *apoptosis*, activate a set of proteases, the *caspases*. Caspases activate each other in an ordered manner by limited proteolysis and also contribute directly to cell death by cleaving a number of cellular proteins (Box 4.16).

TABLE 4.5. Classification of phosphoprotein phosphatases*

TARGET PHOSPHO-AMINO ACID	PROPERTIES	CLASSICAL NAME	NEW NAME
Phosphoserine and/or phosphothreonine	Sensitive to specific protein inhibitors (phospho-inhibitor 1, phospho-DARPP-32, inhibitor 2)	Phosphatase 1	PPP1
	Insensitive to these inhibitors		
	Insensitive to divalent cations	Phosphatase 2A	PPP2
	Activated by Ca ²⁺	Phosphatase 2B (Calcineurin)	PPP3
	Requires Mg ²⁺	Phosphatase 2C	PPM
Phosphotyrosine	Transmembrane "receptor-like" proteins	RPTP	
	Cytoplasmic proteins (usually possess targeting domains)	PTP	
Dual specificity: phosphoserine and/or phosphothreonine and/or phosphotyrosine		Phosphatases acting on MAP kinase or cyclin-dependent kinases	

*Several other Ser/Thr protein phosphatases have been identified, including PP4 and PP6, which are close to PP2A, and PP5 and PPP7. A new nomenclature has been proposed that takes into account the sequence similarities of the catalytic domain. PPP, phosphoprotein phosphatase, PPM, protein phosphatases dependent from Mg²⁺ or Mn²⁺.

TABLE 4.6. Examples of neuronal proteins regulated by phosphorylation/dephosphorylation

REGULATED PROTEIN	PROTEIN KINASE	EFFECT
Ion channels		
Ca ²⁺ (L type)	cAMP-dependent	Increases Ca ²⁺ permeability
K ⁺ (Kv1.2, 1.3)	Tyrosine kinase	Closes the channel
Na ⁺	PKC, cAMP-dependent	Decreases Na ⁺ permeability
Neurotransmitter-gated ion channels		
Glutamate (AMPA-subtype)	cAMP-dependent	Increases response
Glutamate (NMDA-subtype)	PKC, tyrosine kinase	Increases response

CREB	cAMP-dependent, kinases activated by MAP kinases	Increases transcription

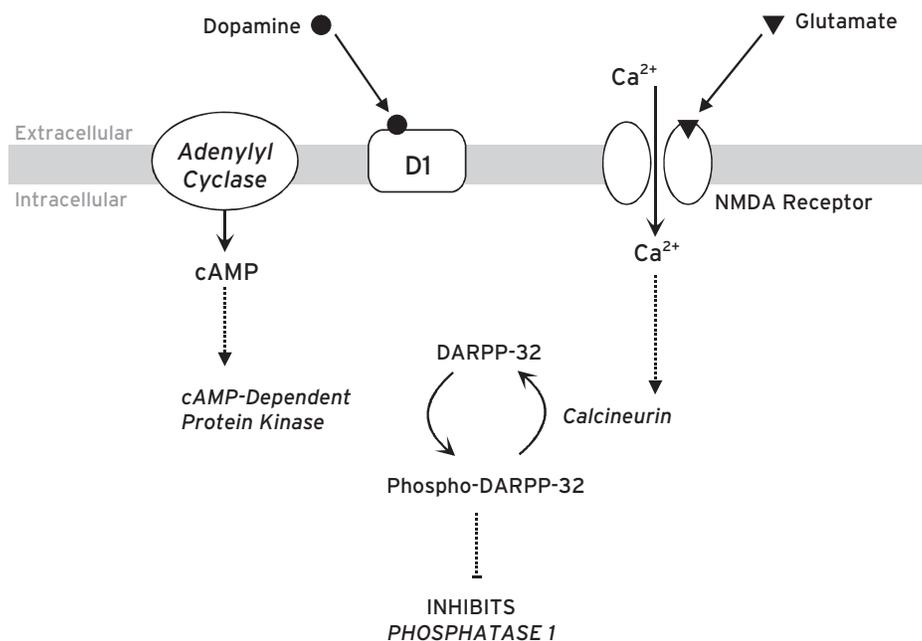

BOX 4.15 REGULATION OF NEURONAL PHOSPHOPROTEIN PHOSPHATASES

The regulation of protein phosphatase activity by neurotransmitters is perhaps best understood in striatonigral neurons. These neurons receive a glutamatergic input from the cerebral cortex, as well as a rich dopaminergic innervation from the substantia nigra and the ventral tegmental area. Dopamine regulates the efficacy and plasticity of corticostriatal transmission. Dopamine, acting on D1 dopamine receptors, stimulates adenylyl cyclase via a G protein (not shown in the figure; see Box 4.9). Increased cAMP levels activate cAMP-dependent protein kinase (PKA). A major substrate for PKA in these neurons is DARPP-32 (*dopamine- and cAMP-regulated phosphoprotein with an apparent molecular weight of 32,000*). When it is phosphorylated, DARPP-32 becomes a potent inhibitor of protein phosphatase 1 (see Table 4.6, Box 4.14). However, glutamate acting on NMDA receptors (Box 4.1) gives rise to

a large influx of Ca^{2+} . This results in the stimulation of a protein phosphatase activated by Ca^{2+} and calmodulin, called *calcineurin* or *phosphatase 2B* (Box 4.14). One of the actions of calcineurin is to dephosphorylate DARPP-32, and thus to relieve the inhibition of phosphatase 1. In this system, the activities of two phosphatases, *calcineurin* and *phosphatase 1*, are regulated by the neurotransmitters *dopamine* and *glutamate*. In turn, phosphatase 1 is important for the regulation of several targets including Na^+ and Ca^{2+} channels, and glutamate receptors. The scheme presented here is a simplification since DARPP-32 is, in reality, regulated by several phosphorylation sites and many neurotransmitters and neuromodulators.

Other abbreviations: cAMP: cyclic adenosine 3'-5'-monophosphate; G protein: guanine nucleotide binding protein; NMDA: N-methyl-D-aspartate.

Other types of intracellular proteases can play a role in signaling, outside of the context of cell death. For example, calpains are proteases activated by increased levels of cytosolic free Ca^{2+} (Table 4.3 in Box 4.11). One important system for the degradation of cellular proteins is a large multiprotein complex called *proteasome*. Proteins are targeted to the proteasome by conjugation to a small polypeptide termed *ubiquitin*, under the action of specific enzymes and cofactors. The ubiquitin “tag” triggers the degradation of improperly folded proteins but also has a role in signaling (Box 4.16). Thus, recently several pathways of regulated proteolysis of specific proteins have been identified as important components of signal transduction not only for programmed cell death, but also during development as well as in the mature nervous system. Moreover, abnormal regulation of proteolysis is likely to be a key aspect in pathological conditions such as Alzheimer’s disease.

REGULATION OF GENE EXPRESSION

Regulation of gene expression is an important target of signal transduction in neurons, as in other cells. Because of its long-lasting effects, it is important in mediating the actions of neurotrophins, as well as in learning and memory (Chapter 5). Signaling pathways involving growth factor receptors and the mitogen-activated protein (MAP) kinase cascade (Boxes 4.3 and 4.8), JAK-STAT associated receptors (Box 4.5), steroid hormones (Box 4.6), cAMP (Box 4.9), and proteolysis (Box 4.16) lead to changes in gene expression. Other pathways involving Ca^{2+} /calmodulin-activated protein kinases, or protein kinase C also exert profound effects on gene expression, via similar mechanisms. In fact, the promoter region of regulated genes often contains several consensus DNA sequences capable of interacting with specific transcription factors (see Chapter 6). The overall rate of transcription of

BOX 4.16 SIGNALING BY PROTEOLYSIS

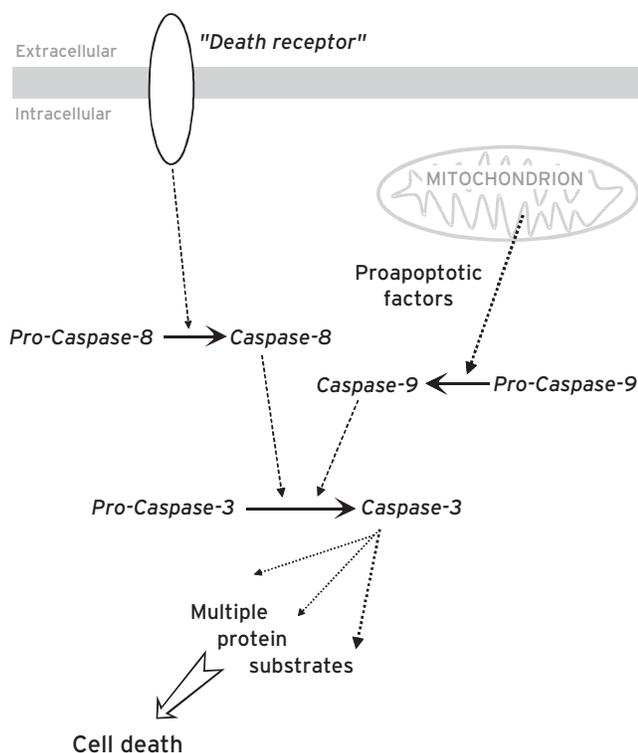

In contrast to phosphorylation, which is reversible, proteolysis is irreversible. Nevertheless it is an important component of several signaling pathways. All cells can undergo a programmed cell death or apoptosis, which is a way to control precisely cell numbers during development and to eliminate abnormal cells. Excessive apoptosis is also a mechanism underlying many neurological diseases. A specific group of evolutionarily conserved proteases are termed *caspases* because they contain a cysteine residue in their active site and cleave their substrates in the vicinity of aspartate residues. Caspases are the final common pathway of apoptosis [see (A)]. Caspases exist as inactive precursors, the procaspases that become active following limited proteolysis. Upstream caspases are activated by autocleavage following interaction with specific factors in response to various signals. For example, procaspase-8 is activated by ligation of "death receptors" such as Fas and the p75 neurotrophin receptor, while procaspase-9 is activated by the release of proapoptotic factors from mitochondria. Once in their active form, these caspases cleave and activate effector caspases, such as caspase-3, which contribute to cell death by

cutting multiple cellular proteins. Degradation of proteins by the proteasome is important for the elimination of abnormal or improperly folded proteins. It is also involved in some signaling pathways. Proteins are targeted for degradation in the proteasome by the attachment to their lysine side chains of one or several polypeptides called *ubiquitin*. For example, this mechanism is important for the activation of the transcription factor NF κ B (*nuclear factor κ B*, named because of its role in the regulation of κ immunoglobulin light chains in B lymphocytes) [see (B)]. NF κ B plays a role in many biological responses ranging from early development to inflammation. NF κ B is a dimer of two subunits maintained in an inactive state in the cytoplasm by interaction with an inhibitor protein termed *I κ B*. Activation of NF κ B in response to stimulation of various receptors involves its dissociation from I κ B, triggered by phosphorylation. I κ B is then ubiquitinated and degraded by the proteasome, allowing NF κ B to translocate to the nucleus and activate transcription of multiple genes, some of which may have antiapoptotic effects.

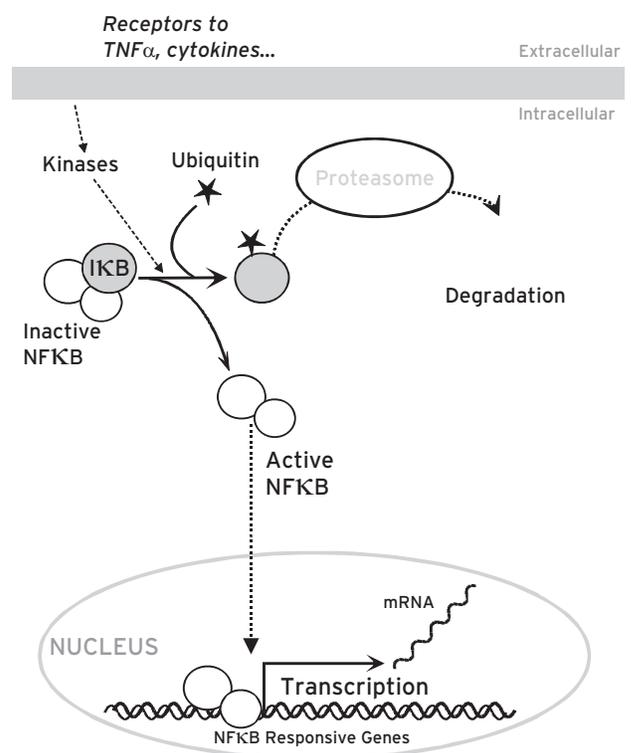

Other abbreviation: TNF α : tumor necrosis factor alpha.

(A) Caspases in Signaling

(B) Proteasome in Signaling

such genes depends on the interaction between various transcription factors and the housekeeping proteins involved in mRNA synthesis. The nuclear localization, DNA-binding, and activity of transcription factors can be modulated by

phosphorylation. In addition, signaling pathways regulate histones, which are basic proteins associated to DNA to form the chromatin, thereby facilitating or preventing the accessibility and transcription of specific genes. These regulations

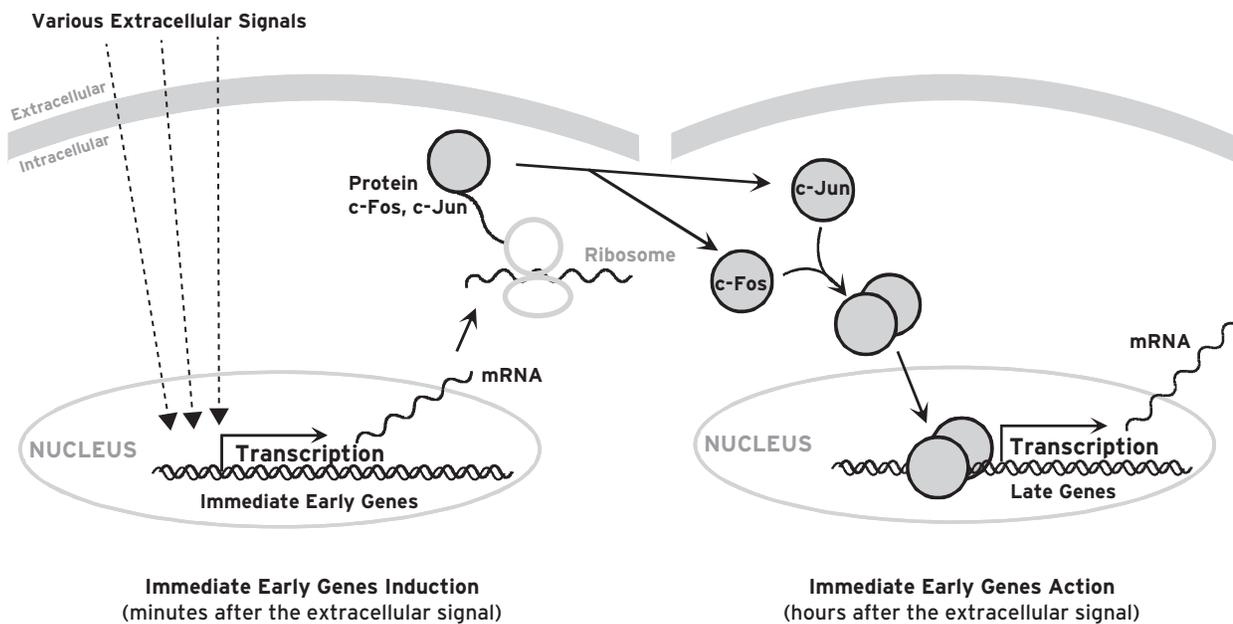

BOX 4.17 IMMEDIATE EARLY GENES

The transcription of genes encoding certain transcription factors, such as *c-Fos* and *c-Jun* depicted here, is readily regulated by extracellular signals that act by various signal transduction pathways involving cAMP, Ca²⁺, or phosphorylation cascades (see Boxes 4.9, 4.12, and 4.8, respectively). The levels of *c-Fos* and *c-Jun* are very low in basal conditions, but their transcription increases dramatically and transiently in many neurons within minutes following various extracellular signals or depolarization. The increased transcription of these genes is the consequence of the phosphorylation of transcription factors that are already present in the cell under an inactive form, and which are activated by phosphorylation (examples of such factors are Elk-1, see Box 4.8, and cAMP-responsive element

binding protein [CREB], see Box 4.9). Such genes are called *immediate early genes*, and stimulation of their transcription does not require protein synthesis to occur. When *c-Fos* and *c-Jun* messenger ribonucleic acids (mRNAs) are translated into proteins, these proteins dimerize and form an active transcription factor that binds to specific DNA sequences in the promoter region of other genes and stimulates their transcription. Transcription of these latter genes occurs several hours after the initial stimuli and is prevented by protein synthesis inhibitors that block the synthesis of *c-Fos* and *c-Jun* proteins (Chapter 6).

Other abbreviations: cAMP: cyclic adenosine 3'-5'-monophosphate.

Further reading: Girault et al., 2007; Guzowski et al., 2005; Hyman et al., 2006.

include different types of modification of histones such as phosphorylation, methylation, and acetylation. Thus, several signal transduction pathways can converge to modulate precisely the levels of gene expression. Some transcription factors are present at low levels in basal conditions but can be rapidly induced in response to extracellular signals. These transcription factors belong to the class of immediate early genes, which include *c-Fos* and *c-Jun* and are useful markers of neuronal activity (Box 4.17).

TERMINATION OF SIGNALS

Intuitively, for cells to adapt swiftly to changes in their environment or incoming signals, it seems critical that they be able to stop rapidly the responses they started, pretty much as driving a car requires both an accelerator and a brake. This may be appropriate either when the external signal itself is off, or when the signal is too intense or too prolonged, so that

excessive responding could become deleterious. In fact, most reactions of signal transduction are reversible and cells have developed highly sophisticated ways to control the duration and intensity of their responses. Most receptors go through several types of inactivation that prevent excessive stimulation. Many ligand-gated ion channels undergo desensitization. This means that in the presence of the neurotransmitter the receptor switches spontaneously into a closed (i.e., inactive) conformation, which is usually rather stable and corresponds to a state of high affinity for the neurotransmitter (see Box 4.1). G protein-coupled receptors also undergo desensitization and down-regulation (removal of the receptor from the cell surface by endocytosis), a process that involves phosphorylation of the receptor. Many G protein-coupled receptors are regulated by phosphorylation by a specific class of protein kinases (*G protein-coupled receptor kinases*, GRKs) that act specifically on the active, neurotransmitter-bound form of the receptor. Phosphorylation of the receptor by GRKs decreases or blocks its ability to interact with G proteins and facilitates

BOX 4.18 PI3 KINASE Akt mTOR PATHWAY

The importance of this pathway was initially identified in the context of insulin actions and control of glucose metabolism and cell growth. Further studies have shown its paramount importance in many cell functions and recently in brain development, function, and diseases. The initial step is the activation of PI3 kinase (PI3K), which is a lipid kinase that phosphorylates phosphatidyl-inositol-4,5 bisphosphate (PIP2, for the class I PI3 kinase depicted here) on the position 3 of the inositol moiety to form phosphatidyl-inositol-3,4,5 trisphosphate (PIP3). There are several classes of PI3 kinases that can be activated by receptor tyrosine kinases in response to growth factors (Box 4.3) or by some G protein-coupled receptors (Box 4.2). The dephosphorylation of PIP3 is catalyzed by PTEN (phosphatase and tensin homolog).

When PIP3 is formed at the inner face of the plasma membrane it recruits proteins that have domains that recognize specifically this phospholipid, such as the pleckstrin-homology (PH) domain. Akt (also termed PKB) and 3-phosphoinositide-dependent protein kinase 1 (PDK-1) are two related protein kinases that have a PH domain [see (B)]. PDK-1 phosphorylates and activates Akt, which, in turn, phosphorylates and regulates many proteins including the tuberous sclerosis complex proteins 1 and 2 (TSC1/2). The TSC1/2 heteromer is a GTPase-activating protein for the small G protein Rheb (Box 4.7). Rheb, when it is bound to GTP, activates the mTOR complex 1 (mTORC1, comprising mTOR and Raptor). mTOR is a protein kinase and was identified as the mammalian target of rapamycin (hence its name), a potent immunosuppressor

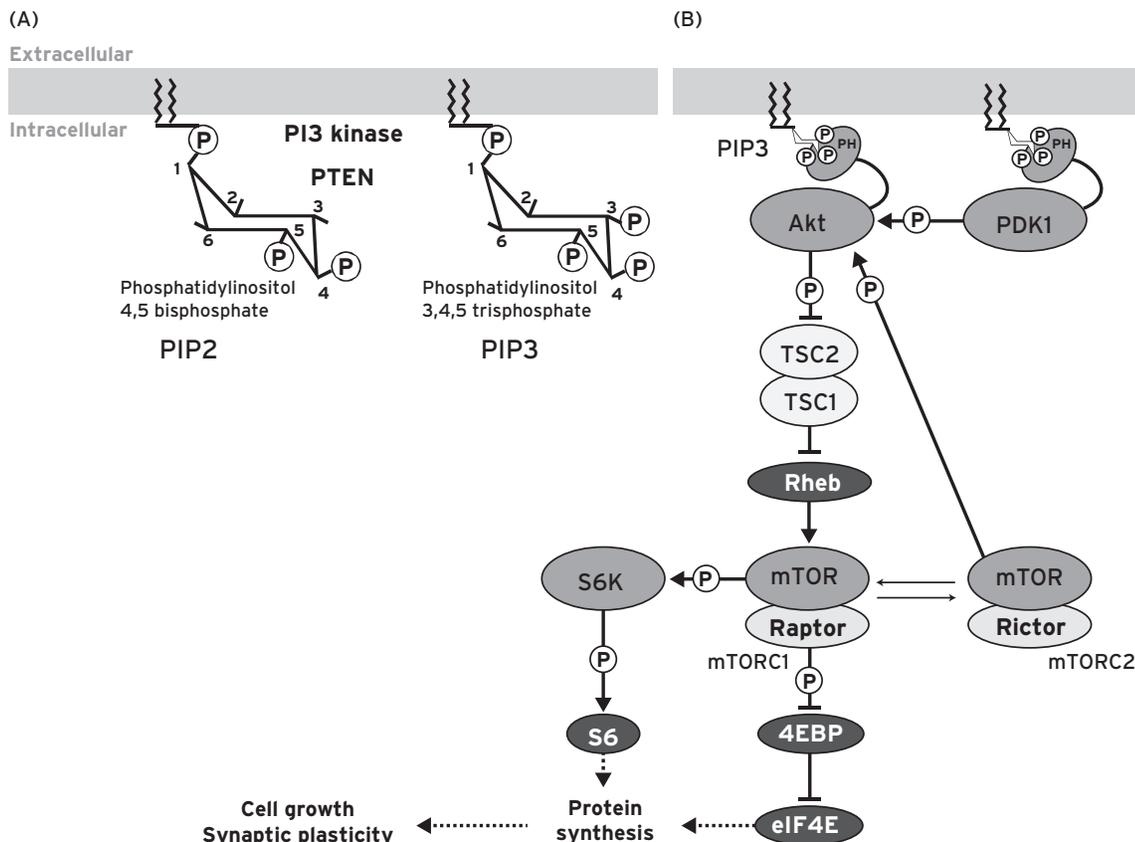

which acts by inhibiting the protein kinase activity of mTORC1. This complex cascade of reactions explains how PI3 kinase and Akt can activate mTORC1 by preventing the action of TSC1/2, which has an inhibitory role through its action on Rheb. mTOR can also associate to a protein termed Rictor to form mTOR complex 2 (mTORC2). The regulation of this complex is less well understood than that of mTORC1, but it plays an important role in the pathway by phosphorylating and activating Akt.

mTORC1 has several substrates including the eIF4E-binding protein (4EBP). 4EBP normally inhibits the action of eukaryotic initiation factor 4E (eIF4E) an essential element for protein translation initiation. Phosphorylation of 4EBP by mTORC1 relieves its inhibitory effect and favors protein translation. Another substrate of mTORC1 is the S6 kinase, which phosphorylates the ribosomal protein S6, further contributing to protein synthesis regulation. In summary this pathway stimulates cell growth through increase in protein translation. Recent work has also shown its implication in synaptic plasticity.

Interestingly, several genes coding for proteins of this pathway, including PTEN, TSC1, and TSC2, are mutated in human conditions associated with epilepsy, mental disability, and autism spectrum disorder. Such mutations appear to result in constitutive activation of this pathway and the possible therapeutic effects of rapamycin are currently being investigated.

The arrows with a pointed head indicate activation, whereas those with a bar indicate an inhibition. The circled P on the arrow indicates that the activation or the inhibition is mediated by phosphorylation.

its endocytosis. Indeed, most receptors, including G protein-coupled receptors, as well as tyrosine kinase receptors and many others, are subjected to endocytosis when they are activated by their cognate ligand. Internalization of the receptor may lead to its degradation or to its recycling to the membrane. In fact, regulation of the number of receptors present at the membrane, by adjustment of their endocytosis and exocytosis rates, appears to be an important mechanism by which cells alter their sensitivity to external signals. For example, regulation of the number of glutamate receptors in the postsynaptic membrane is an important aspect of synaptic plasticity.

G proteins have built-in inactivating mechanisms: spontaneous or induced GTP hydrolysis leads to the inactivation of the G protein (see Box 4.7). The importance of this mechanism is underlined by the dramatic consequences of its blockade. Cholera toxin-induced blockade of GTP hydrolysis by $G\alpha_s$ in the intestinal epithelium is responsible for a potentially lethal water loss, while mutations that hamper the GTPase activity of Ras are potently oncogenic. Second messengers themselves are rapidly degraded by specific enzymes. Phosphodiesterases transform cAMP and cGMP into inactive AMP and GMP, respectively (see Box 4.9). Inositol phosphates are dephosphorylated by specific phosphatases (see Box 4.11). Free cytosolic Ca^{2+} is buffered by binding proteins and rapidly eliminated by various pumps and exchangers either to the outside of the cell or into intracellular stores (see Box 4.12). These various mechanisms can be important pharmacological targets. For example, lithium inhibits phospho-inositol-phosphatases, while inhibitors of cGMP phosphodiesterase have attracted a lot of public attention for their effects on sexual performance through vasodilation.

Protein phosphorylation reactions are also reversible, due to the presence of protein phosphatases (see Box 4.14), and the tightly regulated activity of these enzymes is an integral part of signaling mechanisms (see Box 4.15). It is worth mentioning that in many cases signaling pathways appear to be active to some degree even in the absence of extracellular signals, but that inactivation mechanisms (e.g., GTPases, phosphodiesterases, or phosphatases) counteract this spontaneous activity. What the extracellular signal does is to tilt the balance by enhancing the rate of activation and/or decreasing the rate of inactivation of the signaling. Although this permanent bustle of signaling pathways may, at first sight, appear costly for the cell, it may be advantageous by providing the capability to react very rapidly to extracellular signals.

PSYCHOPHARMACOLOGIC AGENTS AND SIGNAL TRANSDUCTION

Most of the therapeutic agents used at present in psychiatry act at the level of synaptic transmission by altering either the reuptake of neurotransmitters into presynaptic terminals, their degradation, or their action on target nerve cells. Benzodiazepines are potent modulators of GABA-A receptors. Most antipsychotic agents (neuroleptics) are antagonists at dopamine receptors. Most antidepressants are inhibitors of the plasma membrane transporters for norepinephrine

and/or serotonin. Other drugs have intracellular targets such as the monoamine oxidase inhibitor class of antidepressants, which inhibit an enzyme that degrades catecholamines and serotonin. In contrast to agents that act at the level of neurotransmitters, lithium is thought to exert its mood-stabilizing effects in part by dampening phosphatidylinositol turnover. It provides an example of a psychotherapeutic agent that appears to act directly at the level of a signal transduction pathway. Recent work has identified other signaling pathways as potential additional targets for lithium, including the protein kinase *glycogen-synthase kinase-3*. Although few psychotherapeutic drugs used at present act directly on signaling mechanisms, several compounds have already proven their usefulness in other fields of medicine, including cancer treatment and immunosuppression. It is safe to predict that due to the intense research in this field, new classes of drugs with interesting applications in psychiatry will be developed. An example of drug under investigation is rapamycin, initially discovered as an immunosuppressant, which blocks the protein kinase mammalian target of rapamycin (mTOR, Box 4.18). mTOR is an effector of the PI3 kinase/Akt pathway, which controls cell survival, cell growth, and synaptic plasticity. Genetic alterations of this pathway are involved in a large variety of diseases, some of which alter brain development and function.

The antipsychotic effects of neuroleptics, as well as the therapeutic effects of antidepressants, take several days to appear, whereas their actions on receptors, transporters, or enzymes are immediate. This discrepancy indicates that many biochemical steps are probably involved between the primary targets of these drugs and the biological changes responsible for their clinically useful effects. These steps may include signal transduction pathways, which have started to be studied only very recently. It is likely that elucidation of such signaling pathways will be required to explain the therapeutic effects of neuroleptics and antidepressants and will be helpful in the design of new and more rapid active treatments. Likewise the signaling pathways underlying learning and memory at the cellular level are being deciphered at a rapid pace. Recent work has shown that abnormal incentive learning plays an important role in drug addiction (see Chapters 45 and 46), and possibly in other psychiatric diseases. The understanding of intracellular signaling pathways involved in the action of drugs of abuse is progressing rapidly and sheds light on the molecular basis of this frequent condition.

CONCLUSIONS

Signal transduction pathways form a complex network of biochemical reactions that allow cells to translate changes in their environment into appropriate responses. In spite of their complexity, these pathways have been highly conserved during evolution, and neurons use the same types of signaling cascades as other cells. In neurons, they are important for the modulation of the fast reactions involved in neuronal activity. They also provide the basis for the reactions that lead to neuronal growth and synapses formation and plasticity, and

thus for the development of the nervous system, as well as for learning and memory. It is likely that, in the near future, environmental or genetic alterations of signal transduction pathway components will be found to be important in some psychiatric diseases. The understanding of these pathways is just at its beginning. To date, a few compounds acting on signal transduction mechanisms have already found clinical application. Moreover, this is an area of intense research, and it is likely that an increasing number of psychotherapeutic agents will be discovered that act by altering signal transduction mechanisms.

DISCLOSURES

Dr. Girault has no conflicts of interest to disclose. His salary is paid by Inserm (a public national research institute) and work in his laboratory is funded by French (*Agence Nationale de la Recherche*) and European (Framework Program 7, European Research Council) grants.

Dr. Greengard receives grant support from the National Institutes of Health and the U.S. Department of Defense. He has no conflicts of interest with regard to the subject matter of the chapter.

5 | SYNAPTIC AND NEURAL PLASTICITY

SAÏD KOURRICH AND ANTONELLO BONCI

Brain function is generated by an extraordinarily complex yet organized neuronal network where information transmission is orchestrated by elementary cellular mechanisms. Ultimately, the firing patterns of neurons code information within the brain, and the frequency and variation of the firing patterns determine the nature of this information. Information transmission within the brain involves complex and subtle variations in neuronal activity. In particular, electrical signals in the brain are constantly modulated and are heavily influenced by excitatory (glutamate) and inhibitory (gamma-aminobutyric acid, GABA) inputs. These, in turn, are translated into excitatory and inhibitory postsynaptic potentials (EPSPs and IPSPs, respectively), which eventually give rise to action potentials. When triggered, an action potential travels from the somatodendritic compartment along an axon to its presynaptic terminal. Here, it triggers the release of neurotransmitters, which are molecules that transmit information chemically by binding to their specific postsynaptic receptors on adjacent neurons. A persistent change in any of these events will affect information coding and impact underlying cognitive or sensory processes. Potassium (K^+), sodium (Na^+), and calcium (Ca^{2+}) voltage-gated channels all participate in the generation and conduction of action potentials. Because voltage-gated ion channels are heterogeneously distributed throughout neurons (Lujan, 2010), their functional states alter various aspects of neuronal transmission, including action potential generation, neurotransmitter release, and postsynaptic receptor sensitivity. Indeed, synaptic and intrinsic excitability are constantly working in concert to shape global neuronal excitability and control information transmission within the nervous system.

This chapter will provide basic descriptions of the principal forms of activity- and experience-dependent plasticity that can persistently affect neuronal transmission. The first part will present the synaptic factors that determine how well pre- and postsynaptic sides of neurons communicate, that is, *synaptic plasticity*. The second part will describe lasting changes in intrinsic factors that control action potential generation and conduction, that is, *intrinsic plasticity*. The third part will discuss the capacity of a neuron to regulate its function to reach stability based on changes in its environment, that is, *homeostatic plasticity*. Research on this form of plasticity is still in its infancy. Examples will be used to describe how experience, such as learning or exposure to drugs of abuse, can persistently affect each segment of information transmission. We will show that although some of these changes may be adaptive, others become deleterious and lead to neurological and psychiatric disorders.

SYNAPTIC PLASTICITY

BRIEF HISTORY AND BASIC FEATURES

Neuronal plasticity, a concept that emerged at the end of the 19th century with Santiago Ramon y Cajal and others (Berlucchi and Buchtel, 2009), describes the processes by which neurons or synapses change their internal parameters in response to experience. However, it has only been in the mid-20th century that this concept has been seriously considered to underlie higher cognitive functions such as learning and memory (Hebb, 1949). Indeed, Hebb was the first to pose a specific theoretical process by which neuronal plasticity might occur. He postulated that “*when an axon of cell A is near enough to excite B and repeatedly or persistently takes part in firing it, some growth process or metabolic change takes place in one or both cells such that A’s efficiency, as one of the cells firing B, is increased*” (Hebb, 1949: p. 62). In other words, he proposed that the synchronous firing of two neurons, A and B, leads to enduring changes in synaptic efficacy, or how efficiently neurons communicate with each other, and that this synaptic efficacy is the cellular basis for encoding and storing information. Over the last few decades, his theory prompted an intense search for the cellular mechanisms mediating specific behaviors and higher cognitive functions. This search was greatly influenced by the techniques of electrophysiology, a major technical advancement in neural science made around the same time, which allows the recording of neuronal electrical activity.

The idea that long-lasting increases in synaptic transmission could occur in living animals was confirmed in 1973 (Bliss and Lomo, 1973). In their experiment, performed in anesthetized rabbits, Bliss and Lomo applied a repetitive stimulation to the perforant path input to the hippocampus and recorded excitatory postsynaptic potentials generated by the first neuronal relay, dentate granule cells. The authors observed an increased excitatory synaptic transmission that lasted from minutes to hours and named it long-term potentiation (LTP). The discovery of LTP was exciting not just because neuronal transmission persisted but also because it was discovered in the hippocampus, a structure known to be critical for learning and memory. To this day, one of the major questions investigated in this research is whether cellular mechanisms of LTP underlie formation of memories. Despite being most frequently studied in the rat hippocampus, LTP has also been demonstrated *in vitro* and *in vivo* in many other species and regions of the central nervous system, suggesting that perhaps persistent increase in synaptic efficacy is a

physiological mechanism used by the brain to store specific information that is later used for behavioral adaptability in the larger sense.

The features that make LTP attractive as a model for information storage reside in its fundamental properties. In addition to its *persistence*, as mentioned previously, LTP develops only if the firing of a presynaptic neuron is followed by the firing of a postsynaptic neuron; or when multiple inputs weakly stimulate the same synapse to depolarize a cell enough to reach the level of LTP induction, a property called *associativity* or *cooperativity*. Furthermore, changes at one synapse, via a synaptic tagging mechanism, do not spread to other synapses, which is a feature that makes LTP *input-specific*. Because the number of synapses in the brain is estimated to a quadrillion, input specificity is one of the most appealing properties of LTP, as it provides a means to store endless amounts of specific information. For these reasons, increased synaptic transmission has become a model for studying how behavioral experience, such as learning, induces long-term changes in synaptic transmission, and reciprocally how long-term changes in synaptic transmission affect learning capabilities.

As much as LTP is a long-lasting increase in synaptic transmission, it has its counterpart, long-term depression (LTD), which is a long-lasting decrease in synaptic transmission, a phenomenon first discovered in the cerebellum (Ito and Kano, 1982). Whereas high-frequency stimulation is needed to induce LTP, LTD is triggered following low-frequency stimulation.

PHASES OF LTP

LTP is composed of several distinct phases, including (1) a first phase, referred to as short-term plasticity (STP); (2) an early phase, referred to as E-LTP; and (3) a late phase, referred to as L-LTP. Although STP and E-LTP can sometimes share common cellular mechanisms, each of these components is associated with specific changes in synaptic function.

In brief, STP is a form of potentiation that decays in the order of minutes shortly after the post-tetanic potentiation (PTP). STP is characterized by its presynaptic locus and its resistance to protein kinase inhibitors (Lauri et al., 2007). In particular, changes in presynaptic function are usually associated with changes in the probability of neurotransmitter release (P_r), namely, glutamate at excitatory synapses and GABA at inhibitory synapses, and are the likelihood of vesicle fusion and transmitter release occurring at a presynaptic terminal in response to an action potential. The parameters that determine the changes in P_r during STP are not well understood. However, prominent candidates for the mechanism include the size of the readily releasable vesicle pool and the SNAREs machinery for neurotransmitter exocytosis, whose function directly depends on the presynaptic Ca^{2+} concentration. Early-LTP, developing while STP decays, lasts for a few hours. Although both E-LTP and STP are characterized by changes in presynaptic function, E-LTP is sensitive to several kinase inhibitors, but is resistant to protein synthesis inhibitors. The third phase, L-LTP, is thought to last for days and requires protein synthesis (Lauri et al., 2007).

CELLULAR MECHANISMS

As mentioned, LTP is a phenomenon that exhibits critical characteristics that make it an ideal model for the physiological mechanisms of learning and memory. A well-studied form of LTP is Hebbian LTP, a form of plasticity that is induced following Hebbian rules of associativity, namely, LTP develops only if the firing of a presynaptic neuron is followed by the firing of a postsynaptic neuron. In other words, two events have to co-occur to trigger the induction mechanism. This form of LTP has been best characterized in the CA1 field of hippocampus, and as such the cellular mechanisms described in this section are from studies performed in CA1, except when mentioned (Fig. 5.1A). The NMDA receptor, which is a glutamate receptor, has the characteristic of a coincidence detector, meaning it needs two events to occur simultaneously to respond. First, glutamate must bind to the postsynaptic receptor, which means that the presynaptic neuron has been excited and released glutamate. Second, the postsynaptic neuron must be partially depolarized in order to remove the Mg^{2+} block that normally prevents Ca^{2+} from flowing through the NMDAR. This means that the postsynaptic neuron receives glutamate when it is still depolarized due to recent activity. Such a physiological state happens either when high-frequency stimulation is used (*cooperativity*) or when the postsynaptic neuron is significantly excited to send action potentials from the axon hillock back to the dendrite, a phenomenon called back-propagation (*associativity*) (see section paragraph “At the Dendritic Level” in the section “Intrinsic Plasticity”). When these two events occur together, they allow for a large influx of Ca^{2+} into the postsynaptic neuron, which triggers action potentials and a cascade of events in the postsynaptic neuron that induces LTP. Ca^{2+} will trigger activation of Ca^{2+} -dependent protein kinases that are necessary for LTP maintenance (CaMK, PKC, PKA, and tyrosine protein kinase fyn). Ca^{2+} /calmodulin-dependent protein kinase II (CaMKII), which is an enriched forebrain enzyme, is the best characterized of these kinases. CaMKII has the capacity to autophosphorylate in the presence of increased Ca^{2+} concentrations, and will phosphorylate synaptic AMPARs to increase their functions and/or promote their trafficking from intracellular compartments to the plasma membrane, which helps maintain increased synaptic strength (Lisman et al., 2012). For long-lasting maintenance of LTP, *de novo* AMPARs are also added to the synapses via transcriptional events. Increased postsynaptic Ca^{2+} influx activates adenylate cyclase, and through the metabolism of ATP, cAMP is produced, which activates cAMP kinase and allows its translocation into the nucleus. Cyclic AMP kinase phosphorylates the nuclear transcription factor CREB (cAMP-responsive element binding protein), which triggers the expression of new AMPAR subunits to be inserted at the synaptic membrane (Benito and Barco, 2010). Additionally, CREB-dependent gene expressions also lead to the synthesis of proteins that participate in making structural changes. Lastly, through an unknown mechanism, the postsynaptic neuron releases a retrograde messenger (nitric oxide) that can act on presynaptic protein kinases to enhance neurotransmitter release (Fig. 5.1A).

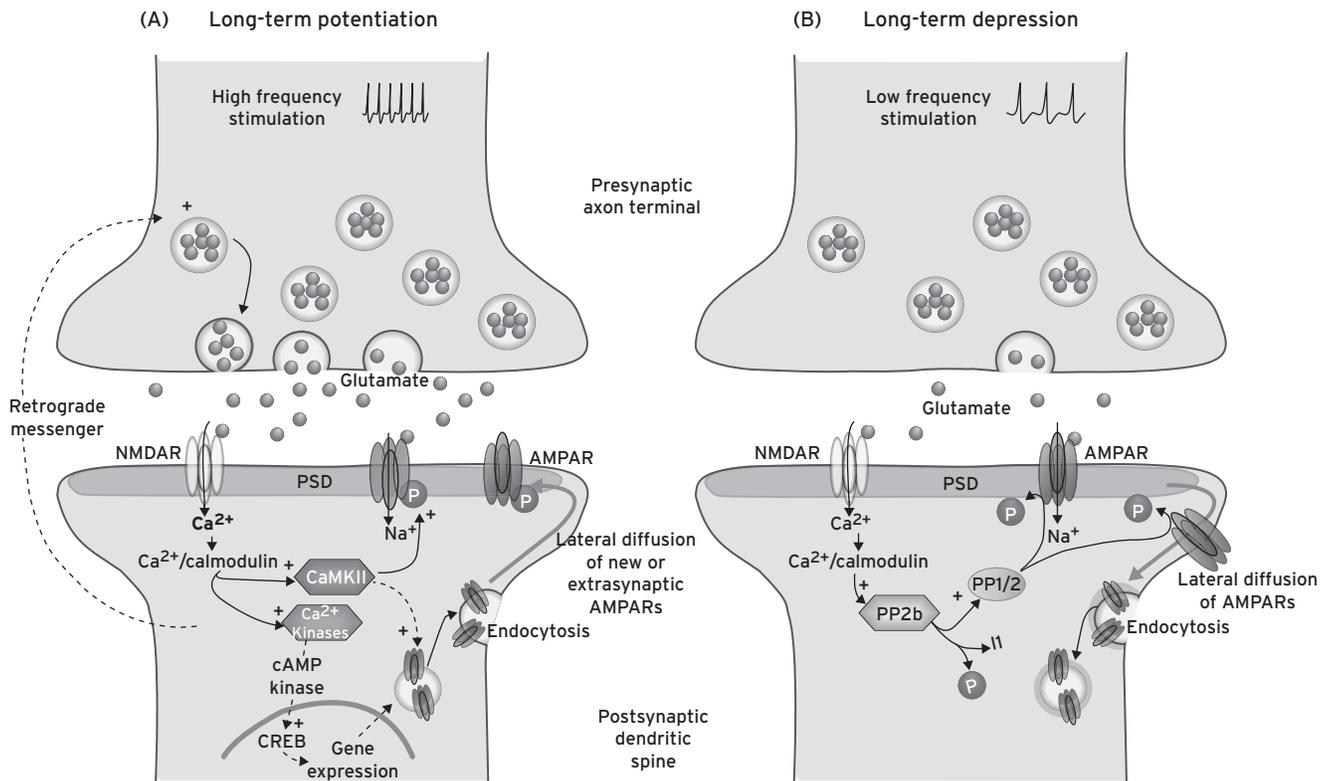

Figure 5.1 Possible cellular mechanisms involved in LTP and LTD in the CA1 field of hippocampus. (A) An intense and brief stimulation (e.g., high frequency stimulation, HFS) induces the release of enough glutamate to trigger a strong activation of AMPARs. Through influx of Na⁺ and efflux of K⁺, AMPARs activation depolarizes the postsynaptic membrane, which frees NMDARs from Mg²⁺ block (not represented). In turn, besides moderate influx of Na⁺ and efflux of K⁺, NMDARs conduct a strong influx of Ca²⁺. Together with NMDARs, voltage-gated Ca²⁺ channels (VGCCs) may also contribute to intracellular rise of Ca²⁺ (not represented), which would trigger activation of several Ca²⁺-dependent protein kinases (CaMKII, PKC, PKA and the tyrosine protein kinase Fyn). Through a phosphorylation mechanism, the active autophosphorylated form of CaMKII increases AMPARs function and trafficking of cytoplasmic inactive AMPARs to the postsynaptic density (PSD), a specialized region of the postsynaptic membrane that is dense in proteins and directly opposed to the presynaptic zone, the site of neurotransmitter release. For LTP maintenance, increased intracellular Ca²⁺ may also activate adenylate cyclase, which through cAMP kinase-dependent phosphorylation pathway activates the nuclear transcription factors CREB (cAMP-responsive element binding). In turn, CREB triggers expression of new AMPARs and other proteins that participate in structural changes. New and cytoplasmic AMPARs are integrated at the synaptic membrane through exocytosis and lateral diffusion from extrasynaptic membrane to the PSD, a mechanism that involves transmembrane AMPA receptor regulatory proteins (TARPs) and various scaffolding proteins (e.g., MAGUKs). The postsynaptic neuron may also release retrograde messengers (e.g., nitric oxide) that act on presynaptic protein kinases and thereby enhance neurotransmitter release. (B) A low-frequency stimulation (LFS) induces a weaker AMPARs-dependent depolarization, which leads to a moderate NMDAR-dependent increase in intracellular Ca²⁺. Similar to LTP, Ca²⁺ binds to calmodulin; however in this case, Ca²⁺/calmodulin activates the protein phosphatase calcineurin (also called PP2b). In turn, calcineurin dephosphorylates inhibitor 1, which was maintaining PP1 and/or PP2 inactive. PP1 and/or PP2 dephosphorylate synaptic AMPARs, which triggers lateral diffusion and a clathrin-dependent endocytosis for endosomal degradation. For clarity, other contributors to synaptic plasticity, including VGCCs and metabotropic glutamate receptors, are not represented. Dashed arrows indicate either cellular mechanisms that are still unknown or mechanisms that require multiple steps.

LTD, which is the opposite of LTP, also requires postsynaptic Ca²⁺ influx through NMDAR activation (Fig. 5.1B). In contrast to LTP induction, which requires strong Ca²⁺ influx, LTD is induced by a low frequency stimulation that yields moderate levels of intracellular Ca²⁺, which also bind to calmodulin to form a complex. However, in the case of LTD, the complex activates Ca²⁺-calmodulin-dependent phosphatase calcineurin (also named PP2b), which triggers a dephosphorylation cascade. By inhibiting inhibitor 1, calcineurin activates protein phosphatase 1 and/or phosphatase 2 (PP1/2). Dephosphorylation of AMPARs by PP1/2 triggers a clathrin-dependent endocytosis of receptors, which results in decreased synaptic efficacy (Fig. 5.1B). Interestingly, PP1/2 also targets the active autophosphorylated form of CaMKII. By dephosphorylating CaMKII, PP1/2 facilitates LTD and may also prevent further LTP from occurring (Collingridge et al., 2010).

Although these processes appear simple, the cellular mechanisms through which LTP and LTD occur following neuronal activity are still heavily researched. For example, while intracellular domains of AMPARs are important for plasticity, it is not yet clear whether activity directly targets the AMPARs themselves. Recent scientific studies have shown that there is a new type of regulatory proteins for AMPARs, the TARPs (transmembrane AMPA receptor regulatory proteins). These auxiliary subunits, closely working with several other types of scaffolding proteins (e.g., membrane-associated guanylate kinases, MAGUKs), are involved in trafficking, synaptic targeting, gating, and pharmacological behaviors of AMPARs (Jackson and Nicoll, 2011). Furthermore, LTP and LTD can be elicited in various brain nuclei and subregions, and each may express differences in induction's of cellular mechanisms.

One of the most striking and unexpected mechanisms is that some forms of LTP and LTD are NMDAR-independent. For example, LTP at the mossy fiber pathway-CA3 relay in the hippocampus is presynaptic and NMDAR-independent, a phenomenon that can also apply to LTD. In this case, the source of Ca^{2+} originates from voltage-gated Ca^{2+} channels and the Ca^{2+} release from intracellular stores that are triggered by the activation of metabotropic glutamate or other metabotropic receptors (Collingridge et al., 2010). At the presynaptic terminal, Ca^{2+} influx, via activation of a cAMP-dependent pathway, promotes glutamate release.

EXPERIENCE-DEPENDENT SYNAPTIC PLASTICITY

SYNAPTIC PLASTICITY IN LEARNING AND MEMORY

Physiologically, LTP exhibits two key properties that support its role in memory formation. The first is its persistence over time, and the second is that LTP develops only if the firing of the presynaptic neuron is followed by the firing of the postsynaptic neuron, that is, the co-occurrence requirement discussed earlier. The requirement for the postsynaptic neuron to be partially depolarized when glutamate binds to receptors is an extremely important characteristic of LTP because it permits neural networks to learn associations. Importantly, LTP can be elicited by low levels of stimulation that mimic physiologically relevant neural activity.

Behaviorally, conditioning tasks can produce LTP-like changes in the hippocampus, and many drugs that influence learning and memory have parallel effects on LTP. Additionally, mutant mice that display little hippocampal LTP have difficulty learning the Barnes circular maze, a task that tests spatial memory (Mayford et al., 1996). In contrast, Joe Z. Tsien's laboratory generated a transgenic mouse that overexpresses the NR2B subunit in the forebrain (Tang et al., 1999). NR2B is an NMDAR subunit that permits a larger influx of Ca^{2+} into the cell. Since NMDAR is a coincidence detector, an increase in NMDAR function should increase the capability of a neuron to detect coincidences and potentially improve learning mechanisms. They found that NR2B-overexpressing mice showed greater LTP associated with improved memory (Tang et al., 1999). Although there is a consensus linking LTP in the hippocampus to learning and memory processes, investigations are still ongoing (Lynch, 2004).

SYNAPTIC PLASTICITY IN NEUROLOGICAL DISORDERS

There is increasing evidence that neurological disorders, including Alzheimer's disease (Spires-Jones and Knafo, 2012) and substance abuse disorders are associated with persistent changes in synaptic strength (Bowers et al., 2010). In this section, we will provide a brief review of the functional evidence linking changes in AMPAR-mediated transmission with substance abuse disorders. A thorough chapter, "Cellular and Molecular Mechanisms of Addiction," is provided by Dr. Peter Kalivas (Chapter 52).

Studies have mainly focused on two brain areas of the mesolimbic reward circuit, the ventral tegmental area (VTA) and the nucleus accumbens (NAc). In the VTA, the ability of

drugs of abuse to produce synaptic plasticity was first demonstrated using a single experimenter-administered cocaine injection. Remarkably, subsequent studies have shown that a single injection of a variety of abused drugs (e.g., cocaine, morphine, nicotine), but not non-abused drugs (fluoxetine or carbamazepine), leads to the potentiation of glutamatergic synapses in VTA dopamine (DA) neurons. This potentiation is mediated by a transient increase in AMPAR-mediated synaptic response (5 days), but is no longer potentiated 10 days after the cocaine injection. Furthermore, cocaine-induced LTP in the VTA was associated with an increase in the proportion of GluR1-containing, GluR2-lacking AMPARs—receptors that exhibit a Ca^{2+} permeability. Regardless of the number of injections, LTP in VTA stayed transient. Because associative learning mechanisms may play a vital role in the development of addiction, changes in synaptic plasticity in VTA DA neurons should also be examined using voluntary cocaine self-administration models. In stark contrast to the consequences of passive cocaine administration, cocaine self-administration enhanced AMPAR-mediated responses in VTA DA neurons for at least 3 months of abstinence. Importantly, self-administration of natural rewards also induced LTP in VTA DA neurons, but this potentiation was transient, lasting for up to 7 days. These findings suggest that learning in relation to natural rewards has much shorter lasting effects on VTA function than does drug self-administration (Bowers et al., 2010).

In the NAc, changes after single or repeated exposure to a drug of abuse are different from those seen in the VTA. As in the VTA, repeated exposure to drugs of abuse can strongly modulate NAc excitatory synaptic transmission. Glutamatergic plasticity has been examined primarily after repeated cocaine exposure, either passively through experimenter administration or actively through self-administration. Interestingly, little or no change in synaptic transmission has been observed in the NAc shell during early withdrawal after repeated drug exposure. However, studies generally agree that repeated passive or active drug exposure and protracted abstinence are associated with increased NAc AMPAR signaling, although there are likely to be differences in the type of AMPAR function that is altered (Bowers et al., 2010).

INTRINSIC PLASTICITY

DEFINITION AND BASIC FEATURES

Intrinsic plasticity is the plasticity of non-synaptic factors that control neuronal excitability. These factors directly affect the probability that a neuron will fire an action potential in response to excitatory inputs. Conceptually, these factors can be any elements located on the soma, dendrites, or axon, that is, remote from the synapse, which passively or actively modulate membrane excitability. However, the study of intrinsic plasticity is still in its infancy and concerns mainly short- and long-term changes in voltage-gated ion channels. These channels are the "building blocks" that shape action potentials, and are also the same "building blocks" that shape firing patterns. Voltage-gated ion channels (Na^+ , Ca^{2+} , and K^+) are ubiquitous transmembrane proteins mediating ionic exchange between extra- and

intracellular compartments and are coded by hundreds of genes. Combined with alternative splicing and heteromeric assembly within subfamilies, they provide neurons with tremendous possibilities and a remarkable ability for fine-tuning intrinsic excitability. However, the K⁺ channels, which tend to hyperpolarize neurons, are exceptionally more complex in their role and structures when compared to other voltage-gated conductances (Hille, 2001). This diversity of K⁺ channels likely illustrates their role in regulating neuronal excitability both tonically and in response to intra- or extracellular stimuli in order to provide appropriate behaviors in specific contexts. This complexity in role is reflected in their subcellular localizations (somatic, dendritic, axonal, or synaptic) and additional auxiliary subunits that regulate their functions. Questions about how experience, for example, learning or exposure to drug of abuse, alters neuronal intrinsic excitability and how these changes relate to behaviors remain unanswered in the field of intrinsic plasticity, and the cellular mechanisms underlying these changes are currently under investigation.

A LOOK AT INTRINSIC PLASTICITY AT THE SUBCELLULAR LEVEL

AT THE DENDRITIC LEVEL

Dendrites express various types of voltage-gated ion channels, and many of these channels are not expressed uniformly throughout the dendrite. This feature provides the dendrite with a unique capability to regulate signal integration. Depending on the strength of the synaptic input, either an EPSP or a dendritic spike is generated. These electrical events are then either dampened and fade away, or increased and generate somatic action potentials. The direction of the effect depends on the population and types of voltage-gated ion channels expressed along the dendrite. For example, a decrease in dendritic K⁺ currents may boost dendritic excitability and allow excitatory inputs generated at the synapse to travel to the soma, which results in the generation of action potentials. In the classical view, these action potentials will travel along the axon and trigger neurotransmitter release at the axon terminal. However, action potentials can also travel back to the dendritic tree, a phenomenon known as back-propagation. Back-propagation is strongly influenced by the electrical properties of dendrites, where voltage-gated Na⁺ channels boost back-propagating action potentials while K⁺ channels (e.g., Kv4.2 subtype) determine their amplitudes and widths (Shah et al., 2010). At the functional level, back-propagating action potentials provide the additional level of depolarization needed for the synapses to trigger the cellular mechanisms necessary to induce some forms of associative synaptic plasticity (Shah et al., 2010) (see also section paragraph “Cellular Mechanisms” in section “Synaptic Plasticity”). In other words, they provide a feedback signal informing the synapses about the output state of the neuron, and the time window in which this occurs determines the direction of synaptic changes. For example, a significantly strong output that arrives shortly after a synaptic input will set the synapse at a permissive state that allows the induction of associative synaptic potentiation. If the constraints imposed by the time window are not met, LTD is favored. It should

be noted, however, that the rules for such phenomena have been updated recently (Caporale and Dan, 2008). It appears that the distribution and types of specific Na⁺ and K⁺ channels expressed along the dendrite play a critical role in the induction of associative synaptic plasticity. Conversely, induction of associative synaptic plasticity triggers a decrease in A-type K⁺ currents mediated by internalization of Kv4.2 channels (Shah et al., 2010), an event that could enhance subsequent synaptic potentials. This illustrates how intrinsic and synaptic excitability work together to shape global neuronal excitability and determine the direction of future changes in synaptic transmission (Fig. 5.2).

AT THE AXOSOMATIC LEVEL

After propagating along the dendrites and soma, excitatory and inhibitory inputs are summed and generate an action potential at the axon hillock if the depolarization level reaches the action potential threshold. A change in axosomatic excitability will then have dramatic effects on the throughput of all the synapses that contact that neuron. Voltage-gated Na⁺ channels are highly expressed on the soma and are a major determinant of action potential threshold, and changes in their function or density affect the generation of action potentials. For example, in dorsal root ganglion neurons, in addition to the downregulation of A-type K⁺ and T-type Ca²⁺ currents, an increase in voltage-gated Na⁺ currents decreases the action potential threshold—an effect that is associated with chronic inflammatory pain. Together, enduring changes in these currents contribute to long-lasting dorsal root ganglion hyperexcitability that is thought to mediate chronic hyperalgesia (Beck and Yaari, 2008) (Fig. 5.2).

AT THE AXON INITIAL SEGMENT (AIS) LEVEL

Immediately distal to the axon hillock, the AIS is the subcellular region with the highest density of Na⁺ channels, a feature that provides it with the lowest action potential threshold. At the AIS, variations in neuronal activity can induce changes in ion channel functions (Na⁺ and K⁺) and/or a shift in AIS position and length. For example, in cultured hippocampal neurons, a long-term increase in neuronal activity shifts the AIS more distally, which returns to its original position when activity renormalizes. On the other hand, a persistent decrease in activity increases the length of the AIS. Because the composition and density of Na⁺ channels at the AIS did not change, this alteration reflected a true change in AIS structure. Physiologically, increased activity that moves the AIS distally is associated with decreased intrinsic excitability. Decreased activity, for example, in the case of auditory deprivation, is associated with more Na⁺ channels that occupy a longer AIS, which translates into increased intrinsic excitability by lowering action potential threshold (Grubb et al., 2011). Such activity-dependent changes set the AIS as a site where homeostatic adaptation can occur. Dynamic changes in its structure and position may be a homeostatic response, which provide the neuron with the remarkable capability to readjust its action potential discharge in response to chronic increases or decreases in neuronal activity (see also next section, “Homeostatic Plasticity”).

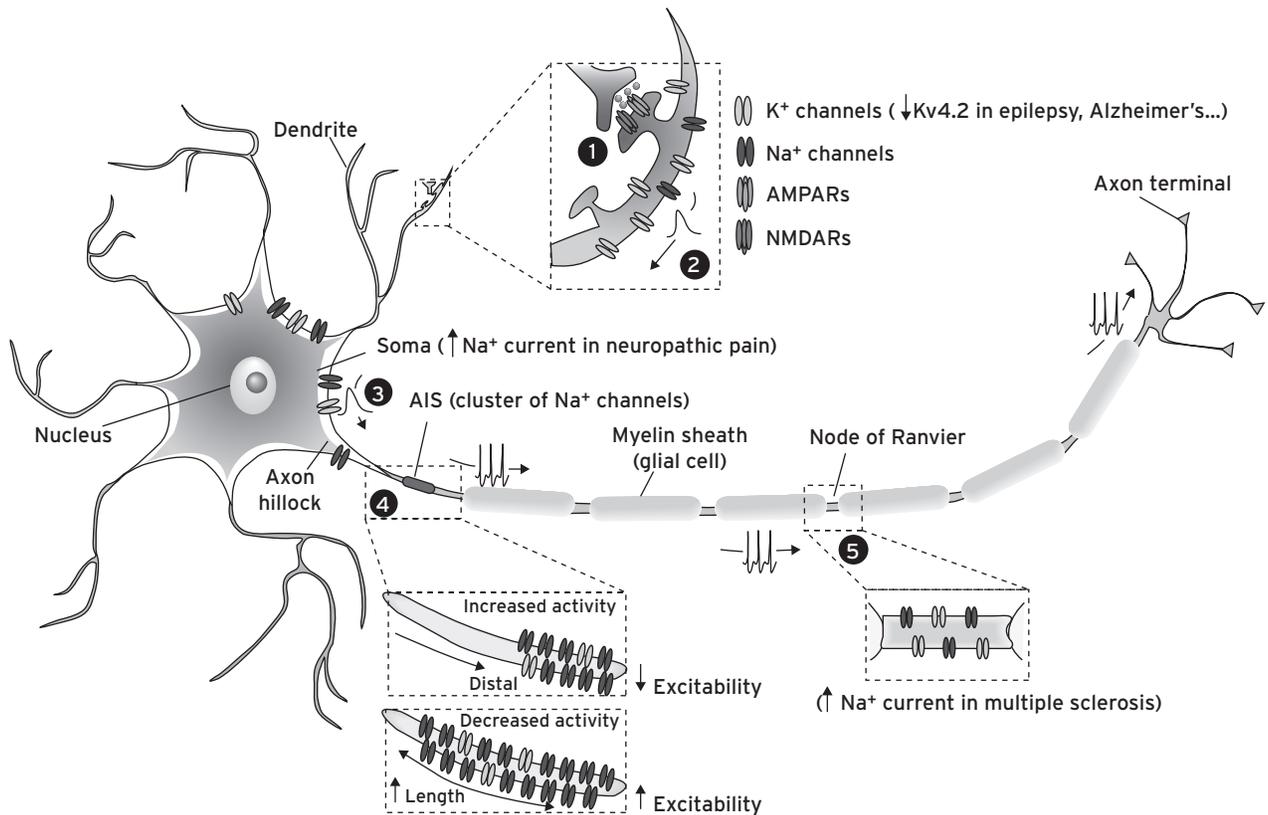

Figure 5.2 Schematic depicting the different subcellular compartments of a neuron and examples of reported changes in factors that influence intrinsic excitability. When a neuron receives a signal through presynaptic neurotransmitter release (1), it travels through successive subcellular compartments before it can transmit the information to the next neuron. In particular, at the synaptic level (1) the signal generates an excitatory postsynaptic potential (EPSP) that travels along the dendrite (2) and the soma (3) before reaching the axon hillock and the axon initial segment (AIS) (4), structures that are rich in voltage-gated Na^+ channels. At this step, if an EPSP is strong enough to depolarize the membrane to action potential threshold, then action potentials are generated. In myelinated neurons, action potentials will travel in a saltatory conduction mode from one node of Ranvier (5) (interruption in myelin sheath) to the next, until they reach the axon terminal, where they will trigger neurotransmitter release. At each of these steps, which can undergo activity- and/or experience-dependent intrinsic plasticity, the signal is modulated by voltage-gated ion channels (Na^+ , K^+ , and Ca^{2+}). The physiological and behavioral consequences of these changes are diverse.

As much as changes in neuronal activity alter AIS function and structure, mutational changes in proteins that are specifically expressed at the AIS can disrupt its proper function and engender neurological disorders. Although little is known about AIS-related disorders, it appears that disruption of AIS excitability may be a potential mechanism for febrile seizures. Mutation in *SCN1B*, a gene that codes for the auxiliary Na^+ channels subunit $\beta 1$ found at the AIS, causes a common form of childhood epilepsy. Mutation in this gene tends to hyperpolarize the action potential threshold by lowering Na^+ channel voltage activation, which increases sensitivity to temperature-triggered seizures (Grubb et al., 2011) (Fig. 5.2).

AT THE AXONAL LEVEL

Once an action potential is triggered, it travels along the axon to the presynaptic terminal where it triggers release of neurotransmitters. Among other factors, action potential conduction is strongly influenced by myelin, an insulating sheath wrap made up of glial cells. At regular intervals, called the nodes of Ranvier, this sheath is interrupted, which allows the generation of electrical activity. This allows the action potential to propagate in a saltatory fashion, which is quicker and uses less energy. Nodes of Ranvier express a specific set of voltage-gated

K^+ and Na^+ ion channels. Alterations in channel function will affect the proper conduction of the signal. However, in some cases, alterations can be beneficial. For example, in the early stages of multiple sclerosis, a demyelinating disease that has debilitating consequences, increases in the expression of Na^+ channels actually compensate for a decrease in action potential propagation induced by loss of myelin (Mantegazza et al., 2010) (Fig. 5.2).

MOLECULAR SUBSTRATES AND MECHANISMS

Ion channels can be modulated through their numbers and functional kinetics. While their numbers often involve either internalization in the case of decreases, or translational processes in the case of increases, mechanisms that lead to changes in their activation kinetics are more complex. The most well known and best described modes of functional modulation of ion channels are the phosphorylation/dephosphorylation mechanisms (Barros et al., 2012). Like many other proteins, ion channels are the substrates of kinases, such as serine/threonine and tyrosine kinases, and phosphatases. Site-specific phosphorylations at the cytoplasmic domains, either at the N- or the C-terminal of the pore-forming α -subunits, have various consequences for

channel function, including regulation of current amplitudes and kinetics (Barros et al., 2012). Such modulations contribute to both short- and long-term regulations of ion influx and thus affect the electrical properties of membranes. Several phosphorylated residues located at the N-terminal are targets for regulating the gating properties of voltage-gated K⁺ channels. Phosphorylations at this site alter the most studied channel inactivation mode, the so-called ball-and-chain or N-type inactivation (fast-inactivation), which consists of an occlusion of the internal mouth of the channel pore by a protein localized at the amino(N)-terminal. For example, PKC-dependent phosphorylation of the Kv3.4 N-terminal slows down or eliminates N-type inactivation, which accelerates repolarization and shortens action potential duration (Barros et al., 2012; Ritter et al., 2012). Kv3.4 is a member of the fast-inactivating A-type K⁺ currents and is expressed in nociceptive dorsal root ganglion neurons. Slowing down or eliminating N-type inactivation of Kv3.4 is hypothesized to be involved in the transition from acute to chronic pain. Other mechanisms of regulations also exist. For example, in chronic epilepsy, dendritic decreases in Kv4.2-mediated A-type K⁺ currents can occur via various signaling pathways that can either change the functions of existing channels through kinase-dependent phosphorylation (PKA/PKC/MAPK) or decrease their availability at the membrane through a clathrin-dependent internalization or a transcriptional downregulation. Interestingly, another mode of regulation that may contribute to declining cognitive functions observed in Alzheimer's disease is the direct block of the Kv4.2 channel by β amyloid, a protein produced by the sequential cleavage of the amyloid precursor protein by secretases (Beck and Yaari, 2008).

EXPERIENCE-DEPENDENT INTRINSIC PLASTICITY

Although the functional and behavioral consequences of persistent changes in intrinsic excitability remain elusive, several hypotheses have been raised. The role of some of the forms of experience-dependent intrinsic plasticity discussed next is to actually render the neural system resistant or predisposed to undergoing future plastic changes, a phenomenon called metaplasticity (Abraham and Bear, 1996).

INTRINSIC PLASTICITY IN LEARNING AND MEMORY

Although synaptic plasticity is widely assumed to mediate learning and memory, a number of studies show that learning experience can modify excitability, implying that the regulation of intrinsic ion channels may contribute to learning and memory processes, and in some cases actually correlates with learning performance (Disterhoft and Oh, 2006; Zhang and Linden, 2003). Since K⁺ currents are highly involved in the fine-tuning of neuronal intrinsic excitability, studies often report functional changes in this ion channel family. Results from multidisciplinary approaches, including genetic manipulations, pharmacological tools, and electrophysiological measurements, seem to indicate that specific K⁺ channels and/or currents are involved in forming specific types of memories

and participating in specific stages of learning depending on their anatomical and subcellular localization and biophysical properties. The first results that showed changes in intrinsic excitability during learning and memory experience were from studies on invertebrates. For example, Cowan and Siegel (1986) observed that a specific deleterious mutation in the *Shaker* gene (coding for a subset of voltage-dependent K⁺ channels) attenuated the acquisition and short-term memory in a classical olfactory conditioning in *Drosophila* (Cowan and Siegel, 1986). Later, experience-dependent changes in K⁺ conductances during memory processes were reported in several other learning paradigms in both invertebrates and vertebrates (Zhang and Linden, 2003). However, because such adaptations may encode or underlie various phenomena, it has been difficult to relate them to specific behavioral or physiological functions. Here, we will briefly cite the most prominent hypotheses.

(1) Savings

Savings is the capability of a system, even after the performance has declined to basal level, to learn faster when retrained on the same or similar tasks. For example, *in vivo* intracellular recordings in cat sensorimotor cortex following an associative conditioning task revealed an increase in spiking capability that persisted even after the conditioning was extinguished, which suggests that this form of cellular memory is not coding the memory of the conditioning itself. Interestingly, subsequent conditionings, similar to the previous and new ones, were acquired faster (Zhang and Linden, 2003). Hypothetically, increased cellular excitability can represent a form of memory that primes the brain for new learning, a phenomenon called *savings*.

(2) Permissive Role

In this case, learning-induced changes in intrinsic excitability disappear when learning is still strong, which suggests again that such changes are not a part of the engram itself. For example, Disterhoft and colleagues measured increased intrinsic excitability in pyramidal hippocampal neurons, characterized by a reduction of action potential afterhyperpolarization (AHP) during a learning task in rabbits. Reduced AHP occurred before a behavioral response was acquired and was no longer present when animals, still showing a strong behavioral response, were tested a few weeks later. Disterhoft and colleagues hypothesized that because increases in pyramidal hippocampal neurons' intrinsic excitability precede acquisition of behavioral responses, they might have a permissive function in memory. In other words, increased neuronal excitability may render the hippocampus hyperexcitable and predispose the neural network to generate long-term neuronal change, for example, LTP, which will *in fine* constitute the memory trace. This hypothesis is supported by the fact that reduced AHP occurs before efficient learning and that AHP reductions are directly correlated with enhanced learning capability (Disterhoft and Oh, 2006) (See also earlier section paragraph "At the Dendritic Level").

(3) Rule Learning and/or Learning Set

As defined by Harry F. Harlow in 1949, learning set is "*the learning how to learn efficiently in the situations the animal*

frequently encounters” (Harlow, 1949: p. 51). An interesting experimental example of this was provided by Barkai and his colleagues (Saar and Barkai, 2009), who showed that rats that have learned to discriminate a pair of odors for a reward exhibited an increased neuronal intrinsic excitability in the piriform (olfactory) cortex. The rats could discriminate subsequent new pairs of odors in fewer trials, but only when the new pair was presented soon (1–3 days) after the first pair, that is, when the increased piriform intrinsic excitability was still present. If this delay was extended to 5–7 days, when changes in intrinsic excitability had disappeared, the rats failed to acquire the task as quickly and took the same time as untrained animals. In summary, recordings in the piriform cortex had an increased neuronal intrinsic excitability, which decayed with a similar time course as the learning capabilities (Saar and Barkai, 2009). This is in stark contrast with the concept of “savings,” where changes in intrinsic excitability outlast the performance in the conditioning task. Here, the capability for faster learning occurs only when increased intrinsic excitability is still present.

INTRINSIC PLASTICITY IN NEUROLOGICAL DISORDERS

Although plasticity of intrinsic excitability can be beneficial, as in the case of learning and memory, it is also emerging as a maladaptive alteration with potentially deleterious outcomes that can lead to neurological disorders. Most of the advancements investigating the role of intrinsic plasticity in CNS disorders have come from studies on epilepsy and neuropathic pain (Beck and Yaari, 2008). For example, it is hypothesized that chronic epilepsy is caused by an increase in hippocampal neuron dendritic excitability. In particular, a single episode of status epilepticus leads to a decrease in A-type voltage-gated K^+ currents, a major regulator of dendritic excitability (Hille, 2001). Whether this phenomenon contributes to the reoccurrence of epileptic seizures is still under investigation. Other disorders have also been associated with decreased dendritic A-type K^+ currents, including traumatic brain injury (TBI) (Lei et al., 2012), an event that can lead to cognitive deficits, and Alzheimer’s disease (Zou et al., 2011). It has only been recently that lasting changes in the function of voltage-gated channels in specific regions of the brain have been linked to various neurological disorders, including chronic stress (Krishnan et al., 2007), affective disorders, and schizophrenia (Roberts, 2006).

Plasticity of intrinsic excitability following experience of drugs of abuse was reported in the early 1970s; however, in the past 10 years this field has drawn increasing attention. One of its critical aims is to understand how chronic experience with drugs of abuse leads to persistent changes in intrinsic excitability, and how these changes relate to the behavioral phenotypes that characterize addiction. In this regard, perhaps the first evidence was provided by George K. Aghajanian’s laboratory (Nestler et al., 1999), where the authors showed that acute *in vitro* or *in vivo* morphine application decreases action potential firing in the locus coeruleus (LC), the major noradrenergic nucleus in the brain. In contrast, repeated *in vivo* morphine renormalized firing rates toward control

levels. Interestingly, naltrexone application, an opioid receptor antagonist that is used in alcohol and opioid dependence, increased firing only in morphine-treated animals—an effect that is dependent on K^+ channels and is tightly correlated with withdrawal symptoms, including irritability and wet dog shakes. This set of intriguing data likely represents the first demonstration of *in vivo* neuronal homeostatic adaptation, where chronic morphine exposure triggered a non-synaptic increase in LC neurons’ excitability to counteract morphine-induced decreased firing rate. Along the same line, exposure to psychostimulant drugs modulates ionic currents as well, including Na^+ , Ca^{2+} , and K^+ . These changes, where K^+ current modulation plays a primary role, translate into transient or persistent firing adaptations. For example, chronic exposure to cocaine or amphetamine leads to a persistent firing rate depression in the shell subregion of the nucleus accumbens (NAc) (Kourrich and Thomas, 2009), a brain region involved in motivation and reward (Kelley, 2004). Although the causal relationship between NAc neurons’ firing capability and addiction-related behaviors is still under investigation, a recent study has demonstrated that NAc firing rate depression enhances behavioral sensitization to cocaine (Kourrich et al., 2012), a behavioral phenotype thought to reflect increased rewarding properties of cocaine that may contribute to the development of addictive processes (Robinson and Berridge, 2008).

Finally, alcohol has also been shown to modulate the firing rate in the NAc. Although the first study to investigate the changes in neuronal intrinsic properties following chronic alcohol drinking was performed in 1984 (Durand and Carlen, 1984), it has only been recently that these changes have been attributed to a specific ion channel, the small conductance Ca^{2+} -activated K^+ channel (SK) (Hopf et al., 2010), a strong regulator of repetitive firing. Chronic alcohol consumption induces a long-lasting reduction of SK3 subtype expression, which enhances the firing rate in the core subregion of the NAc. Interestingly, *in vivo* activation of SK3 reduced motivation for alcohol seeking behaviors (Hopf et al., 2010).

HOMEOSTATIC PLASTICITY

DEFINITION AND BRIEF HISTORY

In the second half of the 19th century, Claude Bernard first defined homeostasis as the capacity for a system to regulate its function according to changes in its environment to reach stability. At the neuronal level, homeostasis has been proposed as a means for the brain to reach stability upon destabilization of the neural circuit activity. In this way, a neuron can adjust its excitability to compensate for perturbations in activity, a process that can require hours to days (Turrigiano and Nelson, 2004). These types of compensations in activity level can affect both intrinsic and synaptic factors that control global neuronal excitability.

Perhaps the first *in vivo* demonstration to show that neurons are capable of compensation for chronic suppression of activity were suggested by a series of articles published between 1970 and 1990 from George K. Aghajanian’s

laboratory (see section paragraph “Intrinsic Plasticity in Neurological Disorders”) (Nestler et al., 1999); however, it is after 1990 that similar phenomena started to be revealed *in vitro*. In particular, Ramakers et al. (1990) demonstrated that chronic activity blockade produces a rebound in hyperexcitability in central neuronal networks *in vitro* (Ramakers et al., 1990), a phenomenon that also occurs in isolated lobster stomatogastric ganglion neurons (Turrigiano et al., 1994), which suggests that neurons regulate their conductances to maintain stable activity patterns and that the intrinsic properties of a neuron depend on its recent history of activation. Later studies demonstrated that neurons could also modulate their synaptic functions by increasing or decreasing AMPAR function in response to chronic alteration in activity (O’Brien et al., 1998; Turrigiano et al., 1998). These studies raised a number of critical questions. For instance, does homeostatic adaptation require changes in the network, that is, pre- and postsynaptic, or are these changes cell-autonomous? Also, what are the sensors and monitors of cell activity that initiate

compensatory changes, and what are the cellular mechanisms that are triggered by chronic changes in activity? This section will provide a brief description of the different types (Fig. 5.3) of homeostatic plasticity as well as descriptions of the monitors of cellular activity, and the known basic cellular mechanisms involved in neuronal homeostatic plasticity (Fig. 5.4).

DIVERSITY IN HOMEOSTATIC PLASTICITY

CELL-AUTONOMOUS

As defined by Turrigiano and Nelson (2004: p. 103), cell-autonomous plasticity is “the plasticity in the properties of an individual neuron resulting from changes in its own activity, independent of the activity of other neurons in the network” (Fig. 5.3A). Two seminal studies addressed this possibility. In the first, synaptic activity was blocked and the postsynaptic neuron chemically depolarized (Leslie et al., 2001). In the second, the neuron was hyperpolarized via a transfection of Kir2.1, an inward-rectifier K⁺ channel involved in maintaining hyperpolarized membrane

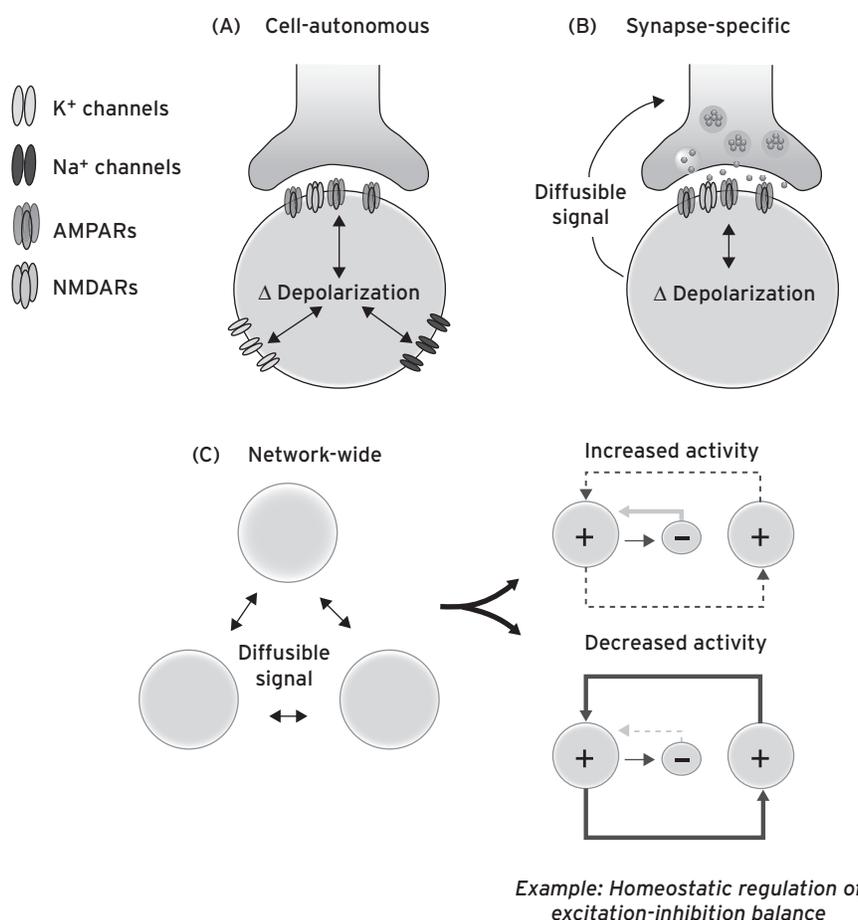

Figure 5.3 Diagrams representing three models of homeostatic neuroadaptations. All modes are supposed to be triggered by variations in postsynaptic depolarization, likely through changes in intracellular Ca²⁺ concentrations. (A) Cell-autonomous homeostasis is when a neuron can sense, integrate, and correct its own neuronal activity to a set value without requiring external factors. (B) Synapse-specific homeostasis is when, at a specific synapse, local signaling regulates pre- and/or postsynaptic excitability. This may involve a retrograde diffusible signal(s) from the post- to presynaptic side to regulate neurotransmitter release. (C) Network-wide homeostasis is when a network of neighboring cells adjusts neural network excitability through a diffusible activity signal. The diffusible signal can act on both the neighboring cells and the neuron itself (not represented) and can either increase or decrease neuronal excitability depending on neuronal types. As an example, homeostatic regulation of excitation-inhibition balance may involve diffusion of brain-derived neurotrophin (BDNF), which can differentially regulate excitability of excitatory versus inhibitory neurons. When activity is increased, the diffusible signal can trigger cellular mechanisms that weaken excitatory transmission (Dotted line) and enhance inhibitory transmission (Solid gray line). If activity is decreased, the opposite mechanism occurs.

potentials (Burrone et al., 2002). In both cases, the neuron compensated for its changes in neuronal activity by either decreasing (Leslie et al., 2001) or increasing synaptic input, which restored neuronal activity to control levels. Interestingly, Leslie et al. (2001) found that these changes were independent of fast excitatory and inhibitory synaptic transmission (AMPA, NMDAR, and GABAR), action potential generation, and activity-dependent release of brain-derived neurotrophic factor (BDNF). These findings suggest that neurons can sense an average level of activity and compensate for it in an autonomous fashion (Turrigiano, 2008). Later studies established unequivocal evidence for cell-autonomous mechanisms and particularly the capacity for a neuron to adjust its synaptic input following changes in its somatic, but not dendritic or synaptic, intrinsic properties (Goold and Nicoll, 2010; Ibata et al., 2008).

SYNAPSE-SPECIFIC

In the synapse-specific model, chronic changes in neuronal activity involve synaptic signaling that will trigger compensatory changes in pre- and/or postsynaptic function, such as changes in presynaptic release probability, quantal size, and the number of postsynaptic glutamate receptors (Turrigiano, 2007) (Fig. 5.3B).

Synapse-specific homeostatic plasticity was originally found in the invertebrate *Drosophila*, where muscle membrane hyperpolarization through overexpression of Kir2.1 triggered presynaptic adaptations in order to compensate for impaired muscle excitability. This compensatory mechanism occurs rapidly and is characterized by increased glutamate release (quantal content) without a change in quantal size. Because changes occurred only on the presynaptic side, it suggests the

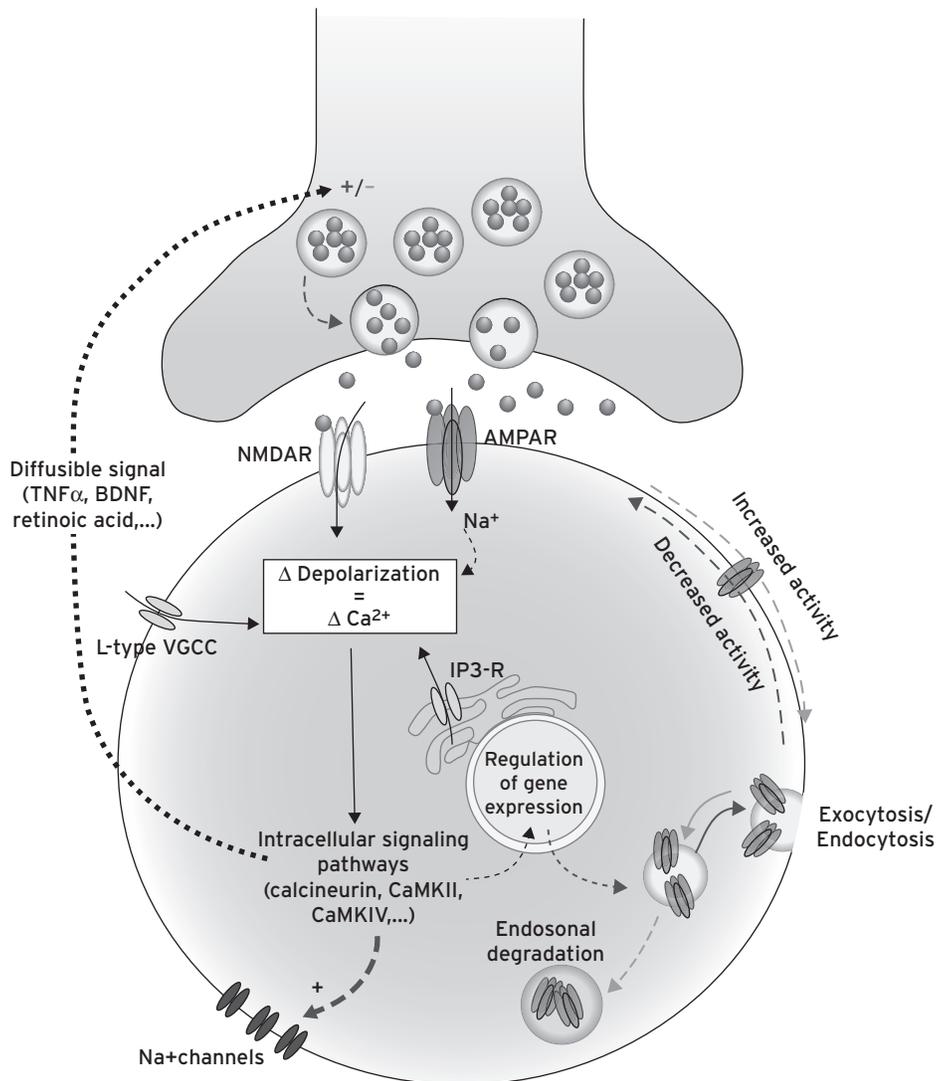

Figure 5.4 Diagram representing a summary of cellular mechanisms that have been shown to be involved in homeostatic plasticity. After sensing its depolarization level (intracellular Ca^{2+}), a neuron can trigger a variety of mechanisms that aim to readjust neuronal excitability to a set value. Via AMPARs activation the neuron depolarizes and allows activation of NMDARs and VGCCs, which directly increases intracellular Ca^{2+} concentration. Ca^{2+} -dependent pathways may also lead to the activation of IP3 receptors and further influence intracellular Ca^{2+} concentration. Intracellular Ca^{2+} can then recruit various intracellular signaling pathways, including CaMKII-, CaMKIV- and calcineurin-dependent pathways, which in turn, likely through phosphorylation/dephosphorylation mechanisms adjust postsynaptic levels of a variety of targets (Na^+ channels, K^+ channels, AMPARs, etc.). Additionally, the postsynaptic neuron may also, through mechanisms that are still unclear, release diffusible activity signals (BDNF, Tumor necrosis factor alpha TNF α , retinoic acid, etc.) that can act presynaptically to regulate neurotransmitter release. In dark gray are examples of mechanisms that are regulated when activity is decreased, and in light gray, when activity is increased.

involvement of a trans-synaptic signaling cascade. Although the signaling mechanism remains elusive, presynaptic homeostasis following postsynaptic changes in activity also occurs at central synapses (Turrigiano, 2007). Though not discussed here, synaptic homeostasis can also involve changes in postsynaptic glutamate receptors with no perceptible changes in presynaptic function (Turrigiano, 2008).

NETWORK-WIDE

Network-wide homeostasis occurs when neurons regulate their synaptic function following changes in network activity. This homeostatic adaptation involves a diffusible signal that is sensed by neurons in the network that triggers changes in their synaptic activity to restore normal neural network activity (Fig. 5.3C). For example, in cultured cortical networks, interneurons decrease their inhibitory inputs to pyramidal neurons when pyramidal neuronal activity is decreased. Specifically, when a pyramidal neuron firing rate is decreased, its capability to release BDNF is decreased as well. Decreased levels of BDNF translate into increased excitatory transmission between pyramidal neurons. Importantly, neighboring interneurons can sense the decreased BDNF and decrease their inhibitory inputs onto pyramidal neurons to restore the firing capability for the neurons in the network (Turrigiano and Nelson, 2004). The mechanism by which decreased BDNF triggers opposite synaptic adaptations in pyramidal neurons versus interneurons is not yet known.

The regulation of synaptic transmission in cortical networks is a critical mechanism that preserves an adequate balance of excitation and inhibition (Fig. 5.3C), and a disruption in the balance of excitation to inhibition can have dramatic consequences. For example, this type of disruption is one of the leading hypotheses to explain some forms of autism where an imbalance occurs in the form of an increased ratio of excitation/inhibition in various systems, including mnemonic, social, sensory, and emotional systems (Rippon et al., 2007; Rubenstein and Merzenich, 2003). Disruption in excitation-inhibition balance has also been reported in neurological disorders as diverse as epilepsy (Fritschy, 2008), schizophrenia (Kehrer et al., 2008), and mental retardation (Eichler and Meier, 2008).

MOLECULAR SUBSTRATES

Homeostatic mechanisms are triggered by perturbations in the level of neuronal activity. However, the means through which a neuron detects variations in its activity are still unclear. Because the level of depolarization directly influences intracellular Ca^{2+} concentration, a prerequisite for many activity-dependent enzymes to function, intracellular Ca^{2+} level has become a prominent candidate for monitoring cellular activity. Ca^{2+} levels are influenced by Ca^{2+} influx through neurotransmitter receptors, voltage-gated Ca^{2+} channels, and Ca^{2+} release from intracellular stores, each of which potentially provides a temporal and spatial readout of cellular activity (Davis and Bezprozvanny, 2001). Once the neuron senses changes in its activity, it activates molecular effectors to execute compensatory changes, likely through Ca^{2+} -calmodulin protein kinases-activated pathways (Fig. 5.4).

A subject of a long series of studies, CaMKII is a Ca^{2+} sensor that is sensitive to the oscillations in the intracellular concentration of Ca^{2+} , a critical feature that encodes information (De Koninck and Schulman, 1998). A unique characteristic of this kinase is its autophosphorylation ability, through which it produces an “autonomous” form that is constitutively active well beyond the activating stimulus. This characteristic allows the kinase to remember previous activity and influences subsequent response to stimuli (Lisman et al., 2012). A facet of CaMKII that makes it an attractive executor for homeostatic adaptations resides in its capability to modulate a variety of targets, including synaptic strength, intrinsic excitability, and gene expression (Lisman et al., 2012; Maier, 2011). Intriguingly, α and β isoforms forming the CaMKII holoenzyme are not only differentially sensitive to Ca^{2+} concentration, but also differentially affect synaptic functions (Thiagarajan et al., 2002). Taken together, these characteristics make CaMKII an ideal monitor and effector that can trigger intracellular signaling to correct chronic variations in neuronal activity. In addition to CaMKII, two recent studies have revealed a critical role for CaMKIV, another type of calmodulin-dependent kinase, in cell-autonomous regulation of synaptic transmission (Goold and Nicoll, 2010; Ibata et al., 2008). Specifically, decreased neuronal activity triggers increased synaptic strength, a mechanism mediated through a drop in somatic Ca^{2+} concentration and reduced activation of CaMKIV (Ibata et al., 2008). The opposite phenomenon was later reported by Goold and Nicoll (2010) where neuronal activity was increased, further supporting a role for CaMKIV in bidirectional regulation of neuronal homeostasis.

CONCLUSION

This chapter succinctly described some fundamental types of neural plasticity. Generally speaking, plasticity is a ubiquitous phenomenon that occurs in various subcellular compartments, where each regulates specific aspects of neuronal communication. Subcellular compartments can engage in a variety of cellular mechanisms targeting voltage- and/or ligand-gated ion channels to change persistently their functions upon exposure to various types of experiences, including learning and exposure to drugs of abuse. For the purpose of brevity, we did not describe structural plasticity in this chapter, which is another type of neural plasticity that is also very important (Bosch and Hayashi, 2011). Combined with the discovery of unequivocal evidence for adult neurogenesis (Lledo et al., 2006), it demonstrates that neurons not only change their functions, but also their shapes and numbers. Now, new challenges for researchers include achieving a better understanding of how diverse types of plasticity occur as well as elucidating their functional relevance and how they relate to changes in behaviors. Moreover, because multiple types of plasticity can coexist in a neural network or even in the same neuron, we need to better understand how they interact with one another to shape neural activity and lead to adaptive or maladaptive behaviors that are observed in neurological and psychiatric disorders.

DISCLOSURES

Dr. Kourrich and Dr. Bonci have no conflicts of interests to disclose. This work was supported by the Intramural Research Program at the National Institute on Drug Abuse.

6 | PRINCIPLES OF MOLECULAR BIOLOGY

STEVEN E. HYMAN AND ERIC J. NESTLER

Advances in molecular biology and in understanding the genetics of complex human phenotypes have opened a new world of possibilities for research on mental disorders and their treatment. However, because the syndromes with which psychiatry is ultimately charged are expressed at the level of behavior, molecular and genetic work must be complemented by ongoing research in the more integrative aspects of neuroscience and behavioral science described elsewhere in this textbook. Thus, for example, the pathophysiology of mental disorders depends on the complex interaction of genetic (bottom-up) factors and environmental (top-down) factors affecting the development and subsequent function of the brain. Many scientific disciplines must contribute to that understanding.

Despite substantial evidence that genes and environment are inseparable partners in brain development and plasticity—and therefore in the formation of personalities, talents, and all other aspects of behavior, including vulnerability to mental illness and very likely responsiveness to treatments for mental illness—simplistic versions of the nature–nurture debate never seem to disappear. It is true that from the time a one-cell embryo is formed from the fusion of sperm and egg, the genetic endowment of that individual is fixed. An important focus of current research, however, is to find out precisely what that means with respect to behavioral traits. It is now becoming increasingly clear that behavioral phenotypes, including vulnerability to serious mental disorders such as schizophrenia, bipolar disorder, depression, and autism, result from the interaction of multiple (perhaps hundreds of) genes, very likely acting at different times during brain development in interaction with the environment. An important goal of psychiatric research is therefore to understand how genetic information is read out during development and how the brain changes as a result of stochastic or random processes during development, as well as in response to experience of the sensory world and other environmental inputs, such as drugs, infections, and injuries.

The goal of this chapter is to describe the fundamental molecular processes by which information is encoded in the genome and how this information is expressed within an environmental context. We describe what genes are, how they function, and how their expression is regulated by signals from outside the cell. This chapter shows that the control of gene expression by extracellular signals is a critical arena for gene–environment interactions relevant to psychiatry (Hyman and Nestler, 1993). Chapter 7 builds on this foundation by describing *epigenetic* regulation in psychiatry, namely, how

stable changes in the structure of *chromatin* (the combination of DNA and proteins that comprise the nucleus) at particular genes—and hence in the behaviors those genes regulate—can be produced without changes in the genetic code itself.

NUCLEIC ACIDS

Deoxyribonucleic acid (DNA) contains the genetic blueprints of cells, that is, the information to produce ribonucleic acid (RNA) and proteins, which in turn create the fundamental structural and functional properties of our cells. The latest estimate is that the human genome contains approximately 25,000 genes, which use about 1.5% of ~3,000,000,000 base pairs of DNA. Deoxyribonucleic acid exists as a double helix, each strand of which is an unbranched chain built out of small building blocks called *nucleotide bases*. DNA and RNA are synthesized from four types of nucleotide bases. The four nucleotides that make up DNA are the *purines*, *adenine* (A) and *guanine* (G), and the *pyrimidines*, *cytosine* (C) and *thymine* (T), each containing a deoxyribose sugar group. In RNA the pyrimidine *uracil* (U) takes the place of thymine, and the sugar group is ribose instead of deoxyribose. Individual nucleotides are joined into strands of DNA or RNA via the phosphate groups that form a phosphodiester linkage.

The alternating deoxyribose sugar and phosphate groups that connect the bases of each DNA strand form a “sugar-phosphate backbone” on the outside of the double helix with the bases arrayed on the inside of the double helix (Fig. 6.1). In DNA, the nucleotide base A is paired with (or is complementary to) T on the opposite strand, and G is paired with C. In RNA, U, which is structurally similar to T, is also complementary to A. The rules of base pairing observed in DNA result from the fact that only complementary pairs of nucleotides form a maximum number of stabilizing hydrogen bonds. Any other arrangement of bases destabilizes the structure of the DNA. A critical property of a linear polymer such as DNA (or RNA) is that it can serve as a template for the synthesis of other macromolecules. The principle of complementary base pairing provides the mechanism by which information can be transferred. An enzyme, a DNA polymerase in the case of DNA replication, or RNA polymerase in the case of transcription of DNA into RNA, can proceed down a template strand of DNA, adding a nucleotide base complementary to the base on the template strand as it forms a new strand of nucleic acid (Fig. 6.1).

Although the actual enzymatic steps involved in the replication of DNA are quite complex, the overall principles are

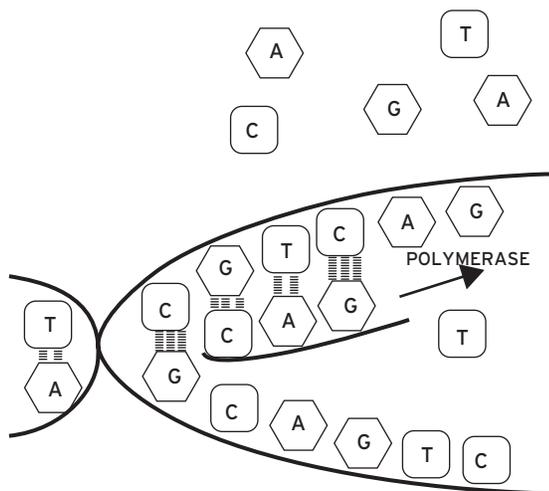

Figure 6.1 Schematic of complementary base pairing of deoxyribonucleic acid (DNA). Two complementary strands of DNA hybridize with one another to form a double helix. The sugar-phosphate backbones of the two strands are found on the outside of the double helix; the bases are found on the inside. Formation of a DNA double helix is stabilized when hydrogen bonds form between complementary bases of the two strands. Two hydrogen bonds form when A is across from T; three hydrogen bonds form when G is across from C. Other appositions of bases are destabilizing and do not occur. A strand of DNA can serve as a template for a second strand of nucleic acid (DNA or ribonucleic acid [RNA]). A polymerase enzyme assembles individual nucleotides into a new strand using the first strand as a template. The sequence of the new strand is therefore determined by the template, permitting the transfer of information across generations. Complementary base pairing is also the fundamental principle in the synthesis of RNA from DNA and in many experimental situations in which it is desirable to detect the presence of a specific DNA or RNA strand.

simple. Replication begins with separation of the two complementary DNA strands in a local region. Each strand then serves as a template for a new DNA molecule by the sequential polymerization of nucleotides. Eventually the replication process generates two complete DNA double helices, each identical in sequence to the original. Replication of DNA is said to be semiconservative because each daughter DNA molecule contains one of the original parental strands plus one newly synthesized strand. Transcription of DNA into RNA is conceptually similar except that only one DNA strand serves as a template and, when synthesis of the RNA is complete, it is released and the DNA strands can reanneal into their stable double-helical structure.

INFORMATION FLOWS FROM DNA TO RNA TO PROTEIN

DNA carries information in its linear sequence of nucleotides. Although the linear polynucleotide structure of DNA is well suited for the stable storage of information and for self-replication, its chemical simplicity and its relatively rigid helical structure limit its biological functions. Thus, the information contained within DNA must be read out to yield RNA and proteins. Like DNA, RNA is chemically quite simple (i.e., composed of four nucleotides), but because it is

a flexible single strand, free to fold into numerous conformations, it is functionally more versatile than DNA.

Messenger RNA (mRNA) functions as an intermediate between the sequence of DNA that comprises the transcribed regions of genes and the sequence of proteins. Not all RNA serve as mRNA, however. Other RNAs function in varied roles in cells. Ribosomes, the organelles on which proteins are synthesized, are constructed out of complexes of several types of ribosomal RNA (rRNAs) with proteins. Transfer RNAs (tRNAs) transport specific amino acids to the ribosomes for incorporation into proteins during the process in which mRNA is translated into protein. More recently, scientists have characterized several other types of non-coding RNAs, categorized as long or short based on their length. These non-coding RNAs are considered a form of epigenetic regulation and are discussed in greater detail in Chapter 7. Briefly, long non-coding RNAs, generally characterized as >200 nucleotides in length, regulate chromatin structure and gene expression (Taft et al., 2010). The most prevalent short non-coding RNAs, termed microRNAs (miRNAs), bind to specific mRNAs and inhibit their translation and/or promote their degradation (Bartel, 2009; Vo et al., 2010). The discovery of miRNAs has been translated into a powerful tool called *RNA interference* or *RNAi*, which uses small hairpin RNAs (shRNAs), which are cleaved into small inhibitory RNAs, to experimentally suppress expression of a targeted mRNA and protein.

Like DNA, mRNA carries information encoded in its linear sequence of nucleotides. DNA and mRNA specify amino acid building blocks for proteins in linear stretches of three nucleotides. Proteins consist of unbranched chains of amino acid building blocks. An amino acid is a small molecule that contains an amino group (NH_2) and a carboxylic acid or carboxy group (COOH) plus a variable side chain. The side chains used by the 20 common amino acids differ markedly in size, shape, hydrophobicity, and charge. Amino acids are linked to each other by peptide bonds that join the amino group of one amino acid to the carboxy group of another amino acid.

Within the portion of an mRNA that is translatable into a protein, each successive group of three nucleotide bases (called a *codon*) specifies either one amino acid or termination of the protein chain. The rules specifying the correspondence between a codon and an amino acid are called the *genetic code*. Because RNA is a linear polymer of 4 nucleotides, there are 4^3 or 64 possible codons but only 20 amino acids. As a result, although each codon specifies only a single amino acid, most amino acids are specified by more than one codon. The genetic code is therefore said to be degenerate. With only a few minor exceptions, the code has been conserved across evolution. The codons in an mRNA molecule do not interact directly with the amino acids they specify; the translation of mRNA into protein depends on the presence of tRNAs that serve as adapter molecules that recognize a specific codon and the corresponding amino acid (Fig. 6.2).

The ribosome is a structure composed of proteins and structural rRNAs; these organelles provide a structure on which tRNAs can interact (via their anticodons) with the codons of an mRNA in sequential order. The ribosome finds a specific start site on the mRNA that sets the reading frame and then moves

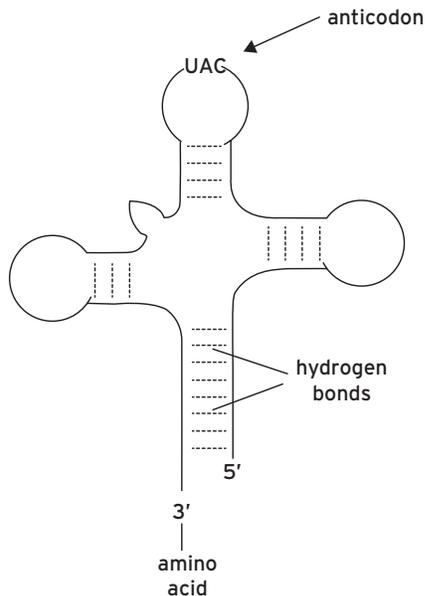

Figure 6.2 Transfer RNA (tRNA): Transfer RNA (tRNA) is a single strand of RNA that folds on itself through the apposition of complementary base pairs and the subsequent formation of hydrogen bonds, indicated by the dashed lines in the figure. One of the loops formed contains the anticodon, the sequence of three nucleotides on the tRNA that binds to the complementary codon on a messenger RNA molecule. For the anticodon AGA shown in the figure, the corresponding codon on the mRNA would be UCU. The free end of the tRNA binds to a specific amino acid. Each tRNA, with a given anticodon, binds only one type of amino acid determined by the genetic code. In the case shown in the figure, the amino acid bound would be serine. along the mRNA molecule progressively, translating the nucleotide sequence one codon at a time, using tRNAs to add amino acids to the growing end of the polypeptide chain (Fig. 6.3).

Over the past decade, it has become clear that a small number of mRNAs, along with associated protein translation machinery, are transported to dendrites of neurons, where they mediate rapid changes in protein synthesis in response to synaptic activity (Wang et al., 2010). This transport is mediated by the presence of specific sequences in the 3'-untranslated region

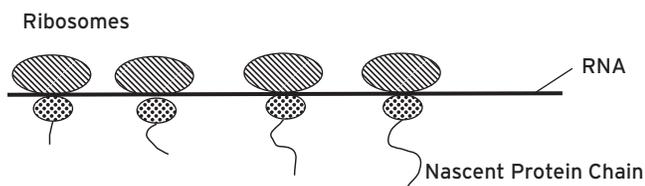

Figure 6.3 Protein translation. Ribosomal subunits bind together on mature messenger ribonucleic acids (mRNAs) to form actively translating ribosomes. The ribosome begins adding amino acids when it reaches a "start codon" on the mRNA and processes down the mRNA, one codon at a time, adding the appropriate amino acid as it is delivered by a transfer RNA (tRNA). When a "stop codon" is reached, the ribosome releases the polypeptide chain and dissociates from the mRNA. Each mRNA that is being actively translated has multiple ribosomes moving sequentially down its length, forming a polyribosome complex. From Hyman and Nestler (1993) reprinted with permission from *The Molecular Foundations of Psychiatry*, (Copyright ©1993). American Psychiatric Publishing.

of certain mRNAs, which are targeted by RNA-binding proteins to form RNA granules for transport. Fragile X mental retardation protein (FMRP) is an example of one of these RNA-binding proteins, which plays an important role in controlling dendritic protein synthesis. Loss of FMRP expression causes Fragile X mental retardation syndrome (see Chapter 7).

In contrast with nucleic acids, which are constructed of four bases that are chemically similar, proteins are constructed out of 20 very different amino acids. By incorporating so many different types of amino acids, each with its chemically diverse side chains, proteins have extraordinary functional versatility, unlike DNA or RNA. The specific properties of proteins depend not only on the linear sequence of their amino acid building blocks (*primary structure*), but also on the tendency of certain combinations of amino acids to form intrinsic structural motifs (*secondary structures*, for example, α helices or β sheets) and by their folded three-dimensional characteristics (*tertiary structure*). In addition, proteins form stable interactions (*complexes*) with other proteins (*quaternary structure*). In such cases, the individual polypeptide chains are called *subunits*. The folding of proteins, and the interactions of proteins with each other and with other molecules such as nucleic acids, is highly regulated by chemical modifications of the protein, most often of particular side chains. For example, one ubiquitous mechanism of regulation of protein function is by the covalent addition of a phosphate group (by specific enzymes called *protein kinases*) to the hydroxyl groups found in serine, threonine, or tyrosine side chains (Chapters 4 and 5). Cells may contain tens of thousands of distinct proteins, each with unique structural and functional properties, including neurotransmitter receptors, neuropeptides, ion channels, enzymes, and a very large number of other types of proteins.

GENES AND CHROMOSOMES

As a first approximation, genes were initially defined as stretches of DNA that encode a single protein or a single functional RNA, such as an rRNA or a tRNA. This rule breaks down quickly, however, because there are mechanisms, such as *alternative splicing* of the primary RNA transcript into different mRNAs, that may intervene between a given gene and a finished protein. Moreover, individual protein precursors may be cleaved into numerous functionally active peptides. As a result of these and other processes, many individual genes actually encode multiple proteins, although we still do not know what fraction of all genes function in this manner.

Genes are arrayed on extremely long chains of DNA called *chromosomes*. Eukaryotic chromosomes contain not only genes, but also large amounts of intergenic DNA. Indeed, within the human genome, the ~25,000 genes take up perhaps only 3% of chromosomal DNA. Moreover, genes are not distributed equally along the chromosomes but are often found in clusters. Some chromosomes are "gene rich" and others are relatively "gene poor." Within intergenic regions there is a great deal of DNA with unique sequences of unknown function, as well as long stretches of tandemly repeated sequences known as *satellite DNA*. Included within these regions are *retrotransposons*, such as LINE-1 (long

interspersed nuclear element-1) repeats, which are transcribed by RNA polymerase and encode several enzymes including reverse transcriptase (an enzyme that synthesizes a strand of DNA from RNA). The resulting DNA strands can then incorporate into the genome, where they can disrupt normal gene expression. An interesting line of current research is to understand the role of LINE-1 and related retrotransposons as a novel mechanism controlling neural gene expression (see Chapter 7).

The chromosomes of eukaryotic cells are so long (~2 meters if stretched out linearly) that they would not fit in the nucleus in their extended form. Thus, stretches of the DNA that are not being actively transcribed are tightly packed into a conformation described as a coiled coil, which permits the chromosomes to fit within the nucleus. To create packed conformations, lengths of DNA are coiled around structural and regulatory proteins, of which the most important are the histones. These structures are termed *nucleosomes*. Regions of DNA that are being actively transcribed into RNA may be greater than 1000-fold more extended than regions that are transcriptionally quiescent. The unwinding of tightly packed nucleosomes, which enables their expression, is mediated by highly complex modifications of histones and many other nuclear proteins, which are discussed in detail in Chapter 7 (Borrelli et al., 2008).

GENE EXPRESSION

As described in the preceding paragraphs, proteins are not synthesized directly from the DNA that encodes them, but in two sequential processes, *transcription of DNA into mRNA*, which occurs in the nucleus, and *translation of the mRNA into protein* according to the rules of the genetic code, which occurs in the cytoplasm. Transcription of protein-coding genes can be divided into three major steps. First, the enzyme primarily involved in

RNA synthesis, *RNA polymerase*, must interact with the gene at an appropriate transcription start site and begin transcribing (*initiation*). Second, the RNA polymerase must successfully transcribe an appropriate length of RNA (*elongation*). Third, transcription of the RNA must terminate appropriately. The resulting RNA is then posttranscriptionally processed. It receives a stretch of adenines, a poly-(A) tail, which makes it more stable in the cell. This process of polyadenylation is dynamically regulated and can exert a powerful influence on expression of the resulting mRNAs (Proudfoot, 2011). It is also spliced to remove internal sequences (*introns*) that are not appropriate for translation into protein in that particular cell. The spliced “exportable” sequences (*exons*) exit the nucleus to be translated into protein in the cytoplasm (Fig. 6.4). Alternative splicing vastly increases the number of protein products produced by the cell, with certain genes, for example, the neurexins, generating hundreds of splice variants (Padgett, 2012).

TRANSCRIPTIONAL CONTROL

We have now reviewed the flow of information from gene to protein. Every step along the way is regulated, but the major control point in reading out the information contained within the genome is transcription initiation. Indeed, this is the step at which environmental signals often exert powerful regulatory control on gene expression, during development and in mature cells. How does this come about?

In addition to encoding information that ultimately directs the synthesis of proteins, genes contain regulatory information. Every cell in our bodies contains all of our genes in its nucleus, but not every gene is active in every cell. Our cells differ—indeed, their identity is defined—by the fact that each type of cell in the body expresses only a subset of the entire

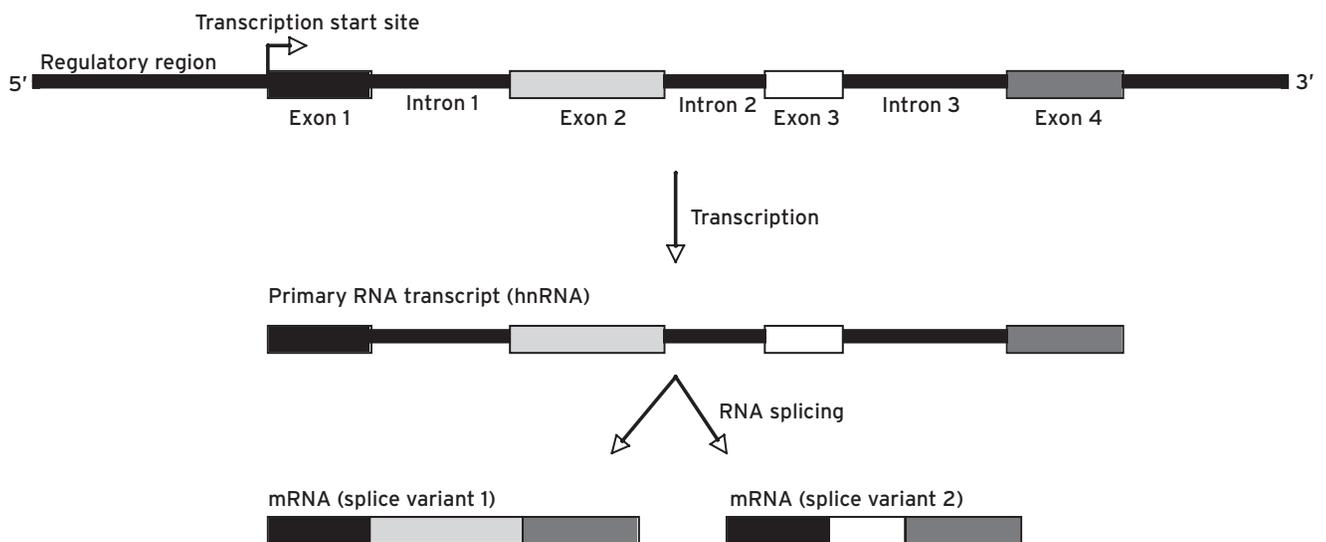

Figure 6.4 RNA splicing. Horizontal black lines represent deoxyribonucleic acid (DNA) regulatory regions and introns. Black, gray, and white rectangles represent exons. The region to the left of the first exon is the 5' regulatory region of the gene, but cis-regulatory elements are also found in introns and sometimes downstream of the last exon. The primary transcript, also known as heterogeneous ribonucleic acid (hnRNA), contains exons and introns and gives rise, in the case shown, to two alternatively spliced messenger ribonucleic acids (mRNAs): one containing exons 1, 2, and 4, and one containing exons 1, 3, and 4. These splice variants, after export from the nucleus and translation in the cytoplasm, give rise to distinct proteins.

complement of genes. In any given cell, some genes are “on,” being read out to make mRNA and hence proteins, and the rest are silent. Thus, for example, in the red blood cell precursors of the bone marrow, the genes that encode globins, proteins that are the critical building blocks of hemoglobin, are actively making globin-encoding mRNA. In our midbrains, a subset of cells are making a protein called *tyrosine hydroxylase*, the rate-limiting enzyme for the synthesis of catecholamines, like dopamine and norepinephrine. It would not be adaptive for these cells to synthesize large amounts of hemoglobin, just as red blood cell precursors need not use energy to synthesize tyrosine hydroxylase. The processes by which certain genes are “silenced” in a tissue-specific manner during development are now increasingly understood at the chromatin or epigenetic level (Chapter 7).

Regulatory sequences within genes work by virtue of their ability to bind specific proteins. Certain regulatory sequences specify the beginnings and ends of segments of DNA that can be transcribed into RNA. Other regulatory sequences determine in what cell types and under what circumstances their gene can be read out. DNA sequences that subservise such control functions are often called *cis-regulatory elements* (Fig. 6.5). The term *cis* refers to the fact that the relevant regulatory sequences are physically linked, on the DNA, to the region being controlled, which is usually a segment of DNA that can be transcribed into RNA. The proteins that bind to *cis* elements have been described as *trans-acting* factors because they may be encoded anywhere in the genome rather than on the same stretch of DNA that they regulate. Those proteins that are involved in specifying whether, and under what circumstances, a gene will be transcribed are more generally known as *transcription factors*. Many transcription factors bind DNA directly; others interact only indirectly via protein–protein interactions with factors that bind DNA.

Those *cis-regulatory* elements that specify the site within a gene at which transcription starts, and on which the complex of proteins that forms the basal transcription apparatus is assembled, are called the *basal* or *core promoter*. The core promoters

for many protein-encoding genes consist of a sequence motif rich in the nucleotides A and T, called the *TATA box*. The TATA box is generally located ~30 nucleotides upstream of the actual site at which transcription of DNA into RNA is initiated. In the nervous system, however, numerous genes do not contain identifiable TATA boxes, which means that their transcription start sites are defined differently. In eukaryotes, transcription of protein-coding genes is carried out by the enzyme RNA polymerase II, which does not directly contact DNA but interacts with the complex of proteins that assembles at the TATA box or distinct transcription start site (Fig. 6.5).

SEQUENCE-SPECIFIC TRANSCRIPTION FACTORS INTERACT WITH THE BASAL TRANSCRIPTION APPARATUS TO PRODUCE SIGNIFICANT LEVELS OF TRANSCRIPTION

The basal transcription complex assembled at the TATA box or other transcription start site is only sufficient to initiate low levels of transcription of DNA into RNA. To achieve significant levels of gene expression, the basal transcription complex requires help from additional transcription factors that recognize and bind to *cis-regulatory* elements found elsewhere within the gene. *Cis*-elements that exert control near the core promoter itself have been called *promoter elements*, and those that act at a distance—often several hundred to more than 1,000 nucleotide base pairs away—have been called *enhancer elements*, but the commonly made distinction between promoter and enhancer elements is artificial. Both are composed of small “modular” sequences of DNA (generally 7–12 base pairs in length), each of which is a specific binding site for one or more transcription factors. Multiple *cis-regulatory* elements arrayed throughout the control regions of a gene, and the proteins they bind, act in combinatorial fashion to give each gene its distinct patterns of expression and regulation.

Transcription factors that are tethered to DNA by binding *cis*-elements are often described as sequence-specific transcription factors. Most such proteins have a modular structure composed of physically separate domains: a domain that recognizes and binds a specific DNA sequence, an activation domain that interacts with the basal transcription complex to activate or inhibit it, and a multimerization domain that permits the formation of homo- and heteromultimers with other transcription factors (Fig. 6.5). Many transcription factors are active only as dimers or higher order complexes. Within transcription factor dimers, whether homodimers or heterodimers, it is common for both partners to contribute jointly to the DNA binding domain and the activation domain. Sequence-specific transcription factors may contact the basal transcription complex directly; in many cases, they interact through the mediation of adapter proteins. In either case, transcription factors that bind *cis-regulatory* elements at a distance from the core promoter can interact with the basal transcription apparatus because the DNA forms loops that bring distant regions in contact with each other (Fig. 6.6A and B). Once bound to DNA, transcription factors serve as scaffolds for the recruitment of many types of activator or repressor proteins that serve to

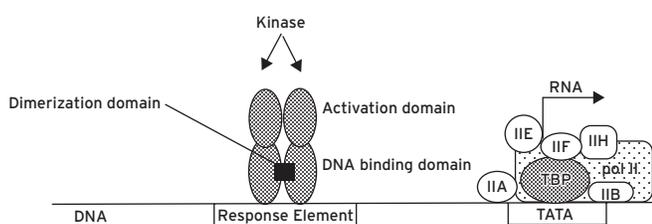

Figure 6.5 *Cis- and trans-regulation.* The figure shows two *cis-regulatory* elements (open rectangles) along the stretch of deoxyribonucleic acid (DNA) (thin line). The element to the left represents a response element that serves as a binding site for a hypothetical transcription factor that binds as a homodimer. The other is the thymine adenine thymine adenine (TATA) element, shown binding the TATA binding protein (TBP). Multiple general transcription factors and ribonucleic acid (RNA) polymerase II (*pol* II) associate with TBP. This basal transcription apparatus recruits RNA polymerase II into the complex and also forms the substrate for interactions with activator proteins, such as those binding to the activator elements shown. The transcription factor shown binding to the response element is a substrate for a protein kinase that phosphorylates its activation domain (see text).

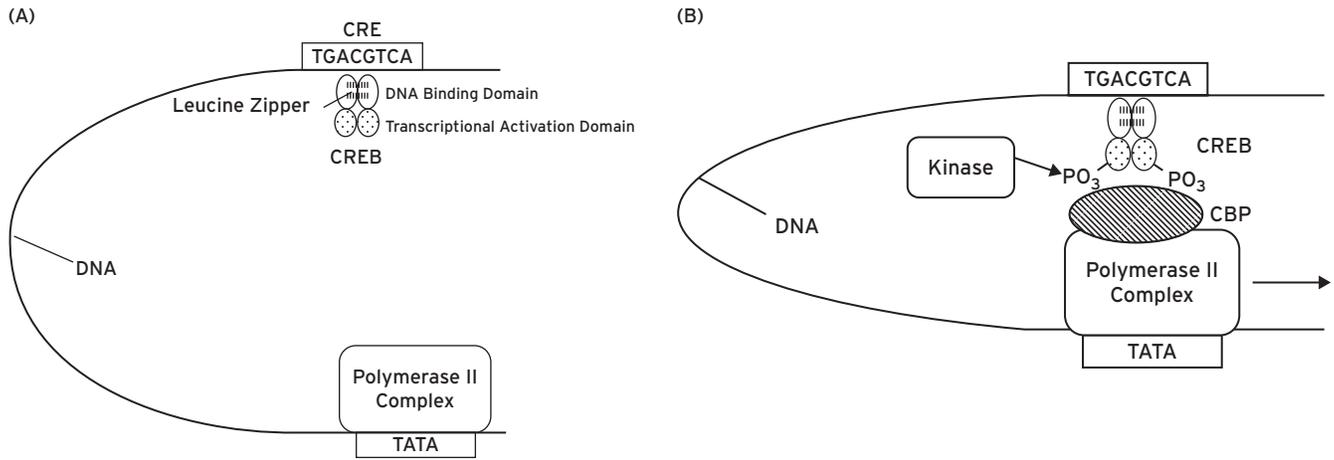

Figure 6.6 Looping of deoxyribonucleic acid (DNA) permits activator (or repressor) proteins binding at a distance to interact with the basal transcription apparatus. In the figure, the basal transcription apparatus is shown as a single box bound at the thymine adenine thymine adenine (TATA) element. The activator protein, cyclic adenosine monophosphate (cAMP)-response element binding protein (CREB), is shown bound as a homodimer to its cognate cis-regulatory element, the cAMP-response element (CRE), at a distance from the TATA element (panels A and B). Upon phosphorylation, many activators such as CREB are able to recruit adapter proteins that mediate between the activator and the basal transcription apparatus. An adapter protein that binds phosphorylated CREB is called CREB binding protein (CBP), a form of histone acetyltransferase (HAT) that acetylates nearby histones to facilitate gene transcription (see Chapter 7). With the recruitment of the adapter, a mature transcription complex forms that permits the synthesis of ribonucleic acid (RNA) by RNA polymerase II (panel B).

epigenetically activate or repress gene expression, respectively (see Chapter 7).

REGULATION OF GENE EXPRESSION BY EXTRACELLULAR SIGNALS

All regulation of gene expression by extracellular signals requires a mechanism that carries a signal from the cell membrane to the nucleus. In many cases, intracellular signaling molecules, such as protein kinases, serve this function. This is illustrated by CREB (cAMP response element binding protein), which mediates many of the effects of the cyclic adenosine monophosphate (cAMP) system, and other intracellular pathways, on gene expression (Altarejos and Montminy, 2011). CREB is bound under basal cellular conditions to its cognate cis-regulatory element (the cyclic AMP-response element, or CRE). Stimuli that increase levels of cAMP activate cAMP-dependent protein kinase (PKA), which results in liberation of the kinase's catalytic subunits (Chapter 4). A portion of the free catalytic subunit then enters the nucleus, where it phosphorylates CREB, permitting it to activate transcription. Similarly, stimuli that activate other intracellular signaling cascades (e.g., Ca^{2+} or extracellular signal-regulated kinase [ERK] pathways) lead to the activation of other protein kinases, which also phosphorylate and activate CREB.

In other cases, a transcription factor, itself activated at the cell membrane or in the cytoplasm, then translocates to the nucleus. This is illustrated by the transcription factor NF- κ B (nuclear factor κ B), which is involved, among other things, in the activation of genes involved in inflammatory responses but also implicated in diverse neural phenomena (Hayden and Ghosh, 2012). Under basal conditions, NF- κ B is retained in the cytoplasm by its inhibitory binding protein (I κ B); this interaction masks a protein sequence within the NF- κ B molecule that serves as a nuclear localization signal. Phosphorylation of I κ B

by I κ B-kinase (I κ K) leads to dissociation of NF- κ B, which permits it to enter the nucleus, where it binds to its response elements; I κ B is then digested within the cytoplasm.

The preceding discussion highlights that the critical nuclear translocation step can involve the transcription factor itself or another signaling molecule. Either mechanism can activate a third scenario: Some transcription factors are expressed only at very low levels when cells are in their unstimulated state. Their genes contain response elements that lead to their synthesis when cells are activated. Thus, gene expression may occur in cascades, with the stimulation of preexisting transcription factors leading to the expression of genes encoding (among many other genes) additional transcription factors, which can then stimulate yet other genes. Activation of genes by preexisting transcription factors occurs more rapidly than activation of genes by factors that must be synthesized *de novo*. Thus, not surprisingly, different neurotransmitters, drugs, and other stimuli may activate gene expression with widely varying time courses ranging from minutes to many hours.

Many transcription factors are members of families, presumably related by evolution, with related structures and functions. In the following section we illustrate the function of representative families of transcription factors, which serve as instructive examples of the diverse mechanisms governing the regulation of transcription in the nervous system.

THE CREB FAMILY OF TRANSCRIPTION FACTORS

CREB was the first-discovered and best-characterized member of a family of related proteins that bind to a particular DNA sequence termed the CRE, as mentioned (Altarejos and Montminy, 2011). The family is composed of CREB, the ATFs (activating transcription factors), and the CREMs (cAMP-response element modulators). CREB itself plays

a major role in mediating the effects of cAMP and Ca²⁺ and of those neurotransmitters that act through cAMP or Ca²⁺, on gene expression. A large number of genes contain CREs, including the gene encoding the transcription factor c-Fos and the genes encoding tyrosine hydroxylase, BDNF (brain-derived neurotrophic factor), and several neuropeptides, such as proenkephalin, prodynorphin, somatostatin, and VIP (vasoactive intestinal polypeptide). Members of the CREB/ATF family bind to CREs as dimers. The dimerization domain used by the CREB/ATF proteins and several other families of transcription factors is called a *leucine zipper*, an alpha helical motif in which every seventh residue is a leucine. The proteins form a coil in which electrostatic interactions stabilize dimer formation.

The methods used to characterize CREs, and indeed all cis-regulatory elements, involve deleting them, or mutating them more subtly, and then reintroducing them into eukaryotic cells in culture by transfection. When a critical base in a DNA regulatory element is mutated, it weakens or destroys the binding site for the relevant transcription factor. If the protein can no longer bind, the gene can no longer be activated by the physiological stimulus under investigation, such as cAMP. By comparing response element sequences that have been investigated by mutagenesis within many genes, an idealized consensus sequence can be derived. The consensus nucleotide sequence of the CRE is TGACGTCA, with the nucleotides CGTCA absolutely required.

The consensus CRE sequence illustrates an important principle, the palindromic nature of many transcription factor binding sites. In the sequence TGACGTCA, it can be readily observed that the sequence on the two complementary strands, which run in opposite directions, is identical. Many cis-regulatory elements are perfect or approximate palindromes permitting binding of transcription factors in the form of dimers, where each member of the dimer recognizes one of the half-sites.

The primary mechanism by which CREB is regulated is through its phosphorylation on a single serine residue (Ser133) by any of several protein kinases, including PKA, Ca²⁺/calmodulin-dependent protein kinase IV (CaMKIV), and several kinases in the ERK cascade (see Chapter 4). CREB is constitutively synthesized so that it exists in neurons under basal conditions, although its expression can be regulated under certain circumstances, such as in response to psychotropic drug treatments. Nonphosphorylated CREB is localized to the nucleus, where it is bound to its response elements without considerable transcriptional activity (Fig. 6.6A). Phosphorylation of CREB activates its transcriptional activity by permitting CREB to interact with CBP (Fig. 6.6B). As noted in the preceding, CBP is called an *adapter protein* because it intervenes between a sequence-specific transcription factor CREB and the basal transcription apparatus, thus activating transcription. Despite its name, CBP provides this adapter function for several regulated transcription factors in addition to CREB family proteins.

The mechanism by which neurotransmitters that increase cAMP levels regulate gene expression via CREB is straightforward. Neurotransmitter-receptor stimulation increases levels of cAMP and of activated PKA. Activated PKA (that is,

free catalytic subunits of the enzyme) is then translocated into the nucleus, where it phosphorylates and activates CREB. Phosphorylation of CREB, in turn, serves to activate the expression of genes that contain CREB bound to their promoter regions. Similar mechanisms operate for neurotransmitters (or nerve impulses) that activate CREB via stimulation of cellular Ca²⁺ signals and for neurotrophic factors that activate CREB via stimulation of ERK cascades.

The convergence of multiple signaling pathways on CREB may be very significant for the function of the nervous system. For example, associative memory appears to result from the integration of multiple signals that converge on target neurons, integration that could be achieved in part via CREB phosphorylation. Indeed, experiments performed by numerous laboratories on multiple species from *Drosophila* to rats, in which CREB was inactivated by different experimental methods, yield organisms with deficits in long-term memory, while increases in CREB function produce animals with enhanced memory (e.g., Josselyn, 2010; Barco and Marie, 2011). CREB has also been implicated in many additional psychiatric phenomena including drug addiction and depression (Blendy, 2006; Cao et al., 2010; Carlezon et al., 2005).

CREB illustrates yet another important principle of transcriptional regulation. As described in the preceding section, CREB is a member of a larger family of related proteins. The ATFs and CREMs (distinct CREM products are generated from a single CREM gene via alternative splicing) bind CREs as dimers; many can dimerize with CREB itself. Activating transcription factor-1 (ATF1) appears to be very similar to CREB; it can be activated by the cAMP and Ca²⁺ pathways. Many of the other ATF proteins and CREM isoforms appear to activate transcription; however, certain CREMs, such as one called ICER (inducible cAMP repressor), act to repress it. Inhibitory CREM isoforms lack a glutamine-rich transcriptional activation domain found in CREB. Thus, certain CREB-CREM heterodimers might bind CREs but fail to activate transcription. Some inhibitory CREMs (e.g., ICER) are induced by CREB itself but with a delayed time course. In this way, these proteins may help terminate genes that had been activated by a CREB signal. Work in recent years has begun to demonstrate the involvement of ATFs and CREMs in an individual's adaptations to numerous environmental stimuli, such as stress and drugs of abuse (e.g., Green et al., 2008).

THE AP-1 FAMILY OF TRANSCRIPTION FACTORS

Another group of transcription factors that plays a central role in the regulation of neural gene expression by extracellular signals is the AP-1 proteins (Morgan and Curran, 1995). The name AP-1 was originally applied to a transcriptional activity, then called *Activator Protein-1*, that was subsequently found to be composed of multiple proteins that bind as heterodimers (and a few as homodimers) to the DNA sequence TGACTCA, the AP-1 sequence. AP-1 proteins are divided into two groups, the *Fos* and *Jun* families. Like the CREB/ATF family, AP-1 proteins dimerize via a leucine zipper. The consensus AP-1 sequence is a heptamer, which forms a palindrome flanking a central C

or G. The AP-1 sequence differs from the CRE sequence by only a single base. Yet this one base difference strongly biases protein binding away from CREB (which requires an intact CGTCA motif) to the AP-1 family of proteins and means that, under most circumstances, this sequence will not confer cAMP responsiveness on a gene. Instead, AP-1 sequences tend to confer responsiveness to growth factor-stimulated signaling pathways such as the ERK pathways and to the protein kinase C pathway. Indeed, the AP-1 sequence was historically described as a TPA-response element (TRE) because the phorbol ester *12-O-tetradecanoyl-phorbol-13-acetate* (TPA), which activates protein kinase C, strongly induces gene expression via AP-1 proteins. It is a staggering illustration of the specificity of cellular regulation that a single base change (from a CRE to an AP-1 site) in a gene thousands of bases long can result in such a profound change in gene regulation.

AP-1 proteins generally bind DNA as heterodimers composed of one member each of the Fos and Jun families. The Fos family includes c-Fos, Fra-1 (Fos-related antigen-1), Fra-2, and FosB (which gives rise to full-length FosB plus a truncated splice variant termed Δ FosB). The Jun family includes c-Jun, JunB, and JunD. Heterodimers form between members of the Fos and Jun families via the leucine zipper. The potential complexity of transcriptional regulation is greater still because some AP-1 proteins can heterodimerize via the leucine zipper with members of the CREB-ATF family (e.g., ATF2 with c-Jun).

Jun proteins, in particular JunD, are expressed constitutively at appreciable levels in neural cells. In contrast, all Fos proteins are expressed at low or even undetectable levels under basal conditions, but with stimulation, can be induced to high levels of expression. Thus, unlike genes that are regulated by constitutively expressed transcription factors such as CREB, genes that are regulated by c-Fos/c-Jun heterodimers require new transcription and translation of these AP-1 proteins.

GENES ENCODING FOS AND JUN FAMILY PROTEINS ARE OFTEN TERMED IMMEDIATE EARLY GENES

Genes, such as the c-Fos gene itself, that are activated rapidly (within minutes), transiently, and without requiring new protein synthesis are frequently referred to as *cellular immediate early genes* (IEGs) (Morgan and Curran, 1995) (see Chapter 4). Genes that are induced or repressed more slowly (over hours), and are dependent on new protein synthesis, may be described as *late response genes*. The term *IEG* was initially applied to describe viral genes that are activated immediately upon infection of eukaryotic cells by commandeering host cell transcription factors for their expression. Viral IEGs generally encode transcription factors needed to activate viral late gene expression. This terminology has been extended to cellular (i.e., nonviral) genes with varying success. The terminology is problematic because there are many cellular genes induced independently of protein synthesis, but with a time course intermediately between those of classical IEGs and late response genes. In fact, some genes may be regulated with different time courses or requirements for protein synthesis in response to different extracellular signals. Moreover,

it must be recalled that many cellular genes regulated as IEGs encode proteins that are not transcription factors (e.g., prodynorphin or BDNF). Despite these caveats, the concept of IEG-encoded transcription factors in the nervous system has been useful heuristically. Because of their rapid induction from low basal levels in response to neuronal depolarization (the critical signal being Ca^{2+} entry) and to second messenger and growth factor pathways, several IEGs have been used as cellular markers of neural activation, permitting novel approaches to functional neuroanatomy. This includes not only the Fos and Jun families of transcription factors, but also Zif268 (also called *Egr1*), which belongs to a distinct family of transcription factors that binds to its own response elements. Examples of the use of c-Fos as a marker of neuronal activation include induction of c-Fos in dorsal horn of the spinal cord by nociceptive stimuli, in motor and sensory thalamus by stimulation of sensory cortex, in supraoptic/paraventricular nuclei by water deprivation, and in numerous brain regions by acute and chronic opiate and cocaine administration, as well as in response to a number of other psychotropic drug treatments.

THE COMPOSITION OF AP-1 COMPLEXES CHANGES OVER TIME

Following acute stimulation of cells, different members of the Fos family are induced with varying time courses of expression, which leads to a progression of distinct AP-1 protein complexes over time (Nestler, 2008). It is believed that these changes produce varying patterns of expression of AP-1-regulated genes, thereby permitting neurons to adapt to the pattern of stimulation to which they are being subjected.

Under resting conditions, c-Fos mRNA and protein are barely detectable in most neurons; however, c-Fos gene expression can be induced dramatically in response to a variety of stimuli. As just one example, experimental induction of a grand mal seizure causes marked increases in levels of c-Fos mRNA in the rat brain within 30 minutes and induces substantial levels of c-Fos protein within 2 hours. c-Fos is highly unstable and is degraded back to low, basal levels within 4–6 hours. Administration of cocaine or amphetamine causes a similar pattern of c-Fos expression in the striatum. In either of these stimulus paradigms, other Fos-like proteins are also induced, but with a longer temporal latency than c-Fos; their peak levels of expression lag behind c-Fos by approximately 1 hour. Moreover, expression of these proteins persists a bit longer than that of c-Fos but still returns to basal levels within 8–12 hours.

With repeated stimulation, however, the c-Fos gene, and to a lesser extent the genes for other Fos-like proteins, become refractory to further activation (i.e., their expression becomes desensitized). However, in most systems, isoforms of Δ FosB continue to be expressed (Nestler, 2008). These isoforms exhibit very long half-lives in brain (1–2 weeks). As a result, Δ FosB accumulates in specific neurons in response to repeated perturbations and persists long after cessation of these perturbations (Fig. 6.7). Such stable accumulation of Δ FosB, which is responsible for desensitizing expression of c-Fos, has been shown to play an important role in mediating the long-term

effects of drugs of abuse and several other treatments on the nervous system.

THE *c-Fos* GENE IS ACTIVATED BY MULTIPLE SIGNALING PATHWAYS

The precise intracellular mechanisms by which extracellular stimuli induce *c-Fos* expression are now well understood (Fig. 6.8). Stimuli that depolarize neurons (e.g., seizure activity, glutamate) induce *c-Fos* through a Ca^{2+} -dependent mechanism that involves the phosphorylation, by CaMKIV, of a CREB protein that is already present in the cell and bound to CREs in the *c-Fos* gene. Neurotransmitters that activate the cAMP pathway in target neurons phosphorylate CREB on the same amino acid residue via PKA. Phosphorylation of CREB, as outlined in the previous section, activates its transcriptional activity and leads to increased *c-Fos* expression.

The *c-Fos* gene can also be induced by the ERK pathway, which is activated by many types of growth factors, via at least two distinct mechanisms, which may operate to different extents in different cell types. One mechanism, discussed in the preceding description of CREB, involves the phosphorylation of CREB by ribosomal S6 kinase (RSK) directly downstream of ERK. A second mechanism involves the phosphorylation and activation, also by ERK, of a different transcription factor termed *Elk-1* (E twenty-six [ETS]-like transcription factor 1). *Elk-1* binds, along with still another transcription factor, serum response factor (SRF), to the serum response element (SRE) within the *c-Fos* gene. A third mechanism mediates *c-Fos* induction by cytokines via activation of the JAK (Janus kinase)-STAT (signal transducers and activators of transcription) pathway. The *c-Fos* gene contains a response element called the SIE (SIF [sis-inducible factor]-inducible element), which binds and is activated by STAT transcription factors. Cytokine regulation of JAK-STAT signaling is described in greater detail in what follows.

The activation of IEG products such as *c-Fos* in response to a large number of stimuli raises the question of how specificity of response is achieved. First, specificity is partly achieved by the particular neural circuitry involved; that is, *c-Fos* and the other proteins are induced only along those particular neural pathways activated in response to the stimulus. Second, specificity is achieved by specialization within neuronal cell types. For example, in particular cell types not every gene that contains an appropriate binding site (e.g., an AP-1 site) to which *c-Fos* can bind is in a chromatin configuration that permits access to *c-Fos*-containing complexes (Chapter 7). Third, individual transcription factors generally cannot act alone to induce or repress the expression of a given gene. Multiple types of transcription factors, binding to distinct regulatory elements within a gene's promoter region, must often act in concert to produce significant effects on gene expression.

Fourth, as alluded to the above-described point, protein products of many IEGs including *c-Fos* can bind DNA with high affinity only after binding to other transcription factors to form heterodimers. Such interactions are well exemplified by *c-Fos* and *c-Jun*. By itself, *c-Fos* is unable to bind DNA with high affinity. *c-Jun* homodimers can bind DNA but do so with relatively low affinity. However, *c-Fos/c-Jun* heterodimers bind

to the AP-1 site with high affinity to regulate transcription. In contrast, heterodimers of *c-Fos* and *JunB* appear to be relatively inactive. Due to the existence of numerous members of the *Fos* and *Jun* families, complex regulatory schemes can readily be imagined by which a great deal of specificity in regulating cellular genes can be attained.

Although the primary mechanism by which *Fos* family members are regulated appears to be at the level of their transcription, the proteins are also regulated by phosphorylation. This is best illustrated by *c-Fos* itself, which is heavily phosphorylated on several closely spaced serine residues in the C-terminal region of the protein by PKA and CaMKs and by protein kinase C. *c-Fos* phosphorylation appears to be a critical regulatory mechanism for the protein: The difference between normal *c-Fos* (cellular *Fos*) and its viral counterpart *v-Fos* (which is oncogenic) is a frame-shift mutation that deletes the serine residues from the viral protein. It has been suggested that phosphorylation of *c-Fos* triggers the protein's ability to suppress its own transcription, thereby providing key regulatory feedback control of the expression of this transcription factor. Another example is the phosphorylation of *Jun* proteins by *Jun*-kinases (JNKs). *Jun*-kinases are activated by cellular forms of stress and, like ERK, are considered to be part of the MAP (mitogen-activated protein)-kinase family (see Chapter 4). The resulting phosphorylation of *Jun* transcription factors is thought to be an important part of a cell's adaptation to stress.

REGULATION OF GENE EXPRESSION BY CYTOKINES AND NONRECEPTOR PROTEIN TYROSINE KINASES

Cytokines subserve a wide array of functions within and outside of the nervous system (Chapters 1 and 2). Such cytokines include leukemia inhibitory factor (LIF), ciliary neurotrophic factor (CNTF), and interleukin-6 (IL-6), to name just a few. Recall from Chapter 4 that each of these cytokines produces its biological effects through activation of the gp130 class of plasma membrane receptor and the subsequent activation of the JAK-STAT pathway, noted earlier (Horvath, 2000; Ihle, 2001). The crucial feeding peptide, *leptin*, also acts via a JAK-STAT linked receptor.

The gp130-linked receptors for these cytokines and related signals do not contain protein kinase domains. Rather, the cytoplasmic portions of the receptors interact with nonreceptor protein tyrosine kinases of the JAK family, which include JAK1, JAK2, and Tyk2. Cytokine receptors show some specificity for the types of JAKs activated in a given cell type. Signal transduction to the nucleus involves the tyrosine phosphorylation, by the JAKs, of one or more of a family of transcription factor proteins called *STATs*. Upon phosphorylation, *STAT* proteins translocate to the nucleus, where they bind appropriate cytokine response elements present in target genes. The transcriptional activity of *STAT* proteins can be illustrated by regulation of *c-Fos*, as depicted in Fig. 6.8. Analogous mechanisms are involved in mediating the ability of cytokines to regulate many neural genes, including those for VIP and several other neuropeptides.

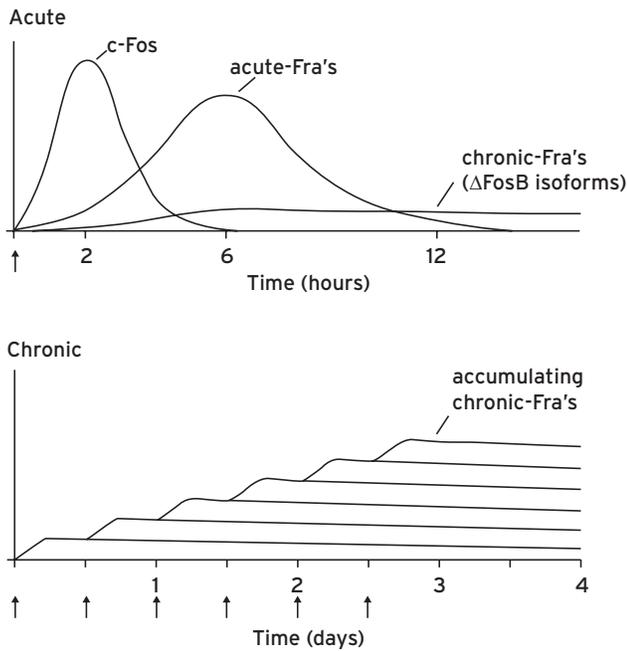

Figure 6.7 Scheme for the gradual accumulation of Δ FosB versus the rapid and transient induction of *c-Fos* and several other Fos family proteins in the brain. (Top) Several waves of Fos family proteins are induced by many acute stimuli in neurons. *c-Fos* is induced rapidly and degraded within several hours of the acute stimulus, whereas others (*FosB*, Δ FosB, FRA-1 [Fos-related antigen-1], FRA-2) are induced somewhat later and persist somewhat longer than *c-Fos*. In contrast, Δ FosB is induced (although at low levels) following a single acute stimulus but persists in brain with a half-life of 1–2 weeks due to its unique stability. In a complex with Jun family proteins, these waves of Fos family proteins form AP-1 binding complexes with shifting composition over time. (Bottom) With repeated (e.g., twice daily) stimulation, each acute stimulus induces a low level of Δ FosB. This is indicated by the lower set of overlapping lines, which indicate Δ FosB induced by each acute stimulus. The result is a gradual increase in the total levels of Δ FosB with repeated stimuli during a course of chronic treatment. This is indicated by the increasing stepped line in the graph. The increasing levels of Δ FosB with repeated stimulation result in the gradual induction of a long-lasting AP-1 complex, which underlies persisting forms of neural plasticity in the brain. Adapted from Nestler (2008).

WNT SIGNALING CASCADES AND THE REGULATION OF GENE EXPRESSION

Wnt (Wingless) is a secreted protein that activates a seven-transmembrane receptor, termed Frizzled (Fzd) (Inestrosa and

Arenas, 2010). (Many of the names given to proteins in this pathway are based on morphological phenotypes seen upon deletion of homologous genes in *Drosophila*.) Wnt activation of Fzd leads to the activation of Disheveled (Dvl) by promoting its polymerization. The primary downstream signaling mechanism of activated Dvl is termed the “canonical” pathway (Fig. 6.9), where Dvl polymerization triggers its binding to Axin, which in turn triggers the AKT (a serine/threonine kinase)-mediated phosphorylation and inhibition of GSK3 β (glycogen synthase kinase-3 β). GSK3 β phosphorylates several downstream targets, including β -catenin, which functions as a transcription factor (Inestrosa and Arenas, 2010). GSK3 β phosphorylation of β -catenin promotes β -catenin’s degradation; hence, Wnt-Dvl, by inhibiting GSK3 β , activates β -catenin-mediated transcription. Dvl polymerization also triggers the activation of Rac1, a small GTPase, which promotes the translocation of β -catenin to the nucleus. β -Catenin is a required cofactor for the transcription factors TCF (T cell transcription factor) and LEF (lymphoid enhancer factor). TCF/LEF binds to TCF/LEF response elements (also known as WREs or Wnt response elements) present in numerous genes to regulate gene expression. The Wnt-Dvl-GSK3 β - β -catenin signaling cascade has been implicated in numerous neuropsychiatric syndromes and is the target for several types of psychotropic drugs, in particular, mood stabilizers such as lithium (e.g., Li and Jope, 2010; Wilkinson et al., 2011). There is thus keen interest in identifying the target genes of this cascade in limbic brain regions that mediate these clinically important behavioral effects.

STEROID HORMONE RECEPTORS ARE LIGAND-ACTIVATED TRANSCRIPTION FACTORS

The differentiation of many cell types in the brain is established by exposure to steroids. For example, exposure to estrogen or testosterone during critical developmental periods results in sexually dimorphic development of certain nuclei. The steroid hormone receptor superfamily (also called the *nuclear receptor superfamily*) includes the receptors for lipid-soluble molecules that diffuse readily across cell membranes, such as glucocorticoids, gonadal steroids, mineralocorticoids, retinoids, thyroid

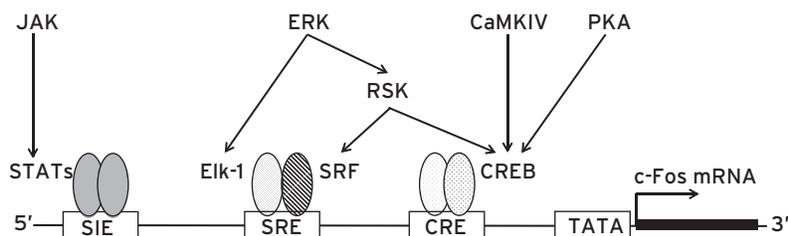

Figure 6.8 Regulation of *c-Fos* gene transcription. A cAMP response element (CRE) binds cAMP response element binding protein CREB, a serum response element (SRE) binds serum response factor (SRF) plus another transcription factor termed Elk-1 (E twenty-six [ETS]-like transcription factor 1) or ternary complex factor (TCF), and a SIF (sis-inducible factor)-inducible element (SIE) binds signal transducers and activators of transcription (STAT proteins). These three elements represent a small number of all known transcription factor-binding sites in the *c-Fos* gene. Proteins that bind at these sites are constitutively present in cells and are activated by phosphorylation. CREB can be activated by protein kinase A, Ca²⁺/calmodulin-dependent protein kinases (CaMKs), or ribosomal S6 kinases (RSKs); Elk-1 can be activated by extracellular signal-regulated kinases (ERKs); and STATs can be activated by Janus kinases (JAKs). Because the activation of *c-Fos* by any of multiple signaling pathways requires only signal-induced phosphorylation rather than new protein synthesis, it can be triggered rapidly by a wide array of stimuli.

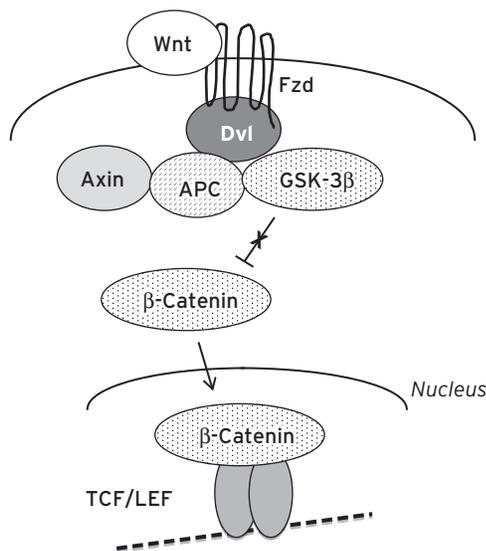

Figure 6.9 Regulation of gene expression by Wnt (Wingless) signaling cascades. Wnt activates the Frizzled (Fzd) receptor, which through Dishevelled (Dvl) binds a complex composed of adenomatous polyposis coli (APC), Axin, glycogen synthase kinase-3 β (GSK-3 β), and other proteins. This leads to the phosphorylation and inhibition of GSK-3 β and to the stabilization and accumulation of β -catenin, which then translocates to the nucleus (a process facilitated by Dvl), where it binds to TCF (T cell transcription factor) and LEF (lymphoid enhancer factor) transcription factors to regulate expression of specific genes. A growing number of neural genes have been recognized in recent years as targets for Wnt signaling.

hormone, vitamin D, and cholesterol-related steroids (Chawla et al., 2001). They act on their receptors within the cell cytoplasm, in marked distinction to the other types of intercellular signals described that act on plasma membrane receptors (see Chapter 4). Another unique feature of the nuclear receptor superfamily is that their receptors are actually transcription factors. Like other transcription factors described, the steroid hormone receptors are modular in nature. Each has a transcriptional activation domain at its amino terminus, a DNA binding domain, and a hormone binding domain at its carboxy terminus. The DNA binding domains recognize different types of steroid hormone response elements within the regulatory regions of genes. The DNA binding domains of the steroid hormone receptors are described as zinc finger domains, a cysteine-rich motif that contains a zinc ion. This motif is used by many other transcription factors (so-called zinc finger proteins), but by few factors that are regulated by extracellular signals.

Once bound by hormone, activated steroid hormone receptors translocate into the nucleus, where they bind to their cognate response elements. Such binding then increases or decreases the rate at which these target genes are transcribed, depending on the precise nature and DNA sequence context of the element. Steroid hormone receptors can therefore be considered ligand-activated transcription factors. In recent years, steroid hormone receptors have been shown to regulate the transcription of genes that do not contain steroid response elements by forming protein-protein interactions with other transcription factors, for example, AP-1 and CREB proteins. This discovery reveals highly complex regulatory mechanisms by which steroid hormones control gene expression (Biddie et al., 2011).

Although the primary mechanism by which the transcriptional activity of steroid hormone receptors is regulated is through their ligand binding and consequent nuclear translocation, the receptors are also regulated *in vivo* at transcriptional and posttranslational levels. The total amount of the receptors expressed in specific target tissues can be altered by numerous types of environment stimuli. For instance, levels of expression of the glucocorticoid receptor are under highly dynamic regulation within several limbic brain regions in response to chronic stress, and can mediate life-long changes in stress vulnerability (Zhang and Meaney, 2010).

DISCLOSURES

Dr. Nestler serves on the scientific advisory boards of PsychoGenics, Inc., Merck Research Laboratories, and Berg Pharma. He also is an ad hoc consultant for Johnson & Johnson.

Dr. Hyman serves on the Novartis Science Board and has advised Astra-Zeneca within the last year. Both advisory roles focus on early stage drug discovery. His research is funded by the Stanley Foundation.

7 | EPIGENETICS OF PSYCHIATRIC DISEASES

BRYAN E. MCGILL AND HUDA Y. ZOGHBI

Coined by Conrad Waddington in 1946, the term *epigenetic* was originally used to describe the effect of gene-environment interactions on the expression of particular phenotypes. Today, the same word commonly refers to stable changes in gene expression that occur without altering the underlying deoxyribonucleic acid (DNA) sequence. Epigenetic changes are characterized by being mitotically stable, meaning that they can be faithfully inherited through generations of somatic cell division. Furthermore, epigenetic changes result in stable phenotypic alterations for the organism. In recent years, a number of molecular pathways have been identified that mediate the establishment, maintenance, and interpretation of the epigenetic code (Goldberg et al., 2007). In this chapter, we provide a brief primer on the epigenetic mechanisms that are currently known to exist in humans: DNA methylation, covalent histone modification, chromatin remodeling by polycomb-group (PcG) and trithorax-group (trxG) proteins, ribonucleic acid (RNA) interference, and imprinting. Following that, we discuss examples whereby errors in these processes contribute to the pathogenesis of psychiatric diseases, using examples culled from research using *in vitro* systems, animal models, and humans where applicable.

MECHANISMS OF EPIGENETICS

DNA METHYLATION AND METHYL-CpG-BINDING PROTEINS

In humans (and other mammals), the cytosine base in DNA can be covalently modified at the carbon-5 position of its ring structure by the addition of a methyl group. The modified bases, designated 5-methylcytosines, are found primarily in symmetric CpG dinucleotide pairs. A minority of CpG pairs is found scattered throughout the genome. In large part, these are methylated, and they are involved in establishing a transcriptionally repressive environment. The majority of CpG dinucleotides are located in so-called CpG islands, which primarily occur in the promoters of protein-encoding genes. The remainder of CpG islands occupy sites within genes that identify alternative transcriptional initiation sites. Similar to the effect of methylation on cytosine in isolated CpG pairs, methylation of cytosines in CpG islands suppresses downstream transcription and silences local genes (Defossez and Stancheva, 2011; Illingworth and Bird, 2009; Suzuki and Bird, 2008).

In mammals, a class of proteins known as DNA methyltransferases (DNMTs) mediates DNA methylation. This

family of proteins includes five polypeptides: DNMT1, DNMT2, DNMT3a, DNMT3b, and DNMT3L (Goll and Bestor, 2005). DNMT1, the first of this family to be identified, was originally distinguished by a preference for hemimethylated DNA compared with unmethylated DNA (Yoder et al., 1997). Given that methylated DNA is replicated semiconservatively, this resulted in the description of DNMT1 as a “maintenance DNA methyltransferase,” as it was inferred that DNMT1 would faithfully curate the methylation pattern of DNA from parent to offspring during cell division. Subsequent data identified a *de novo* DNA methyltransferase function of DNMT1 and noted that under some conditions DNMT1 methylates hemimethylated and unmethylated DNA with equal efficiency, making the relative contribution of this enzyme to maintenance and *de novo* DNA methylation less clear (Svedružić, 2011). In any case, DNMT1 activity is critical to normal development, as evidenced by the embryonic lethal phenotype of *Dnmt1* knockout mice (Li et al., 1992).

DNMT3a and DNMT3b are *de novo* methyltransferases and methylate hemimethylated or unmethylated DNA without preference. DNMT3a and DNMT3b also methylate cytosine in CpA and CpT dinucleotides in addition to cytosine in CpG dinucleotides. Mice lacking DNMT3a die within a month of birth, and mice lacking DNMT3b die *in utero*. Human mutations in the DNMT3b gene are notable for causing ICF (immunodeficiency-centromeric instability-facial anomalies) syndrome, a neurodevelopmental disorder characterized by intellectual disability (Chédin, 2011).

DNMT3L and DNMT2 bear structural similarities to the other DNA methyltransferase proteins, but they lack the ability to methylate DNA. DNMT3L interacts with DNMT3a and DNMT3b and is necessary for appropriate methylation of imprinted genes. The phenotype of DNMT3L null mice illustrate the relevance of this function, as both males and females of this strain are viable but sterile (Chédin, 2011). DNMT2 has a protein domain that is structurally identical to the catalytic core of the bacterial methyltransferase enzyme *HhaI*, but it appears to have little or no DNA methyltransferase activity under laboratory conditions. It methylates transfer RNA (tRNA). DNMT2 knockout mice have no apparent phenotypic abnormalities (Schaefer and Lyko, 2010).

Besides playing a role in normal development, DNA methylation is critical to the function of terminally differentiated neurons. Mice deficient for both *Dnmt1* and *Dnmt3a* in neurons perform poorly compared with control animals in behavioral assessments of long-term memory, and they have impaired long-term potentiation, an electrophysiologic

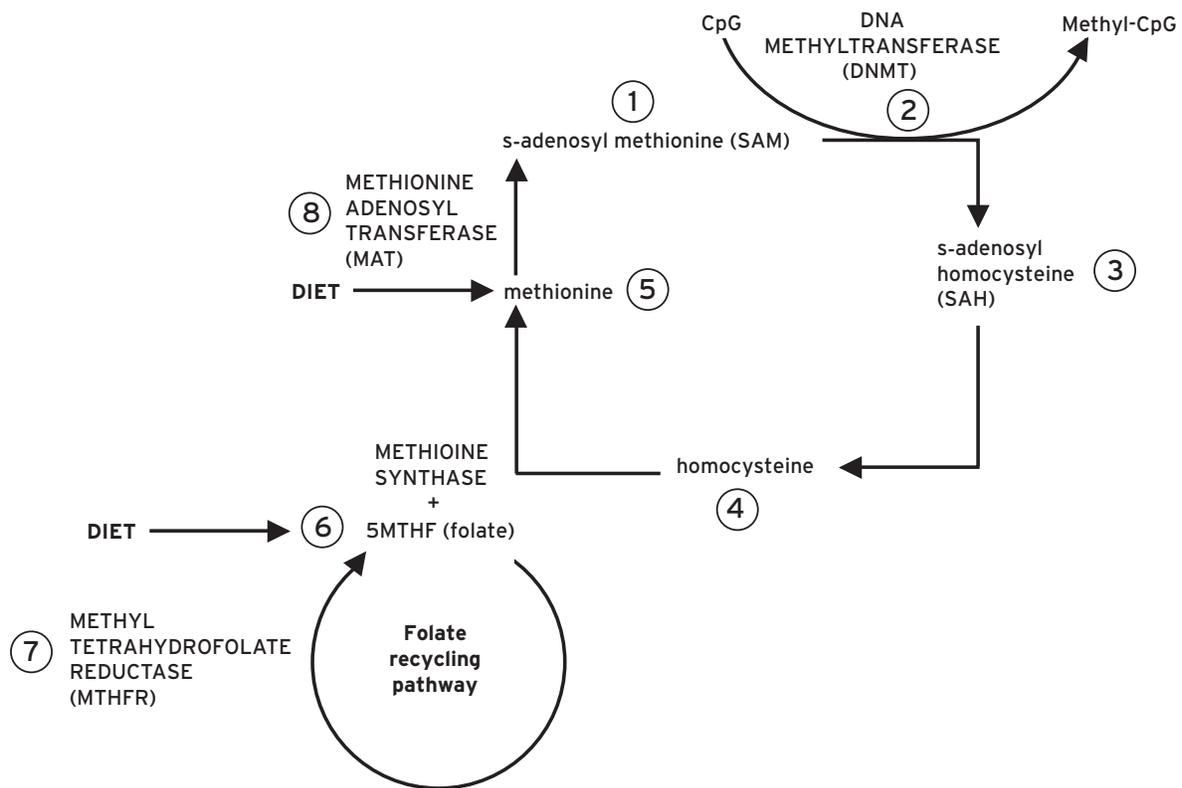

Figure 7.1 Biochemical pathways link dietary folic acid and methionine to DNA methylation. (1) S-adenosyl methionine (SAM) provides the methyl group that (2) DNA methyltransferase (DNMT) uses to methylate CpG dinucleotides in DNA. When SAM donates its methyl group to DNMT, it is converted to S-adenosylhomocysteine (SAH) (3). Then, SAH is converted to homocysteine (4). Homocysteine is converted to methionine (5) by methionine synthase in a reaction that consumes 5-methyltetrahydrofolate (5MTHF), the major circulating form of the nutrient folic acid (6). Folate is regenerated in a series of enzymatic reactions, the last of which is carried out by methylene tetrahydrofolate reductase (MTHFR) (7). SAM is generated from the methionine by the enzyme methionine adenosyltransferase (MAT) (8). Food is the ultimate source of methionine and folic acid.

correlate of long-term memory. These same mice have reduced levels of DNA methylation upstream of genes important for neural activity and synaptic plasticity, and this correlates with increased gene expression, at least for the immediate early gene *Stat1* (Feng, Zhou, et al., 2010). Further illustrating this point, pharmacologic inhibition of DNMT1 function has been shown to impair long-term recall of conditioned fear memory (Miller and Sweatt, 2007). These findings suggest that DNMTs regulate expression of genes critical to learning and memory, both during development and in adult animals (Day and Sweatt, 2011).

DNA methyltransferases obtain the methyl group used to methylate DNA from the methyl donor S-adenosylmethionine (SAM) (Fig. 7.1). SAM is produced from methionine by the enzyme methionine adenosyl transferase. DNA methylation depletes the available pool of SAM and generates the metabolite S-adenosyl-homocysteine, which is converted to homocysteine. The ultimate source of methionine, the precursor of SAM, is the diet. However, methionine can also be regenerated from homocysteine by the enzyme methionine synthase. This reaction requires the methyl donor 5-methyl tetrahydrofolate (5MTHF), the major circulating form of the nutrient folic acid (folate). As with methionine, dietary intake is the ultimate source of folate. In this way, levels of DNA methylation are closely linked to the nutritional status of the organism (Muskiet and Kemperman, 2006).

DNA methylation regulates gene expression via at least two mechanisms (Fig. 7.2). First, methyl-CpGs directly interfere with the binding of some transcription factors (Watt and Molloy, 1988). Second, DNA methylation regulates gene expression via the methyl-CpG-directed recruitment of methylated DNA binding proteins that bind methylated DNA and act as scaffolds to recruit protein complexes that primarily repress, and in some cases activate, gene transcription (Defossez and Stancheva, 2011).

The first family of methylated DNA binding proteins is characterized by the presence of a conserved methyl-CpG-binding domain (MBD), and includes the proteins MeCP2, MBD1, MBD2, and MBD4. MBD1 and MBD2 participate in gene silencing; MBD4 has DNA glycosylase activity and helps repair DNA damage (Defossez and Stancheva, 2011). MeCP2, the first member of this family to be purified (Lewis et al., 1992), binds methylated CpGs in proximity to a run of at least four adenine or thymine nucleotides. Once bound, MeCP2 recruits a variety of corepressor complexes, including one containing Sin3a and the histone deacetylases HDAC1 and HDAC2. In addition, MeCP2 recruits histone methyltransferases, DNA methyltransferases, and transcriptional activators like ATP-dependent chromatin remodeling proteins and the transcription factor CREB1 (Chahrour et al., 2008; Chahrour and Zoghbi, 2007). MBD3, MBD5, and MBD6 proteins exist as well,

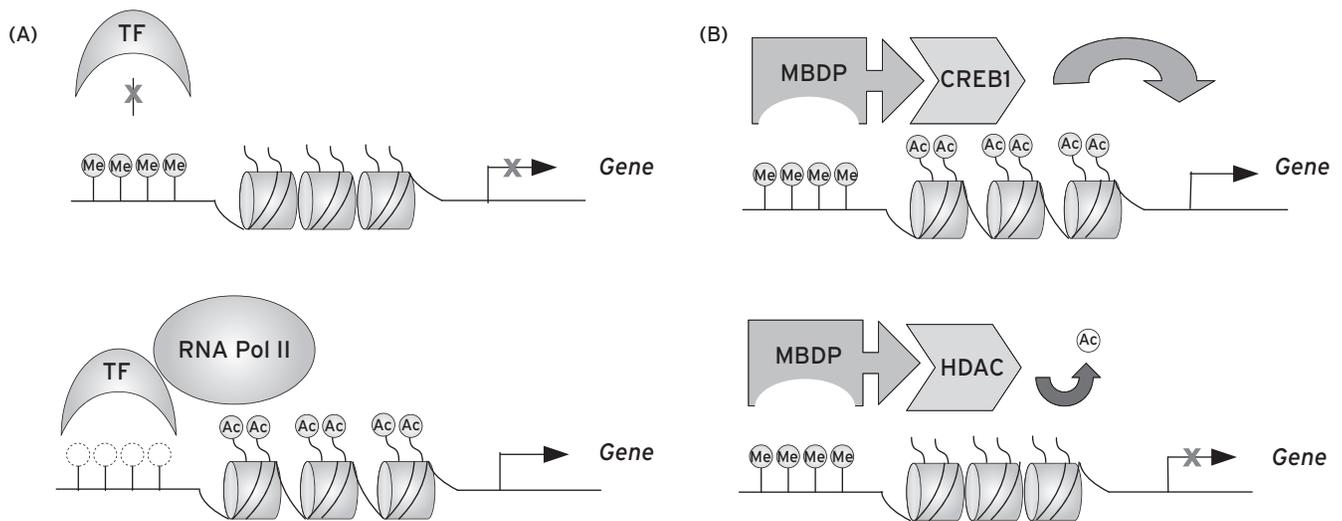

Figure 7.2 Mechanisms of epigenetic gene regulation by DNA methylation. (A) DNA methylation may cause gene repression by interfering with transcription factor binding. The transcription factor binds unmethylated DNA, recruits RNA polymerase II (RNA pol II), and the target gene is transcribed. (B) Alternatively, DNA methylation may attract methyl-CpG binding proteins (here labeled MBDP). In turn, methyl-CpG binding proteins recruit coactivators, such as CREB1, or corepressors, such as histone deacetylases (HDACs). In this figure, the DNA strand is represented by a dark gray line, nucleosomes are represented by gray cylinders, histone tails are represented by squiggly lines, and histone modifications (here, acetylation) are represented by circles atop the squiggly lines. DNA methylation of CpG sites is represented by shaded lollipops. The absence of DNA methylation is represented by dotted lollipops.

but they lack functional MBD domains and do not bind methylated DNA (Defossez and Stancheva, 2011).

The second family of methylated DNA binding proteins includes Kaiso and the Kaiso-like proteins ZBTB4 and ZBTB38. These proteins are zinc finger transcription factors that preferentially bind a specific DNA sequence called a Kaiso binding site (KBS), which is characterized by a central TpG dinucleotide. TpG shares structural similarity with methyl-CpG, and in fact Kaiso and its relatives bind methyl-CpG with equal affinity to the canonical KBS (Defossez and Stancheva, 2011).

UHRF1 (also known as ICBP90) and UHRF2 comprise the third and final family of methylated DNA binding proteins. These proteins bind methylated DNA via an SRA (SET and Ring finger Associated) protein domain. UHRF1 also interacts with histone proteins and has enzymatic activity, functioning as a ubiquitin E3 ligase. UHRF2 was identified by virtue of its close structural similarity to UHRF1, but other than its interaction with methylated DNA little is known about its function (Defossez and Stancheva, 2011).

Although much is known about the proteins that methylate DNA and interpret DNA methylation, far less is understood about DNA demethylation. Numerous studies have pointed to the occurrence of DNA demethylation during both embryonic development as well as during gametogenesis (Feng, Jacobsen, et al., 2010), although some have refuted this (Li and O'Neill, 2012). Two methods of DNA demethylation exist: active and passive demethylation. Passive DNA demethylation is accomplished by preventing DNMT1 from interacting with replicating DNA. Because duplication of DNA methylation patterns occurs in a semiconservative manner, each successive round of DNA replication further dilutes the original complement of methylated cytosines, resulting in demethylation. Therefore, passive demethylation is dependent on DNA replication,

which occurs only during cell division during development (Morgan et al., 2005).

Active demethylation requires neither DNA replication nor cell division, and is therefore accessible to mature neurons, unlike passive demethylation. In mammals, there is evidence to support three ways by which demethylation occurs in postmitotic cells. The first and simplest process uses a 5'-methyl-cytosine DNA glycosylase and the base excision repair pathway, normally a DNA damage repair mechanism, to demethylate 5-methyl cytosines. First, a 5'-methyl-cytosine DNA glycosylase cleaves the covalent link between the 5mC and the deoxyribose sugar. Then, an endonuclease removes the deoxyribose sugar. Finally, a DNA polymerase and a DNA ligase insert an unmethylated cytosine into the same spot (Zhu, 2009). In mammals, MBD4 has DNA glycosylase activity at guanine/thymine nucleotide mismatches, at least *in vitro* (Zhu, 2000). In mammalian cell lines, the non-enzymatic protein Gadd45a promotes DNA demethylation in a process that requires both XPB, a DNA helicase, and XPG, a DNA 3' endonuclease (Barreto et al., 2007). Although intriguing, a subsequent study in cells did not find proof of Gadd45a involvement in DNA demethylation (Jin et al., 2008). However, *in vivo* studies in mice found evidence of activity-dependent upregulation of *Gadd45b* expression in the dentate gyrus, a domain of the hippocampus important in learning and memory formation. In response to electrical stimulation of the brain, *Gadd45b* localized to the *Bdnf* regulatory region IX and the *Fgf1* promoter and decreased methylation was observed at these sites. The same gene regulatory regions remained methylated in *Gadd45b* knockout mice in response to the same stimulus (Ma et al., 2009). Thus, although the components of this demethylation pathway remain unknown, evidence is accumulating that DNA demethylation occurs in mammals.

Another proposed mechanism of DNA demethylation begins with deamination of 5-methyl cytosine to generate thymine. Then, a glycosylase that recognizes guanine/thymine DNA base mismatches removes the thymine base. Finally, just as with the first mechanism described in the preceding, an endonuclease removes the deoxyribose sugar, and a DNA polymerase and a DNA ligase together insert an unmethylated cytosine into the same spot (Zhu, 2009). *In vitro*, the mammalian proteins Dnmt3a and Dnmt3b demonstrate 5-methyl cytosine deaminase activity. In an experimental system in cell culture, estradiol treatment leads to demethylation of the *pS2* gene promoter and subsequent *pS2* transcription. Prior to demethylation, Dnmt3a and Dnmt3b bind the *pS2* promoter in association with the DNA glycosylase TDG and base excision repair proteins. Pharmacological inhibition of Dnmt3a and Dnmt3b blocks *pS2* demethylation, suggesting that these proteins are responsible for demethylation of the *pS2* promoter (Métivier et al., 2008). Further studies will be needed to confirm these findings and determine whether or not they apply to whole organisms as well.

A third mechanism of demethylation involves initial chemical conversion of 5-methyl cytosine to 5-hydroxymethyl cytosine. This is followed by deamination of 5-hydroxymethyl cytosine to thymine, and subsequent replacement of thymine with unmethylated cytosine using base excision repair. In mammals, the Tet1 protein performs the initial hydroxylation step, and Apobec1 deaminates 5-hydroxymethyl cytosine. Initially worked out in cell culture, there is evidence that this pathway also exists in mouse brain, where interference with either Tet1 or Apobec1 expression blocks electrical stimulation-induced demethylation at the *Bdnf* regulatory region IX and the *Fgf1* promoter (Guo et al., 2011).

COVALENT HISTONE MODIFICATION

Nuclear DNA is organized into a three-dimensional molecular structure known as chromatin. The most basic form of chromatin is the nucleosome, which is composed of DNA wrapped around a complex of eight histone proteins, including two copies each of protein H2A, H2B, H3, and H4. Nucleosomes are separated from one another by short stretches of naked DNA, and the alternating sequence of nucleosome-naked DNA-nucleosome forms a filament with a “beads on a string” appearance called a 10nm fiber. The 10nm fiber represents an open chromatin configuration known as euchromatin, and it is this configuration that allows for active gene transcription. The 10nm fiber coils further in a solenoid pattern to form a 30nm fiber, and most DNA maintains this degree of compaction during interphase. Compacted, transcriptionally inactive chromatin is known as heterochromatin. During cell division the 30nm fiber condenses further to generate the chromosome complement of every human cell (Ruthenburg et al., 2007; Fussner et al., 2011).

It is evident that chromatin configuration (i.e., open or closed, euchromatin or heterochromatin) determines the complement of active genes in the cell nucleus, and that manipulating chromatin compaction alters the cohort of expressed genes. Covalent chemical modification of histone proteins represents one method of controlling chromatin configuration. Research over the last two decades has identified histone modification

as a major mechanism of transmitting and maintaining epigenetic information (Strahl and Allis, 2000).

Histone proteins are primarily modified on their N-terminal tails, which jut out from the globular nucleosome core like spokes on a wheel. Numerous chemical modifications have been identified on the amino acids that form these tails, including methylation, acetylation, phosphorylation, glycosylation, formylation, hydroxylation, and crotonylation (Tan et al., 2011). Additionally, the small proteins ubiquitin and SUMO can be covalently attached to various histones, leading to histone ubiquitylation and SUMOylation, respectively. These modifications change chromatin structure, and thereby gene expression, via multiple mechanisms (Fig. 7.3). First, covalent modifications change the

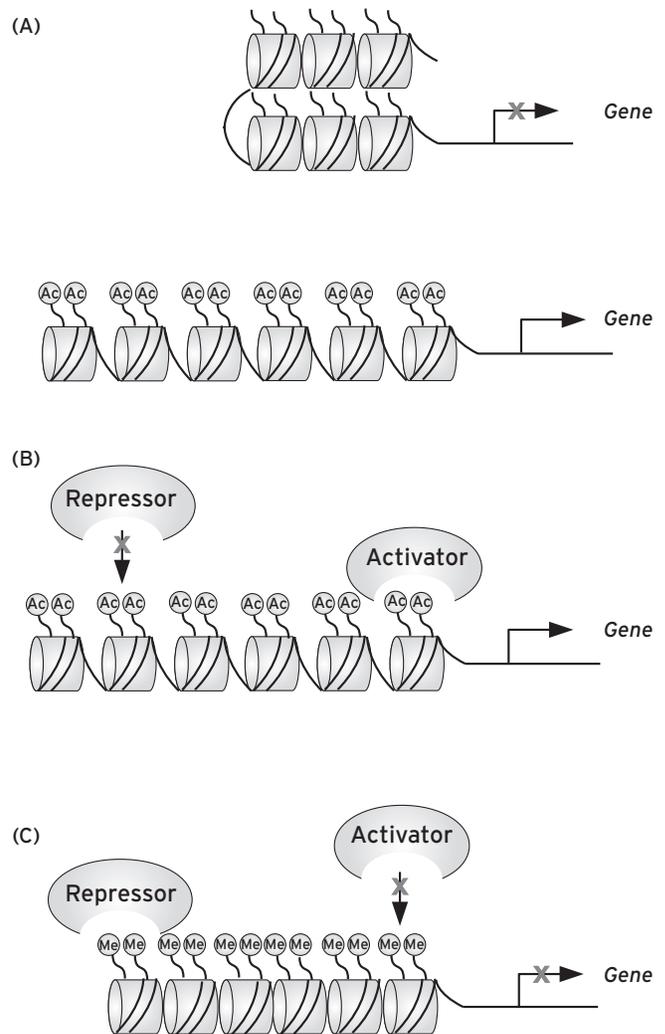

Figure 7.3 Mechanisms of epigenetic gene regulation by covalent histone modification. (A) Covalent histone modification may directly alter chromatin compaction by altering the affinity of histone proteins for one another or for DNA. (B) Alternatively, modifications may attract transcriptional activators that recognize particular chemical moieties or repel transcriptional repressors that ordinarily bind histones in the absence of a particular modification. (C) Other modifications may have the opposite effects on transcriptional activators and repressors. In this figure, the deoxyribonucleic acid (DNA) strand is represented by a dark gray line, nucleosomes are represented by gray cylinders, histone tails are represented by squiggly lines, and histone modifications [here, acetylation in (B) and methylation in (C)] are represented by circles atop the squiggly lines.

electrostatic charge of specific amino acids. For example, lysine residues are positively charged, and histone lysine acetylation removes that charge. The net effect of numerous such chemical modifications is enough to change chromatin structure on a larger scale both by affecting individual nucleosome interactions with DNA in *cis* and nucleosome-nucleosome interactions in *trans*. Second, posttranslational covalent modifications to histone proteins changes the molecular topology of nucleosomes such that they may attract or interfere with the binding of various chromatin-modifying enzymes, transcriptional coactivators, and transcriptional corepressors to DNA. In this way, the combination of histone modifications at a particular locus can determine cell specific gene transcription (Ruthenburg et al., 2007).

Of the various chemical modifications to histone tail amino acid residues, methylation and acetylation are the most well understood. Histone methylation occurs on the basic amino acid residues lysine (K), arginine (R), and histidine (H). Lysine can be mono-, di-, or trimethylated on a single residue, whereas arginine can be mono- or dimethylated, and histidine accommodates only monomethylation. Enzymes that methylate lysines include SET domain containing proteins and DOT1-like proteins. Arginines are methylated by protein arginine methyltransferases, or PRMTs. Histidine methyltransferases remain undiscovered. Lysine demethylases include the amine oxidases and the jumonji domain containing iron-dependent dioxygenases. There are no known arginine or histidine demethylases. Various protein domains recognize each individual histone methylation mark, and the effects of individual marks can have dramatically different effects on chromatin conformation and gene expression. For example, histone H3 lysine 4 trimethylation (H3K4me3) is a mark of active chromatin, whereas histone H3 lysine 27 trimethylation (H3K27me3) is a mark of inactive chromatin. Combinatorial effects are also possible. As a case in point, the combination of H3K4me3 and H3K27me3 results in activated chromatin (Greer and Shi, 2012).

Histone acetylation, which occurs on lysine (K) residues, is also well characterized. In general, histone acetylation is associated with an open chromatin conformation and correlates with transcriptionally active genes. Histones are acetylated by enzymes called histone acetyltransferases (HATs), which are recruited to chromatin by transcriptional activators. Some HATs are also able to directly bind chromatin on their own. Acetylation neutralizes the positive charge of lysine residues, decreasing the affinity of histone proteins for the negatively charged DNA double helix and opening the chromatin structure. Acetylation also provides a binding surface for specialized proteins that mediate the effects of this histone modification, including proteins that promote open chromatin conformation, such as the SWI/SNF family of proteins. These proteins recognize acetylated lysines with protein domains called bromodomains, which allow binding of the modified residues (Choi and Howe, 2009).

In contrast to acetylation, histone deacetylation generally promotes a closed chromatin conformation and repression of gene transcription. Deacetylation is carried out by histone deacetylases (HDACs), and exposes positively charged lysine residues on histones, which are then free to interact with the

negatively charged DNA strand. Just as histone acetylation recruits proteins that open chromatin and promote gene transcription, histone deacetylation attracts proteins that promote a repressed chromatin state. Proteins containing SANT (SWI3, ADA2, N-CoR, and TFIIB) domains recognize deacetylated lysines on histone proteins and recruit HDACs to help maintain gene repression (Shahbazian and Grunstein, 2007).

An important exception to the rule that histone deacetylation correlates with gene repression is the case of histone H4 lysine 16 (H4K16). Deacetylation of this residue correlates with gene activation when it occurs in euchromatic regions of DNA. This finding suggests that other individual acetylated residues may have specific effects on gene expression, and represents an active area of research for scientists interested in histone modification (Shahbazian and Grunstein, 2007).

In addition to the role of histone tails in the control of gene expression, other mechanisms exist whereby histones may modulate the epigenetic transfer of information. For example, splice variants of each of the core histone proteins exist, some of which can be modified at alternative sites. Inclusion of another histone protein not part of the nucleosome, HP1, allows further condensation of chromatin into a more heterochromatic state by linking nucleosomes to one another (Zeng et al., 2010).

CHROMATIN REMODELING BY POLYCOMB- AND TRITHORAX-GROUP PROTEINS

Another mechanism of epigenetic gene regulation involves the manipulation of higher order chromatin structure by polycomb-group (PcG) and trithorax-group (trxG) proteins. Both groups of proteins were initially discovered in the fruit fly, *Drosophila melanogaster*, where they organize development along the anterior-posterior axis by regulating the expression of so-called homeotic genes. PcG and trxG proteins regulate gene expression in mammals as well, particularly at imprinted loci, making them relevant to epigenetic processes occurring in humans (Schuettengruber et al., 2007).

In general, PcG proteins repress gene expression by combining to form one of two multimember protein complexes, PRC1 and PRC2. PRC1 is composed of the mammalian homologs of four core proteins found in *D. melanogaster*: Polycomb, Polyhomeotic, Posterior sex combs, and Sex combs extra. Polycomb has a chromodomain that binds trimethylated histone H3 at lysine 27 (H3K27me3); Sex combs extra ubiquitylates histone H2A, and Posterior sex combs is a cofactor for the ubiquitin ligase function of Sex combs extra (Simon and Kingston, 2009). The repressive function of Polyhomeotic depends on its ability to self-associate and form polymerized chains of Polyhomeotic protein (Robinson et al., 2012a). The mechanism by which PRC1 represses gene transcription is not known. One hypothesis proposes that PRC1 blocks transcription by interfering with the disassembly and reassembly of nucleosomes that is required for transcriptional elongation. Another hypothesis proposes that PRC1-induced ubiquitylation of histone proteins blocks transcription by interfering with RNA polymerase movement along the DNA strand (Simon and Kingston, 2009).

Like PRC1, PRC2 is composed of four core subunits, the mammalian homologs of the *D. melanogaster* proteins Enhancer of Zeste, Suppressor of Zeste, Extra Sex Combs, and nucleosome remodeling factor 55 (NURF55). Enhancer of Zeste is a SET-domain containing histone methyltransferase that carries out the primary repressive function of PRC2 by trimethylating histone H3 at lysine 27 (H3K27me3). The other core proteins allow PRC2 to bind histones and stimulate its histone methyltransferase function (Simon and Kingston, 2009).

Similar to PcG proteins, trxG proteins form multi-subunit protein complexes of their own that fall into two categories: histone modifying complexes and ATP-dependent chromatin remodeling complexes. The former category includes COMPASS, COMPASS-like, TAC1, and ASH1. These complexes stimulate gene transcription by trimethylating histone H3 at lysine 4 (H3K4me3), and acetylating histone H4 at lysine 16 (H4K16ac) and acetylating histone H3 at lysine 27 (H3K27ac). The latter category includes SWI/SNF, ISWI, and CHD1, CHD2, CHD3, CHD4, CHD6, CHD7, and CHD8. These complexes expend ATP energy to alter chromatin structure in one of three ways: by disrupting DNA-nucleosome interactions, by repositioning nucleosomes along the chromatin fiber, and by ejecting or exchanging entire nucleosomes (Schuettengruber et al., 2011).

RNA INTERFERENCE

RNA interference (RNAi) is an epigenetic mechanism that is mediated by the production of various types of non-coding RNA (ncRNA). ncRNA species include micro RNA (miRNA), Piwi-interacting RNA (piRNA), long non-coding RNA (lncRNA), and the small RNA subspecies called small interfering RNA (siRNA), small nucleolar RNA (snoRNA), and repeat-associated siRNA (rasiRNA). Experimental evidence is accumulating for other varieties of ncRNA, and it is likely that further subtypes will be delineated in the future. The various forms of ncRNA are differentiated from one another by their sizes and cellular functions. miRNAs, the best described among the ncRNAs, are 23-nucleotide-long RNA species transcribed from DNA by RNA polymerase II. Initially present in the nucleus as a hairpin structure, miRNAs in mammals are processed by the enzyme Drosha and exported to the cytoplasm by the RAN-GTPase exportin 5. Once there, miRNAs are further processed by a protein called Dicer. The mature miRNA is incorporated into the RNA-induced silencing complex (RISC), the key component of which is the protein Argonaute. RISC separates the two strands of the miRNA and uses the so-called guide strand to target specific mRNA sequences. These mRNA targets may be degraded by the RNase H, or “slicer,” activity of the Argonaute component of RISC. Alternatively, RISC can suppress mRNA translation and shunt the mRNA to other endogenous cytoplasmic RNA degradation pathways (Fig. 7.4). A similar mechanism is utilized by siRNA small RNAs. Targets of this pathway include genes that encode key members of other epigenetic signaling pathways, including the DNA methyltransferases DNMT1, DNMT3a, and DNMT3b, and EZH2, a histone methyltransferase and component of the

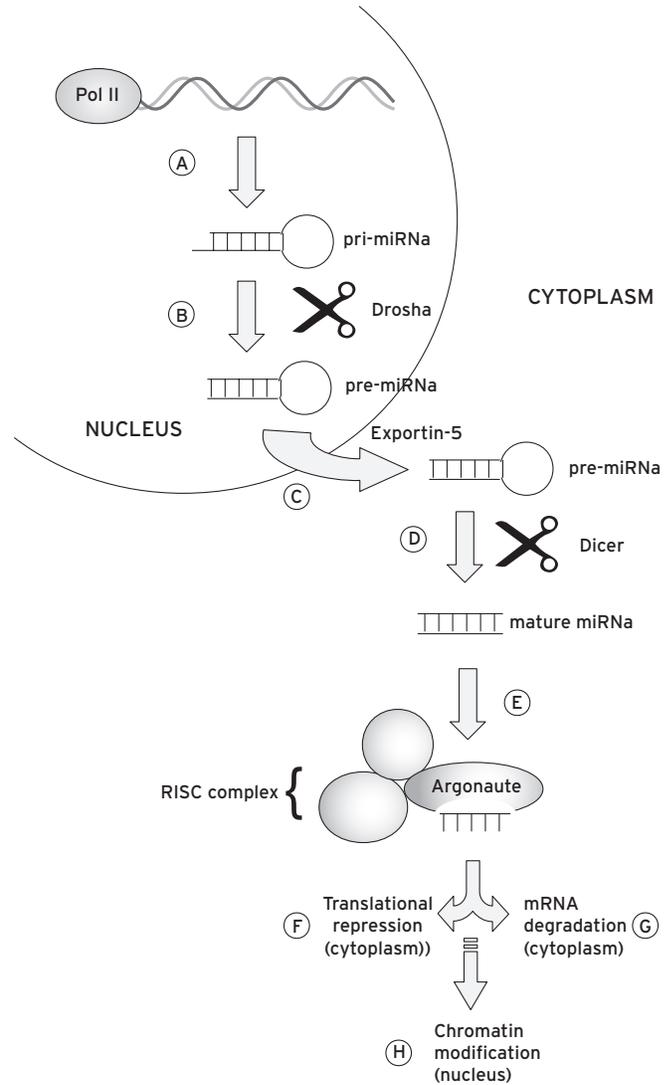

Figure 7.4 The RNA interference pathway. pri-miRNA, the initial miRNA precursor, is transcribed from palindromic DNA sequences by RNA polymerase II (A). pri-miRNAs are trimmed by the enzyme Drosha in the nucleus (B) to make pre-miRNAs and exported to the cytoplasm by Exportin-5 (C). There, pre-miRNA is further processed by Dicer to mature miRNA (D). miRNA is cleaved into its complementary strands and the guide strand is loaded into the RISC protein complex, the major component of which is the protein Argonaute (E). miRNA can suppress translation by sequestering mRNA (F) or targeting it for degradation (G). Alternatively, miRNA can return to the nucleus, where it regulates transcription and chromatin formation via mechanisms that are still being investigated (H).

polycomb complex PRC2 (Cam, 2010; Costa, 2010; Wiklund et al., 2010).

In addition to directing mRNA degradation, ncRNA regulates the establishment of heterochromatin. This occurs when an ncRNA associates with the RNA-induced transcriptional suppressor (RITS) complex in the nucleus. The ncRNA is used to target promoter RNA (pRNA), which is RNA transcribed from the promoter region of a gene. This leads to the recruitment of histone methyltransferases that methylate local chromatin, particularly at histone H3 lysine 9 (H3K9), which in turn attracts histone deacetylases. The combination of histone methylation at H3K9 and deacetylation produces a

closed chromatin structure that suppresses gene transcription (Wiklund et al., 2010).

IMPRINTING

The term *imprinting* describes an epigenetic phenomenon in which a gene is expressed differentially (often monoallelically) in a parent-of-origin-specific manner. Approximately 131 imprinted genes have been identified at the time of this writing (July 2012). Most imprinted genes occur in clusters throughout the genome and frequently occur in close association with CpG islands. The functions of imprinted genes are tightly linked to specific developmental and somatic processes, including neural activity, energy use and metabolism, the development of specific tissues, and intrauterine growth.

At least three mechanisms exist to regulate imprinted gene expression. The first and best characterized mechanism is illustrated by the *Igf2* gene (Fig. 7.5A). *Igf2* is normally repressed on the maternal chromosome, which instead expresses the *H19* non-coding RNA (ncRNA). The maternal chromosome contains an imprinting control region (ICR) upstream of the *H19* gene. The ICR remains unmethylated on the maternal chromosome and binds the CTCF protein and the cohesin protein complex. This protein-DNA interaction denies the *Igf2* gene access to its enhancer sequence and suppresses *Igf2* expression on the maternal chromosome. Instead, *H19* is expressed. Meanwhile, on the paternal chromosome, cytosines in the ICR are methylated, which impairs CTCF and cohesin binding. This allows access to the *Igf2* enhancer, which activates *Igf2* expression. In this context, *H19* is suppressed.

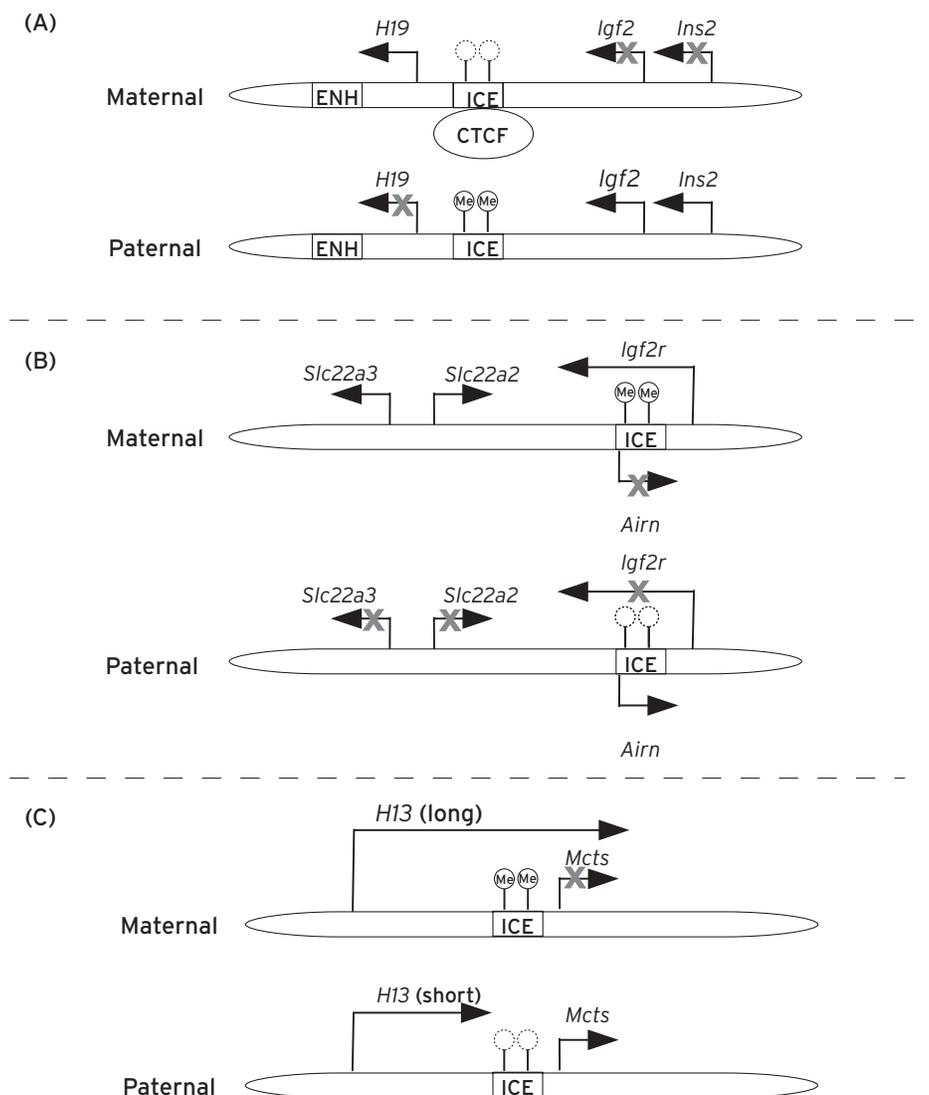

Figure 7.5 Mechanisms of imprinting. There are three general mechanisms by which genes are imprinted. (A) In the first model, DNA methylation at the imprinting control region (ICR) regulates binding of a protein like CTCF. The presence or absence of the protein dictates which imprinted genes are expressed. (B) In the second model, DNA methylation at the ICR controls expression of an antisense transcript, like *Airn*. When expressed, the antisense transcript interferes with transcription of the sense transcript from the same allele, leading to differential expression of the target gene. (C) In the third model, DNA methylation at the ICR controls polyadenylation site choice, leading to expression of a short or long form of a gene. In this figure, DNA methylation of CpG sites is represented by shaded lollipop (see text for details).

The second mechanism of imprinted gene regulation is exemplified by the *Igf2r* gene (Fig. 7.5B). *Igf2r* contains an intronic CpG island within its sequence that functions as an ICR. On the maternal chromosome, this CpG island is methylated, and the *Igf2r* gene is expressed. On the paternal chromosome, the CpG island is unmethylated. The unmethylated sequence functions as a promoter for the *Airn* gene, which is transcribed antisense to the *Igf2r* gene. *Airn* encodes an ncRNA, which suppresses *Igf2r* expression via a mechanism that is still being investigated.

The *H13* gene provides an example of the third mechanism of imprinted gene regulation (Fig. 7.5C). *H13* has multiple alternative polyadenylation sites separated by an ICR that serves as the promoter for the *Mcts* gene. On the maternal allele the ICR is methylated, which blocks expression of *Mcts* and allows a long, functional form of the *H13* gene to be transcribed. On the paternal allele, the ICR is unmethylated and *Mcts* is expressed. In the presence of *Mcts* expression the *H13* gene is transcribed using an alternative polyadenylation site that yields a truncated, inactive form of the *H13* transcript (Barlow, 2011; Bartolomei and Ferguson-Smith, 2011; Koerner and Barlow, 2010).

NEUROPSYCHIATRIC DISORDERS ASSOCIATED WITH EPIGENETIC DEFECTS

ADDICTION

Epigenetic mechanisms of gene regulation have proven to be fundamental to the development of addictive behaviors in preclinical animal models. To date, most data collected have focused on the effects of cocaine on epigenetic gene regulation. Cocaine treatment leads to increased histone H3 and H4 acetylation, a mark of gene activation, at immediate early genes that are activated by the drug, including *cFos*, *Bdnf*, and *Cdk5* (Kumar et al., 2005). This effect is mediated by both cocaine-induced recruitment of the histone acetyltransferase, CREB binding protein (CBP) (Levine et al., 2005), and cocaine-induced inhibition of the histone deacetylase, HDAC5 (Renthal et al., 2007). Genes encoding the histone deacetylases Sirt1 and Sirt2 are among those that are transcriptionally activated by cocaine, and may be responsible for sustaining the transcriptional response to the drug (Renthal et al., 2009). Supporting this concept, genetic and pharmacologic manipulations of HATs and HDACs predictably alter the behavioral response to cocaine in animals. For example, mice heterozygous for a *Creb1* null mutation (predicted to decrease histone acetylation) have reduced acetylation at *cFos*, reduced *cFos* expression, and reduced locomotor activity in response to cocaine (Levine et al., 2005). Likewise, viral mediated enhancement of HDAC expression (also predicted to decrease histone acetylation) in mice impairs cocaine induced place preference, a behavioral model for addiction in humans (Kumar et al., 2005). Conversely, small molecule inhibitors of HDAC enzymatic activity enhance *cFos* expression and the behavioral response to cocaine (Kumar et al., 2005).

Histone acetylation also underlies the effects of other drugs of abuse, such as nicotine. Chronic nicotine treatment of mice

leads to hyperacetylation of histone proteins and increased *FosB* expression. In addition to mediating the rewarding effects of drugs of abuse, histone acetylation may also play a role in priming the users of one drug to the addictive effects of another. For example, chronic use of nicotine prior to treatment with cocaine enhanced *FosB* expression more than cocaine alone without prior nicotine treatment. This effect was mediated by a nicotine-induced reduction in HDAC activity, and a similar effect was achieved using a small-molecule inhibitor of HDACs. Epidemiologic analysis indicates that humans who used cocaine and who concurrently smoked cigarettes had a higher incidence of cocaine dependence, suggesting that similar epigenetic mechanisms operate in humans and are responsible for regulating complex addictive behaviors (Levine et al., 2011).

In addition to histone acetylation, histone methylation has been implicated in addiction. Chronic cocaine use causes genome-wide reduction in histone H3 lysine 9 trimethylation (H3K9me3), a histone modification associated with gene silencing and heterochromatin formation, in nucleus accumbens. This leads to de-repression of intergenic regions of DNA and activation of retrotransposons (Maze et al., 2011). Similar analysis of histone H3 lysine 9 dimethylation (H3K9me2) and histone H3 lysine 27 dimethylation (H3K27me2), both repressive marks, found that repeated cocaine treatment led to increased methylation at these sites at nearly 900 genes, as compared with a reduction in methylation at these sites in fewer than one third as many genes (Renthal et al., 2009). Together, these findings indicate that repeated cocaine use both dampens gene expression and transcriptionally activates genes at the same time, reinforcing the concept that epigenetic changes in response to environmental stimuli are exceedingly complex, even in isolated brain regions and even in response to well-defined stimuli. As with histone acetylation, it is possible to interfere with the effects of cocaine by manipulating histone methylation. For example, cocaine downregulates the G9a histone methyltransferase, and genetic upregulation of *G9a* expression reduces behavioral sensitivity to the drug (Maze et al., 2010). This suggests that treatments targeting epigenetic systems may be powerful tools in the fight against addiction.

DNA methylation also plays a role in mediating the addictive properties of cocaine. Cocaine decreases global DNA methylation in the prefrontal cortex of mammals. This may be mediated by *Dnmt3b*, the expression of which is downregulated following cocaine treatment. Dietary supplementation with methionine, a methyl donor, rescues *Dnmt3b* expression and abolishes conditioned place preference, a model of addictive behavior in animals (Tian et al., 2012). Likewise, cocaine downregulates *Dnmt3a* expression in the nucleus accumbens, and methionine supplementation and *Dnmt3a* overexpression there abolish addictive behaviors in mice (LaPlant et al., 2010). These results are particularly exciting because they suggest that simple dietary modification with methionine supplementation can interfere with the addictive effects of cocaine.

RNA interference by non-coding RNA (ncRNA) also regulates addictive behaviors. This has been most convincingly demonstrated for the ncRNA, miR-212, which is transcribed in the dorsal striatum of animals under conditions of unfettered

access to cocaine. Surprisingly, miR-212 appears to protect against the effects of chronic cocaine use, as siRNA knock-down of miR-212 increased cocaine intake and enhanced its addictive properties in mice, whereas miR-212 upregulation protected against these effects (Hollander et al., 2010). Interestingly, miR-212 is negatively regulated by MeCP2, thereby implicating yet another epigenetic marker in the process of addiction (Im et al., 2010). Thus, even though the crucial histone modifications, ncRNA transcripts, and methylated sites vary between addictive substances examined and even between brain regions for the same substance, it is clear that epigenetic systems are crucial to establishing and maintaining an animal's sensitivity to drugs of abuse.

DEPRESSION

The genetics of affective disorders, including major depressive disorder, have proven to be relatively intractable to traditional forward genetic analyses. Studies of monozygotic twins, which find a 50% discordance rate for major depressive disorder (MDD), suggest that a major reason for the failure of forward genetics to solve MDD is that it is less heritable by traditional Mendelian genetics. This seems to agree with clinical experience, which suggests that susceptibility to MDD is based on complex gene x environment interactions. Epigenetic mechanisms are thus attractive to researchers interested in the biological basis of MDD as they provide a mechanism whereby environmental perturbations can lead to gene expression changes, which in turn affect behavioral phenotypes (Sun et al., 2012). The last few years have seen an explosion of preclinical data evaluating epigenetic mechanisms of depressive behaviors in animals, as outlined in the following paragraphs.

Both covalent modifications of histone proteins and DNA methylation have been tied to depression. In the setting of chronic stress, increased DNA methylation occurs at multiple *Bdnf* promoters, and the transcripts from these promoters are downregulated. The antidepressant imipramine abrogates this effect. Imipramine also increases histone acetylation at the same *Bdnf* promoters that are silenced by DNA methylation in the setting of chronic stress, and this hyper-acetylation is accompanied by increased *Bdnf* expression. Remarkably, genetic upregulation of histone deacetylases, which reverses the effect of imipramine on histone acetylation, is sufficient to block the antidepressant effect of this drug (Tsankova et al., 2006).

Similar to the effect of chronic stress on *Bdnf*, chronic stress also silences *Gdnf* expression in BALB mice, which are susceptible to depressive behavior in the setting of chronic stress. Following stress, BALB mice have increased DNA methylation upstream of *Gdnf* at a CpG site that is bound by a protein complex including MeCP2 and HDAC2. Predictably, these mice have decreased acetylation at histone H3 at the *Gdnf* locus. Imipramine blocks these effects of stress, leading to reduced CpG methylation, reduced MeCP2 and HDAC2 recruitment, and increased histone H3 acetylation at *Gdnf*. Imipramine-treated BALB mice have increased *Gdnf* expression and less depressive behaviors than their untreated counterparts. In contrast, B6 mice, a stress-resistant strain, recruit MeCP2 complexed with CREB, a transcriptional activator, to

the same methyl-CpG site upstream of *Gdnf* in response to chronic stress. B6 mice have increased histone H3 acetylation at *Gdnf* and increased *Gdnf* expression in response to stress (Uchida et al., 2011). This suggests that subtle alterations in the epigenetic control of gene expression may underlie individual differences in the behavioral response to stress, and that successful therapeutic interventions may hinge on reversing maladaptive epigenetic changes.

Broad, unbiased evaluation of histone modifications have also yielded insight into the epigenetic response to stress. For instance, both social defeat stress and social isolation stress affect histone methylation similarly by increasing dimethylation at histone H3 lysine 27 (H3K27me2) and at lysine 9 (H3K9me2) in the nucleus accumbens. Both modifications enhance transcriptional repression. Nearly three quarters of the genes repressed under both paradigms overlap, supplying evidence that different stressors activate epigenetic programs that are largely identical (Wilkinson et al., 2009). However, acute and chronic stress affect histone modifications differently. In the hippocampus, acute stress increases the overall level of trimethylation at histone H3 lysine 9 (H3K9me3), whereas chronic stress decreases H3K9me3 (Hunter et al., 2009). Remote effects of stress on histone modifications are possible as well; histone H3 acetylation initially decreases one hour after the last session of chronic stress, only to significantly increase by 10 days afterward. Decreased expression of HDAC2 occurs concurrently with increases in histone acetylation in mice exposed to chronic stress. Postmortem samples from humans with depression also demonstrate decreased HDAC2 and increased histone acetylation, indicating that epigenetic responses to stress may be similar across species (Covington et al., 2009).

In addition to providing new avenues for understanding the molecules that mediate depression, the study of epigenetic mechanisms has led to a greater understanding of the biological basis for the effects of antidepressants. For example, fluoxetine prevents reductions in global histone acetylation in hippocampus in response to chronic stress, such that levels of histone acetylation in stressed animals exposed to fluoxetine closely resemble those of unstressed animals (Hunter et al., 2009). Imipramine reverses the effects of social defeat stress on dimethylation at histone H3 lysine 9 and histone H3 lysine 27 in the nucleus accumbens. The histone methylation pattern observed after imipramine treatment overlaps considerably with the histone methylation pattern observed in stress-resilient mice, again emphasizing that different methods of overcoming stress appear to utilize similar epigenetic programs (Wilkinson et al., 2009).

The fact that traditional antidepressants alter histone acetylation and methylation has led to investigation of new drugs that directly interfere with the enzymatic mediators of these histone modifications. MS-275, an inhibitor of HDACs, has potent antidepressant properties in multiple behavioral settings in preclinical animal models (Covington et al., 2009; 2011), and it has a similar effect on gene expression patterns as fluoxetine (Covington et al., 2009). SAHA, another HDAC inhibitor, also works as an antidepressant in preclinical animal models (Covington et al., 2009). Further study of

compounds like these may lead to improved therapies for mood disorders.

Besides histone modification, DNA methylation plays a role in depression by controlling the neuroendocrine response to stress. Specifically, it regulates the expression of key components of the limbic-hypothalamic-pituitary-adrenal (LHPA) axis, which is activated in states of depression and anxiety. This was first demonstrated in a series of experiments examining the methylation status of the *Nr3c1* gene, which encodes the glucocorticoid receptor. Rat pups raised in a highly nurturing environment had decreased DNA methylation of *Nr3c1*. The reduced methylation status of this gene was accompanied by increased glucocorticoid receptor expression, leading to increased feedback inhibition on the LHPA axis, which relies on glucocorticoid-glucocorticoid receptor interaction to inactivate it after exposure to a stressor. Rat pups raised in a poorly nurturing environment experienced the reverse effect, methylating their *Nr3c1* gene, downregulating *Nr3c1* expression, and hyperactivating their LHPA axis with exposure to subsequent stressors (Weaver et al., 2004). Intriguingly, an investigation of the methylation status of the human glucocorticoid receptor gene (*NR3C1*) in postmortem samples from human suicides found increased methylation of the gene and decreased glucocorticoid receptor expression in suicides with a history of child abuse, as compared with suicides without such experience, suggesting that a similar mechanism may underlie the human LHPA response to stress (McGowan et al., 2009).

DNA methylation also plays a key role in regulating the expression of the corticotropin releasing hormone gene, which encodes CRH, a neuropeptide released by the paraventricular nucleus of the hypothalamus in response to stress. At baseline the promoter region of the *Crh* gene is methylated in mice, but it is demethylated in mice susceptible to the effects of chronic social defeat stress, a model of human depression, whereas mice resistant to the effects of this stressor maintain *Crh* methylation. Predictably, *Crh* expression is increased in the susceptible mice. Increased *Crh* expression in these mice is associated with increased expression of the *Gadd45b* gene, which encodes a demethylating enzyme, and decreased expression of the *Dnmt3b* gene, which encodes a DNA methyltransferase, in the hypothalamus, suggesting that changes in *Crh* methylation status occur in concert with exposure to environmental stressors such as the social defeat paradigm utilized in these experiments (Elliott et al., 2010). Changes in *Crh* methylation appear to be a common response to a variety of chronic stressors, as similar results have been observed in rodents exposed to maternal deprivation and chronic variable stress. Moreover, DNA methylation at this locus is persistent, suggesting that it provides a long-term memory of the experience within the animal's brain (Chen et al., 2012; Sterrenburg et al., 2011).

Just as the LHPA axis is induced by alterations made to DNA methylation, there is evidence that these changes are reversible. For example, *Crh* demethylation in response to stress was attenuated by the antidepressant imipramine in one animal model (Elliott et al., 2010). Treatment with the methyl-donor methionine reversed the effects of remote maternal deprivation stress on *Nr3c1* gene expression in adult animals, suggesting that changes in DNA methylation, far from being permanent,

are amenable to interventions made throughout an animal's lifetime (Weaver et al., 2005).

SCHIZOPHRENIA

Interest in epigenetics as a source of pathology in schizophrenia stems from observations in the early part of the 20th century suggesting a link between diet and the development of schizophrenia. First, children born to women who became pregnant during famines in China and the Netherlands were found to be at higher risk for developing schizophrenia later in life (St. Clair et al., 2005; Susser et al., 1996). These children were also at higher risk for the development of neural tube defects, which other studies have linked to folic acid deficiency. Thus, it has been hypothesized that low serum folate levels during pregnancy also contribute to an increased risk for developing schizophrenia (Susser et al., 1996).

As described in the preceding, folic acid provides a dietary source of methyl groups that can be used to methylate DNA. Thus, one reason why gestational folate status may be an important risk factor for the development of schizophrenia could be that DNA methylation patterns are initially established during pregnancy in humans (Morgan et al., 2005). Malnutrition leading to folic acid deficiency may interfere with the establishment of a normal pattern of DNA methylation during prenatal development, or so some have argued. In support of this, studies in rodents demonstrate that altering the amount of folic acid available to pregnant dams affects the degree of DNA methylation that is observed in their pups (Waterland, 2006).

In light of this argument, numerous attempts have been made to link DNA methylation to the pathogenesis of schizophrenia, but these have met only limited degrees of success. With respect to DNA methylation, initial candidate gene approaches identified methylation changes correlating with disease (schizophrenia) state for the genes *RELN*, *COMT*, and *SOX10*. However, the findings related to *RELN* and *COMT* were not replicated in independent experiments, and further studies have not reevaluated the *SOX10* gene (Akbarian, 2010). A single study examining methylation changes in CpG islands upstream of 50 candidate genes for schizophrenia failed to identify any consistent differences in DNA methylation between samples from patients with schizophrenia and controls (Siegmund et al., 2007). To date, only one unbiased screen of DNA methylation in schizophrenia has been performed. This experiment succeeded in identifying approximately 100 loci that were differentially methylated between schizophrenics and controls in prefrontal cortex. Bioinformatic analysis of the genes identified indicated that they tended to cluster in functional categories thought to be relevant to schizophrenia, including GABAergic signaling. However, follow-up validation of gene expression changes identified in the initial screen verified only 5 of 12 (40%) of the candidate genes that were tested, suggesting that these results must be interpreted cautiously (Mill et al., 2008).

Histone modifications have also been examined in schizophrenia. Akbarian et al. (2005) examined covalent histone modifications in postmortem prefrontal cortex tissue from schizophrenics and found evidence of increased

levels of histone H3 arginine 17 methylation in a subgroup of patients with schizophrenia with reduced metabolic gene expression. Another subgroup, this one with increased expression of the ornithine aminotransferase (*OAT*) gene, was found to have increased levels of histone H3 serine 10 phosphorylation and histone H3 lysine 17 acetylation. Meanwhile, Huang et al. found a correlation between reduced *GAD1* gene expression and decreased trimethylation at histone H3 lysine 4 (H3K4me3), a mark for open chromatin, in postmortem samples from women with schizophrenia, but not from men (Huang et al., 2007). Further study will be required to determine whether these results are reproducible. In addition, the significance of abnormal histone modification to the pathogenesis of schizophrenia remains to be determined.

Expression profiling of micro-RNAs from postmortem brain tissue from schizophrenics and case controls has implicated a list of 14 different miRNAs in the pathogenesis of the disease. However, with the exception of miR-132, which was identified in two studies by separate researchers, there has been no independent validation of the other targets. miR-132 is attractive to scientists since it targets transcripts encoding BDNF and NMDA receptor subunits (Mellios and Sur, 2012). More recently, a consortium of scientists reported the results of a large genome-wide association study (GWAS) that found evidence of linkage to an SNP within the miR-137 transcript. Although it is a single report, the strength of the data is related to the large cohort of samples analyzed (over 20,000) and the finding that four of the seven other loci identified are predicted targets of miR-137 (Ripke et al., 2011).

RETT SYNDROME

Evidence for the role of epigenetic processes in psychiatric disease also comes from genetic disorders with prominent psychiatric phenotypes. Some of these disorders are caused by mutations in genes encoding components of epigenetic systems (Table 7.1). For example, mutations in *MECP2*, the

X-linked gene that encodes the methyl-DNA binding protein *MECP2*, cause Rett syndrome (RTT) (Amir et al., 1999). The clinical features of Rett syndrome are silent during the first 6 to 18 months of life, at which point children undergo a period of developmental regression and lose milestones they had previously attained, especially language. Children with RTT develop microcephaly, growth restriction, hypotonia, and ataxia. Features of autonomic nervous system dysfunction appear, including abnormal breathing patterns (hyperventilation and apnea are common), and vasomotor instability. Movement disorders are characteristic. As young children, patients with RTT have upper extremity stereotypies, such as hand wringing. Later in life, spasticity, dystonia, and parkinsonian features appear. Behavioral features also figure prominently in RTT. Autistic features, including minimal to absent language skills, repetitive behaviors, and social withdrawal, are a core component of the RTT phenotype. Low mood, inconsolable crying, anxiety, and periodic screaming in fits of apparent terror are observed in RTT as well (Chahrour and Zoghbi, 2007; Samaco and Neul, 2011).

Besides RTT, mutations in *MECP2* cause a host of other neuropsychiatric phenotypes. For example, some *MECP2* mutations cause autism alone. Other *MECP2* mutations, particularly in the 3' UTR of the gene, have been linked to juvenile onset schizophrenia, psychosis, alcoholism, phobia, and attention-deficit/hyperactivity disorder (ADHD) (Cohen et al., 2002; Shibayama et al., 2004). The A140V *MECP2* mutation causes the PPM-X syndrome, which is characterized by intellectual disability, manic-depressive psychosis, pyramidal tract signs, parkinsonism, and macroorchidism (Klauck et al., 2002). *MECP2* duplication causes a unique syndrome, which in part is characterized by autistic features and mood disorder (Van Esch, 2012).

The phenotypic variability associated with mutations in *MECP2* is in part due to its physical location on the X chromosome, which makes it subject to X chromosome inactivation (XCI). Thus women who carry two X chromosomes may

TABLE 7.1. Syndromes with prominent neuropsychiatric phenotypes that are linked to mutations in genes regulating epigenetic processes

DISEASE	GENE(S)	NEUROPSYCHIATRIC PHENOTYPE(S)
Rett syndrome	<i>MECP2</i>	Anxiety, autism, childhood-onset schizophrenia
Rubinstein-Taybi syndrome	<i>CREBBP, EP300</i>	Hyperactivity, mood lability, obsessive behaviors, autistic features
α -thalassemia/mental retardation syndrome, X-linked	<i>ATRX</i>	Autistic features, mood lability, emotional outbursts, self-injurious and obsessive behaviors
Angelman syndrome	<i>UBE3A</i>	Autistic features
Prader-Willi syndrome	Unknown. Linked to paternally expressed genes at 15q11-q13	Autistic features
Fragile X syndrome	<i>FMR1</i>	Autistic features, attention deficit/hyperactivity
Kabuki syndrome	<i>MLL2, KDM6A</i>	Autistic features, aggressive/oppositional behavior, hyperactive/impulsive behavior, anxiety, and obsessions

manifest partial features of RTT depending on XCI patterns. Favorable XCI, which occurs when a majority of cells express the wild type (WT) *MECP2* allele instead of the mutated *MECP2* allele, accounts for the partial neuropsychiatric phenotypes in females. Males with severe *MECP2* mutations suffer from early lethality because they have only one X chromosome. However, males with mild *MECP2* mutations may develop less severe disease manifesting as a neuropsychiatric disorder compatible with life (Chahrour and Zoghbi, 2007).

How mutations in *MECP2* cause RTT has been an area of active investigation for more than a decade now. Mouse models of RTT have contributed a great deal to this effort. Both the complete absence of MeCP2 and the replacement of endogenous MeCP2 with a truncated, mutant protein recapitulate the features of RTT in mice (Chen et al., 2001; Guy et al., 2001; Shahbazian et al., 2002). Neuron-specific *Mecp2* knockout mice, which lack MECP2 throughout the brain, are indistinguishable from animals that lack MECP2 throughout their entire body (Chen et al., 2001; Gemelli et al., 2006). Mice have also been generated that lack MECP2 specifically in forebrain neurons, aminergic neurons, hypothalamic neurons, and astrocytes (Ballas et al., 2009; Chao et al., 2010; Fyffe et al., 2008; Gemelli et al., 2006; Maezawa et al., 2009; Samaco et al., 2009). These animals display varying degrees of pathology and recapitulate one or more aspects of the RTT phenotype. Deletion of *MeCP2* in adult mice also causes RTT, indicating a lifelong need for the MeCP2 protein to maintain normal brain function (McGraw et al., 2011). Importantly, expressing wild type MECP2 in animals lacking a copy of the gene (MECP2 “null” animals) rescues the RTT phenotype (Guy et al., 2007; Robinson et al., 2012b), and expression of MeCP2 in either astrocytes or in microglia prolongs breathing, motor function, and survival (Derecki et al., 2012; Lioy et al., 2011) suggesting that therapeutic approaches when discovered might hold some promise for treating the disease in the future (Samaco and Neul, 2011).

Currently our understanding of the mechanism by which *MECP2* mutation produces the RTT phenotype is limited and incomplete. Initially, researchers focused on identifying the genes regulated by MeCP2, theorizing that a complete description of this complement of genes would readily explain aspects of the RTT phenotype. The *Bdnf* gene, encoding the neuropeptide brain-derived neurotrophic factor (BDNF), is one such MeCP2 target gene. Reduction of endogenous *Bdnf* levels via genetic engineering exacerbates the phenotype of *Mecp2* null mice, whereas genetic overexpression of *Bdnf* extends the life span of *Mecp2* null mice (Chang et al., 2006), and drugs that enhance BDNF levels improve synaptic function in neurons (Ogier et al., 2007) and improve disease symptoms in mice (Tropea et al., 2009).

Another MECP2 target is *Crh*, the gene encoding corticotropin releasing hormone (CRH). Released in response to stress, CRH elicits anxiety-like behavior in animals and induces the release of adrenal corticosteroids (cortisol in humans, corticosterone in mice). Mice expressing a truncated version of MECP2 have enhanced *Crh* expression and increased anxiety-like behavior (McGill et al., 2006). Disruption of *Crh* signaling via genetic downregulation of *Crh* expression or

pharmacologic blockade of CRH signaling was sufficient to reverse anxiety-like behavior in *MECP2* transgenic mice. Thus *Crh*, like *Bdnf*, is a MECP2 target gene that can be modified to ameliorate RTT phenotypes (Samaco et al., 2012).

Classically, MECP2 has been thought of as a transcriptional repressor, binding specific promoters and recruiting corepressor proteins to shut down gene expression. However, recent data have challenged this view. For example, genome-wide expression profiling studies have revealed that many genes are downregulated in absence of MeCP2 and upregulated when it is overexpressed. In fact, more genes are activated by MeCP2 than are repressed, at least in the hypothalamus (Chahrour et al., 2008; Yasui et al., 2007). Perhaps more surprisingly, MeCP2 is present in neurons at concentrations akin to those of histone proteins, and binds chromatin every two nucleosomes. In the absence of MeCP2, more histone protein H1 is bound to chromatin, suggesting that one of MeCP2's roles is to function as a chromatin remodeling protein (Skene et al., 2010).

Finally, evidence is accumulating in favor of a role for MECP2 in activity dependent gene regulation and experience-dependent synaptic plasticity. Some of this evidence comes from studies of addiction in rodents (see “Addiction” section in this chapter). Neuronal activity has been shown to elicit MECP2 phosphorylation, and early experiments suggested that this posttranslational modification changed the affinity of MECP2 for DNA at specific sites, including the *Bdnf* promoter (Chen et al., 2003; Martinowich et al., 2003). However, a more recent genome-wide evaluation of MeCP2 binding sites did not replicate this finding (Cohen et al., 2011). One view is that MeCP2 phosphorylation changes local chromatin structure, although this remains untested. Mice genetically engineered to express a phosphorylation deficient form of MeCP2 display different phenotypes depending on the mutated sites. Mutation of S421A causes lack of habituation to familiar objects and mice, and seems to render mice less able to distinguish between the novel and the familiar (Cohen et al., 2011). In contrast, mutations of S421A/S424A lead to several phenotypes reminiscent of the features observed in mice that overexpress MeCP2 (Li et al., 2011).

ANGELMAN SYNDROME AND PRADER-WILLI SYNDROME

Imprinting errors at chromosome 15q11-q13 cause two childhood neurological disorders, Angelman syndrome (AS) and Prader-Willi syndrome (PWS). Angelman syndrome is characterized by a constellation of features including intellectual disability, epilepsy, and ataxia. Patients with AS have unique behavioral features that set them apart from other neurodevelopmental disorders. They display frequent outbursts of laughter, sometimes out of context. They appear happy, and often smile. They have some autistic features, most prominently poor or absent language and stereotypic hand-flapping movements, but unlike children with autism, they are sociable and many enjoy interacting with others. Additional behavioral features include poor sleep, restlessness, short attention span, and hyperactivity (Mabb et al., 2011; Williams, 2010).

AS is caused by failure to express the maternal allele of the gene *UBE3A*. For the vast majority of patients with AS (75%), this is a result of a maternally inherited deletion of the 15q11-q13 region that includes the *UBE3A* gene. Other patients (15%) inherit a more conventional missense or nonsense mutation that renders the maternal copy of the *UBE3A* gene nonfunctional. Fewer patients (7%) have paternal uniparental disomy and inherit both copies of *UBE3A* from their fathers. Finally, a minority of patients with AS (3%) inherit a microdeletion that eliminates the maternal copy of the AS imprinting control region (ICR), which causes the maternally inherited allele to function as a paternally inherited allele (Mabb et al., 2011) (Fig. 7.6).

Intense research has focused on uncovering the molecular mechanisms that govern imprinting at chromosome 15q11-q13, the site crucial to the development of AS and PWS. The locus containing the *UBE3A* gene can be transcribed in the forward direction, which produces the *UBE3A* protein, and in

the reverse direction, which produces a non-coding antisense transcript, *UBE3A-ATS*. DNA methylation at the AS ICR on the maternal allele blocks transcription of *UBE3A-ATS*. As a result, *UBE3A* is transcribed without interference. However, DNA methylation is lacking on the AS ICR of the paternal allele. As a result the *UBE3A-ATS* transcript is produced, which blocks expression of the *UBE3A* gene from that allele (Mabb et al., 2011). Recent studies using genetic manipulations in mice suggest that *Ube3a-ATS* is an atypical non-polyadenylated RNA Polymerase II transcript that represses *Ube3a* on the paternal allele (Meng et al., 2012).

The phenotype of PWS differs significantly from AS. Infants with PWS typically come to clinical attention because of hypotonia, poor suck, and resultant failure to gain weight. Later in childhood, children with PWS develop hyperphagia and are at risk to develop morbid obesity if access to food is not carefully controlled. Hypogonadism is another characteristic feature of PWS, and both males and females may have small genitalia.

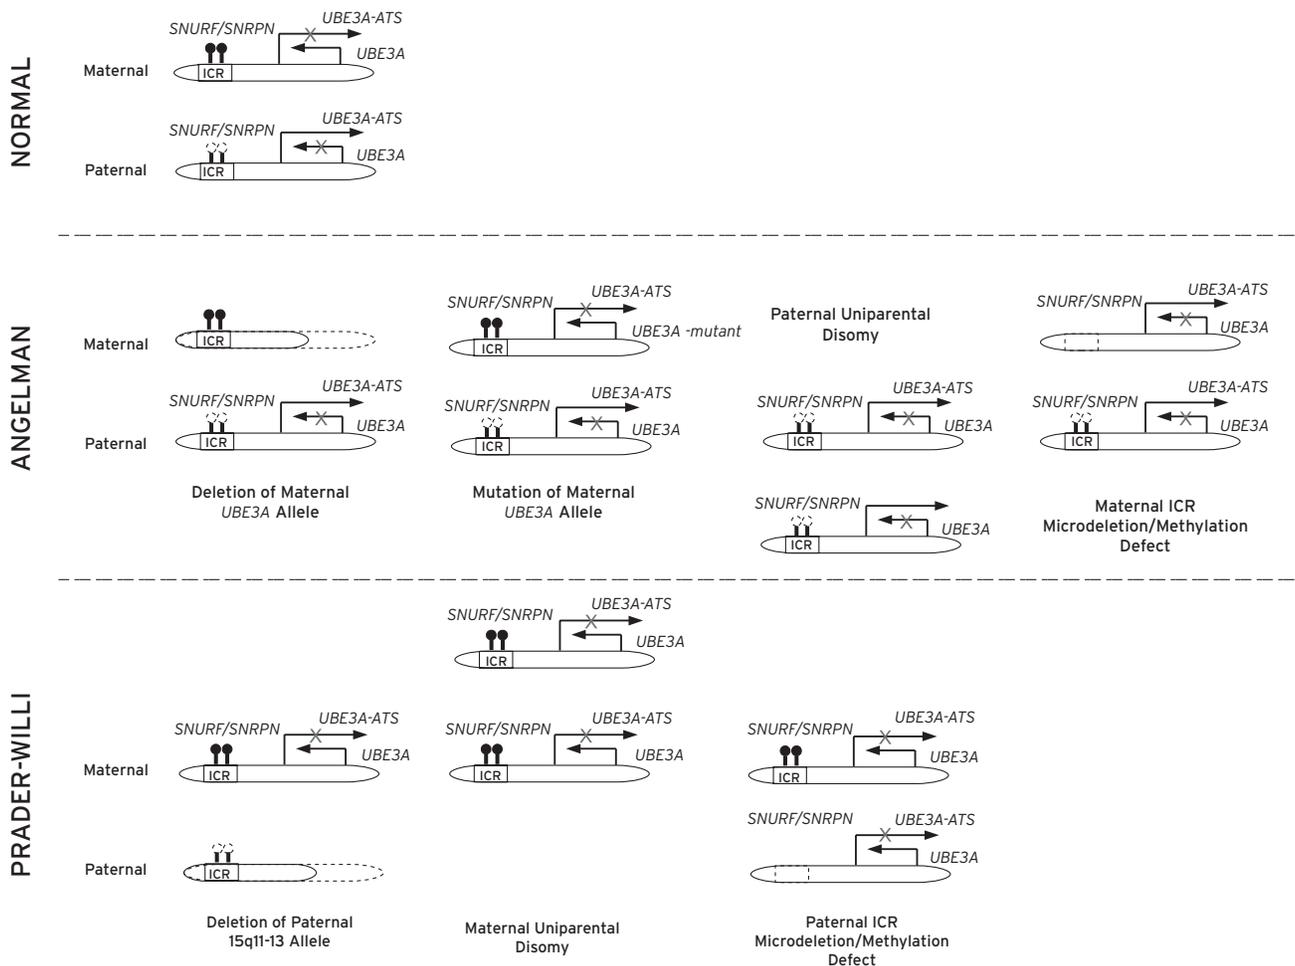

Figure 7.6 Causes of Angelman syndrome and Prader-Willi syndrome. Angelman syndrome (AS) and Prader-Willi syndrome (PWS) are caused by mutations and imprinting errors at chromosome 15q11-q13. Normally, *UBE3A* is expressed from the maternal chromosome, while a group of genes, including *SNURF-SNRPN*, are expressed from the paternal chromosome. The 3' terminus of the *SNURF-SNRPN* gene cluster contains *UBE3A-ATS*, an antisense transcript that transcriptionally silences *UBE3A*. Expression of *UBE3A-ATS*, *SNURF-SNRPN*, and the other paternally expressed genes is regulated by the differential methylation of the AS imprinting control region (not shown) and the PWS imprinting control region (labeled as "ICR" in the figure). Differential methylation of the AS-ICR occurs transiently during embryonic development and is not shown here. DNA methylation at the PWS-ICR is represented by shaded lollipop, whereas unmethylated DNA at this site is indicated by dotted lollipop. AS is caused by mutations and epimutations that result in decreased expression of the maternal copy of *UBE3A* or the function of its protein product, *UBE3A*. PWS is caused by mutations and epimutations that disrupt the expression of paternally imprinted genes in the *SNURF-SNRPN* gene cluster at chromosome 15q11-q13 (see text for more details).

Endocrine dysfunction is common, and central deficiencies of growth hormone, adrenal hormones, and thyroid hormone may coexist. Intellectual disability in the moderate to severe range occurs as a rule for PWS. Behavioral features of the syndrome include autism, present in 20% of patients, psychosis, present in 10%–20% of adult patients with PWS, hyperactivity, and compulsive behaviors (Cassidy et al., 2012; Whittington and Holland, 2010).

In contrast to AS, the most common cause of PWS (65%–75%) is deletion of the paternal allele containing the 15q11-q13 region. Another 20%–30% of PWS cases are caused by maternal uniparental disomy for this chromosomal region. A minority of cases (1%–3%) are due to microdeletions of the paternal copy of the PWS imprinting control region (ICR) or defects in DNA methylation at this site (Buiting, 2010). The PWS ICR is located just upstream of the *SNURF-SNRPN* gene and is contiguous with a CpG island located within the proximal 5' portion of this gene. On the paternal allele of the 15q11-q13 region, the PWS ICR is unmethylated, whereas it is methylated on the maternal allele. Again, this leads to *UBE3A-ATS* transcription and blockade of *UBE3A* expression. In addition to *UBE3A-ATS*, the unmethylated PWS ICR on the paternal allele permits expression of a number of other genes that are not expressed from the maternal allele. These include the genes *MKRN3*, *MAGEL2*, *NECDIN*, *C15orf2*, *SNURF-SNRPN*, and multiple genes encoding small nucleolar RNAs (snoRNAs). Rare patients with deletions of one of these snoRNA genes, *SNORD116*, display most features of PWS, suggesting that this gene plays a major role in the PWS phenotype. However, the exact contribution of other genes in this cluster remains to be determined (Buiting, 2010; Cassidy et al., 2012).

FRAGILE X SYNDROME

Fragile X syndrome (FXS) is the most common cause of X-linked intellectual disability (ID) and the second most common cause of ID overall after Trisomy 21. In addition to ID, features of FXS include dysmorphic features such as elongated faces, enlarged ears, a prominent jaw, and macroorchidism. Psychiatric features figure prominently in the FXS phenotype and include autistic spectrum disorders (autism and pervasive developmental disorder), which are present in a third of people with FXS. The vast majority (90%–95%) of people with FXS have symptoms of inattentiveness and hyperactivity. Anxiety may be crippling in FXS, and emotional lability can lead to aggressive outbursts and stereotyped behaviors (Tranfaglia, 2011).

FXS is caused by expansion of a cytosine-guanine-guanine (CGG) nucleotide triplet repeat in the 5' untranslated region of the *FMR1* gene, located within the gene's first exon. Normal alleles of *FMR1* contain less than 45 repeats, whereas the presence of more than 200 repeats causes FXS. Alleles containing 55–200 repeats are termed “premutations,” and are prone to spontaneous expansion in subsequent generations. Premutation alleles cause an adult onset progressive neurodegenerative disease, Fragile X associated tremor ataxia syndrome (FXTAS), further discussion of which is outside the scope of this chapter (Penagarikano et al., 2007).

Disease-causing *FMR1* alleles are hypermethylated within the triplet repeat and also within a CpG island located in the *FMR1* promoter. The hypermethylated, disease-causing alleles are transcriptionally silenced and fail to express the *FMR1* product, the fragile X mental retardation protein (FMRP). In addition to the direct effects of DNA methylation on silencing *FMR1*, local changes in covalent histone modifications have been identified at the expanded *FMR1* allele. Histone H3 and H4 acetylation is reduced, and trimethylated histone H3 lysine 9 and trimethylated histone H3 lysine 27 is increased at the disease-causing allele, whereas the normal, unexpanded allele has the opposite histone marks. This indicates that in addition to DNA methylation, local chromatin modifications at the expanded allele contributes to *FMR1* silencing by maintaining a condensed and transcriptionally restrictive structure (Penagarikano et al., 2007). Additionally, the 5' UTR of *FMR1* is transcribed in both sense and antisense directions, which makes it conceivable that it generates double stranded RNA capable of activating the RNA-induced transcriptional silencing (RITS) pathway. Thus, some investigators have put forward the hypothesis that RNA interference may play a role in *FMR1* silencing. However, this remains unproven (Kumari and Usdin, 2009).

KABUKI SYNDROME

Kabuki syndrome is a neurodevelopmental disorder with characteristic dysmorphic features, including high arched eyebrows, elongated palpebral fissures, everted lower eyelids, large, prominent ears, a depressed nasal tip, various skeletal abnormalities, and fetal fingertip pads. Approximately 85% of patients with Kabuki syndrome have developmental delay and intellectual disability. In addition, autistic features are prominent in a subset of patients with Kabuki syndrome, and some patients have other psychiatric features, including aggressive/oppositional behavior, hyperactive/impulsive behavior, anxiety, and obsessions (Adam and Hudgins, 2005; Ho and Eaves, 1997). Recently, Kabuki syndrome was linked to epigenetic phenomena when the gene *MLL2* was identified as the cause of 56%–76% of cases. *MLL2* encodes a histone lysine methyltransferase and functions as a trithorax-group protein, preferentially mediating trimethyl modification of histone H3 lysine 4 (Ng et al., 2010). Further studies of Kabuki patients lacking *MLL2* mutation identified mutations in *KDM6A*, a gene encoding an *MLL2* interacting protein, as causative of some cases of Kabuki syndrome. Like *MLL2*, *KDM6A* is a trithorax-group protein. It functions as a histone demethylase that removes mono-, di-, and trimethylation marks from histone H3 lysine 27 residues, thereby activating gene transcription. *KDM6A* also interacts with the SWI/SNF protein, Brg1, and participates in repositioning nucleosomes to change chromatin structure (Lederer et al., 2012). At this time it is not known whether or not there is a mechanistic link between *MLL2*, *KDM6A*, and the neuropsychiatric features of Kabuki syndrome.

RUBINSTEIN-TAYBI SYNDROME (RSTS)

Errors in covalent histone modification also have been linked to the pathogenesis of Rubinstein-Taybi syndrome (abbreviated

RSTS). Patients with RSTS have characteristic facial features including microcephaly, down-slanted palpebral fissures, a beaked nose, micrognathia, a high-arched palate, and dental anomalies. Broad thumbs and great toes also help identify people with RSTS. Intellectual disability is a prominent feature of RSTS, and other neuropsychiatric pathology including hyperactivity, mood lability, obsessive-compulsive behaviors, and autistic features also occur frequently in RSTS (Roelfsema and Peters, 2007; Verhoeven et al., 2010).

Mutations in the gene *CREBBP*, encoding cAMP-response element binding (CREB) binding protein (CBP) account for about 60% of RSTS cases, and mutations in a related gene, *EP300*, encoding the E1A binding protein p300, account for another 3% of RSTS cases. The cause of the remaining 45% of cases is unknown but could be due to further genetic heterogeneity, somatic mosaicism for mutations in *CREBBP* and *EP300*, or mutations in distant regulatory regions of *CREBBP* and *EP300*. Both CBP and p300 are histone acetyltransferases, and mutations that disrupt the acetyltransferase domain of CBP are sufficient to cause RSTS, illustrating the relevance of histone acetylation to human health (Roelfsema and Peters, 2007).

A variety of genetically engineered mouse models of RSTS have been produced, including *Crebbp* knockouts, forebrain specific *Crebbp* knockouts, and transgenic mice overexpressing an inactive form of *Crebbp*. All of these animals have impaired long-term memory, a cardinal feature of RSTS. Molecular analysis indicates that these mice have reduced histone acetylation and altered expression of immediate early genes in the hippocampus, a brain region crucial to the consolidation of long-term memories. Importantly, histone deacetylase inhibitors reverse the memory phenotype, even in adult mice, suggesting that elements of the RSTS phenotype may be overcome by treatments that modulate the same epigenetic system that is dysregulated by disease-causing mutations in *CREBBP* and *EP300*. Further investigations focusing on how disrupted histone acetylation accounts for the behavioral features of RSTS will provide an avenue to discover how alteration of epigenetic processes causes psychiatric disease (Roelfsema and Peters, 2007; Valor et al., 2011).

X-LINKED ALPHA THALASSEMIA MENTAL RETARDATION SYNDROME (ATRX)

X-linked alpha thalassemia mental retardation syndrome (ATRX) is a rare disorder with characteristic physical features including short nose, anteverted nares and epicanthal folds, microcephaly, hypotonia, and abnormal genitalia. Some patients develop alpha thalassemia. Patients with ATRX have moderate to severe intellectual disability with prominent language impairment. The behavioral phenotype of ATRX includes autistic features, rapid mood swings from manic to depressive states, and repetitive activity (Gibbons, 2006).

ATRX is caused by mutations in the *ATRX* gene, which encodes a SWI/SNF family helicase/ATPase. The ATRX protein contains a domain with homology to DNMT3 that permits DNA binding and a domain that permits binding to trimethylated histone H3 lysine 9. ATRX interacts with other proteins that are key epigenetic regulators, including MeCP2.

Recently, a macromolecular protein complex containing ATRX, MeCP2, and other proteins was found to regulate the expression of imprinted genes in the brain. ATRX loss of function disrupted expression of these imprinted genes. For one of these genes, *H19*, inappropriate overexpression was associated with increased acetylation at histone H3 and H4 and decreased trimethylation at histone H4 lysine 20 and histone H3 lysine 9, changes associated with a more open chromatin configuration (Kernohan et al., 2010). In addition to gene expression changes, ATRX loss of function also leads to the loss of fore-brain neurons in mice. As with the other neurodevelopmental disorders described, research has yet to bridge the gap between the dysregulation of epigenetic gene expression and the neuropsychiatric phenotype of ATRX (Gibbons, 2006).

CONCLUSION

Although epigenetics as a field of study is young, the discipline of psychiatric epigenetics can genuinely be described as in its infancy. Fundamental questions regarding the exact role of epigenetic processes in the development and pathogenesis of psychiatric disease remain unanswered. How are global and local patterns of epigenetic modification different in patients with psychiatric diseases as compared to the general population? Are epigenomic changes the cause or the consequence of psychiatric disease? Are any psychiatric diseases epigenetically inherited? Do environmental effects on the epigenome contribute to the development of psychiatric disease? Can treatments that modify epigenetic marks be used to successfully treat psychiatric conditions successfully? Although there are many unknowns, one thing is certain: As our understanding of the basic mechanisms controlling the establishment, maintenance, interpretation, and modification of the epigenetic code increases, so too will our ability to apply this knowledge to answer these and other questions.

DISCLOSURES

Dr. Zoghbi serves on the advisory board of the Mcknight Neuroscience fund and is a senior editor for *eLife*. She receives compensation from both. She is also member of the jury for the Vilcek Prize, Gruber Genetics Prize, and Janssen Prize (and receives compensation), and for the Lasker Prize (no compensation). She receives grant support from HHMI, NIH, IRSE, and RSRT. Dr. Zoghbi holds a patent for MECP2 Rett testing.

Dr. McGill has no conflicts of interest to disclose.

SECTION II | NEW METHODS AND NEW TECHNOLOGIES FOR PRECLINICAL AND CLINICAL NEUROBIOLOGY

KARL DEISSEROTH

The mammalian brain is extraordinarily difficult to study. Whether in the clinical or the preclinical realm, investigators focusing on psychiatric disease not only lack fundamental understanding of the key pathophysiological processes but also lack understanding of the normal function of the relevant circuits (or even knowledge of which are the relevant circuits). This challenge is due in large part to technological limitations linked to the complexity and inaccessibility of the circuitry, and for this reason the future of mental illness research depends upon the development and application of new technologies for studying brain function. Collected here in this volume are chapters from leading developers and pioneers of new neuroscience technologies relevant to mental illness.

In Chapter 8 transgenic tools and animal models of mental illness are addressed. Recent exciting progress not only in accelerating mouse genetic targeting, but also in advancing the genetic tractability of rats, has been and will continue to be crucial for delivering causal understanding of the impact of specific genetic modifications or manipulations. Of course, even technologically novel genetic methods do not stand alone but, rather, require smooth integration with physiology, pharmacology, behavior, and more recently, viral engineering and transduction methods. Together these genetic manipulation approaches show great promise for advancing our understanding of the mechanisms and physiology underlying brain function in health and in psychiatric disease-related states.

In Chapter 9 the influence of stem cell technology is discussed in opening up a new landscape for investigating the processes underlying both normal human brain development and developmental pathogenesis of psychiatric disease-related states. It is now possible to generate renewable sources of human neurons from normal or disease-impaired individuals, via (among other methods) cellular reprogramming, thereby defining a novel translational bridge between animal studies and human disease. Such research will not replace but, rather, complement traditional animal models, while at the same time representing a paradigm shift in our investigation of neural substrates of mental disorders.

In Chapter 10 optogenetic technologies are addressed; optogenetics is defined as the combination of genetic and optical methods to achieve gain- or loss-of-function of temporally defined events in specific cells embedded within intact living tissue or organisms, usually via introduction of microbial opsin genes that confer to cells both light detection capability

and specific effector function. This approach has now been used to control neuronal activity in a wide range of animals, resulting in insights into fundamental aspects of circuit function, as well as circuit dysfunction and treatment in pathological states. Here we review the current state of optogenetics for neuroscience and psychiatry, and address the rapidly evolving challenges and future opportunities.

In Chapter 11 applications of focused ultrasound are reviewed, which may help address the fact that current treatments of neuropsychiatric disease are limited by the lack of noninvasive, reversible, and regionally selective brain-directed drug delivery methods (in large part because of the blood-brain barrier or BBB). Focused ultrasound (FUS) has been found to provide the capability of noninvasively, locally, and transiently opening the BBB in the context of central nervous system diseases. Remaining challenges that are discussed in the chapter include (1) safety and efficacy tradeoffs, (2) mechanism, (3) quantitative measures of BBB change properties, and (4) practical aspects of application for both small (rodent) and large (nonhuman primate) animals.

Chapter 12 reviews some of the advances made in genetic technologies and their application to large-scale gene-mapping efforts in neuropsychiatric disease. From genome-wide association studies to whole-exome sequencing, the sheer amount of data recently generated is unparalleled. Studies of both common and rare variation in diseases such as schizophrenia, bipolar disorder, and autism are now yielding convergent and robust findings, although the high degree of genetic complexity of these diseases (particularly in terms of the number of genes implicated) has also been made evident.

In Chapter 13 the epigenome is explored—as defined by DNA methylation, posttranslational histone modifications, and other regulators of genome organization and function. In the context of psychiatric disorders, these aspects of genetic control have all become increasingly relevant and widely studied. Related therapeutic options—largely based on preclinical studies in rodents—are also addressed, with linkages forged to human brain biology and the pharmacology of mental illness.

In Chapter 14 novel genetic modeling approaches are reviewed that may enable therapeutic predictions and inform decision making. These approaches will range from deciding on genes to probe experimentally, to defining the best treatment for an individual given detailed molecular, genetic, and other personal data. It will be crucial to infer causality and maintain rigorous quantitative methodology with high-dimensional, large-scale

data structures, as large and complex as those encountered by climatology and astrophysics. A new breed of mental health researchers with a new set of tools and styles of thinking are coming to the field, with transformative possibilities emerging.

Chapter 15 reviews neuroimaging modalities that can reflect and inform different aspects of brain anatomy and physiology. Key to the research potential of neuroimaging is noninvasiveness, with clear advantages for global and unperturbative observation as well as speedy clinical translation of applications for insight, diagnosis, and treatment. This chapter focuses on key emerging methodologies that may exert substantive impact on mental illness research in the near future.

Finally, Chapter 16 provides an overview of the ways in which brain imaging modalities may interact with, and guide, brain stimulation. These interactions can arise from structural or functional scans on a subject later used to guide offline treatment planning in terms of stimulation site choice. Key caveats, limitations, and opportunities are reviewed. Additionally, scans

can be used to track effects of brain stimulation. In a key distinction, such feedback can be processed and analyzed offline or, alternatively, in real time as the brain is being stimulated, employing modalities such as positron emission tomography (PET), single-photon emission computed tomography (SPECT), and functional magnetic resonance imaging (fMRI). This is an exciting avenue of research that provides potential for insight into the global and individualized causal physiology underlying mental illness.

Together, the chapters in this section endeavor to review the principles and possibilities linked to a range of exciting new methodologies for brain research. While translational approaches are emphasized, it is anticipated that basic scientists will also find this compendium helpful as a resource and guide. Technological limitations and opportunities linked to the complexity of the mammalian central nervous system will continue to define the frontiers of neuroscience research for decades to come.

8 | TRANSGENIC TOOLS AND ANIMAL MODELS OF MENTAL ILLNESS

LISA M. MONTEGGIA, WILLIAM A. CARLEZON, JR., AND RALPH J. DILEONE

INTRODUCTION

Genetics researchers often utilize the study of mutants to better understand the function of genes. For many decades, the field used mutation analysis to identify important genes. However, the completion of the genome project and the development of high-throughput genomic techniques have made it possible to rapidly evaluate expression of hundreds of genes. These approaches can be used on populations of RNA or protein from specific tissue sources or cell types, and have resulted in a massive influx of gene regulatory data. While expression changes under different conditions may suggest a function, it is necessary to conduct more traditional genetic analysis in model organisms to define gene function. This conversion of extensive genomic data to *functional* genomic understanding is multidisciplinary and has implications for many fields, including psychiatry.

Mutant analysis in model systems has helped to define and elucidate signal transduction pathways and transcriptional hierarchies. While yeast, flies, and worms have helped define basic genetic pathways, the use of mice as the representative organism of complex mammalian systems has become increasingly popular. The mouse is particularly relevant in neuroscience and psychiatry, where the development of effective models is dependent on complex mammalian brain circuitry and behavior. Although the current technology will be emphasized here, the infrastructure established over decades of work made the modern techniques both possible and more powerful.

The extensive history of mouse studies has enabled large-scale efforts to understand gene function. A consortium of mutagenesis centers has generated novel mouse mutants that will likely provide new insights into the pathophysiology of neurobiological and psychiatric disorders. However, modern mouse research also takes advantage of transgenics and targeted gene knockouts, where specific genes are added or removed from the mouse genome. This “reverse genetic” strategy (from a cloned gene to mutant animal) has redefined experimental possibilities and has dominated the landscape of mouse genetics for the last 20 years. As new genes are implicated in a biological process, it is possible to directly assess their relevance in a complete animal system. The reverse genetic approach is increasingly needed since the completion of the genome project has shown that a large number of genes

cannot be placed into a functional category from their primary sequence information.

This chapter focuses on how genetic animal models are relevant for advancing our understanding of psychiatric disorders. The creation of genetically modified animal models has led to our ability to study the contribution of individual genes and their products in the brain. These genetic models have also complemented and extended our understanding of heuristic and pharmacological models of psychiatric diseases. We will discuss conventional approaches to generating transgenic mice, in which a gene of interest is added to the animal, and knockout mice, in which a gene of interest is disrupted or inactivated. We will also address technologies such as viral-mediated gene transfer that allow for spatial and temporal control over gene function. The use of these technical advances has elevated the use of the rat, another well-studied model in neurobiology and behavioral studies, as a genetic model. Finally, many of these transgenic techniques, especially viral-mediated gene transfer, are being used with a powerful new system, called optogenetics, whereby specific sets of neurons are controlled with pulses of light. Optogenetics depends upon expression of light-activated ion channels, or pumps, to elicit action potential firing or to suppress activity in neurons. Transgenic resources have thus become more important in the field, since they allow for control of specific neurons with light (Tye and Deisseroth, 2012).

TRANSGENIC MICE

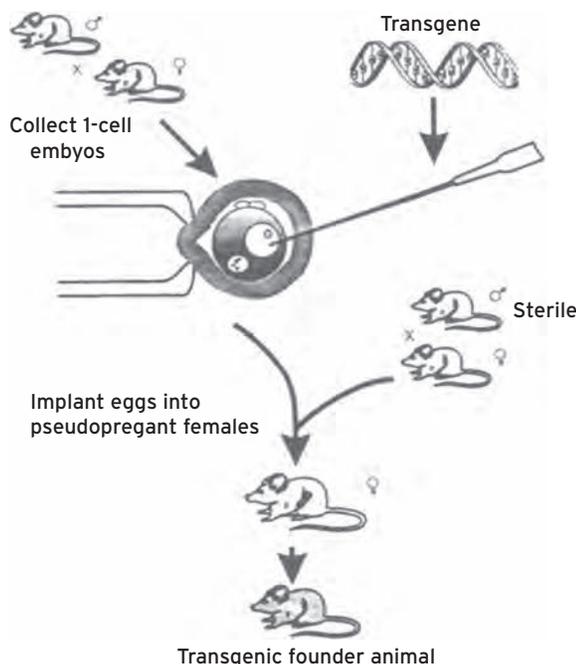

Transgenic mice are created by adding DNA directly to the genome (Box 8.1). As the first efficient approach to taking previously isolated genes and evaluating possible functions *in vivo*, this technique revolutionized mouse genetics by allowing for direct tests of gene function in an entire animal system. Transgenic experiments are often used to: (1) overexpress a gene at high levels, (2) misexpress a gene in the wrong place or at the wrong time, (3) express a mutant or modified form of a gene, or (4) study gene regulation via reporter gene constructs. Gene overexpression can yield important information of the dosage sensitivity of the gene product while misexpression experiments can indicate whether or not a gene will cause defects when abnormally expressed. Expression of certain

mutant forms can also be used to reduce the function of the endogenous gene (“dominant negative”).

Transgenic mouse lines can be made and established rapidly. Transgenic mice are generated via nuclear microinjection of cloned DNA into fertilized mouse eggs. The DNA construct usually inserts into a single random site of the genome as multiple copies (usually between 5 and 50). Since this transgene integration often occurs at the one- or two-cell stage, the transgenic founder mouse contains the transgenes in most cell types and can pass the transgene directly to progeny. Expression is then mediated by regulatory elements contained within the original construct (Box 8.1). However, transgene expression is usually influenced by DNA sequences surrounding the insertion site,

BOX 8.1 TRANSGENIC MICE PRODUCTION: TRANSGENIC DISEASE MODELS

Transgenic mice are commonly used to model human disease states and to test hypotheses concerning the genetic causes of the disease. The isolation of genes that cause neurological disease has allowed transgenic mice to be used to model the disease by directly mimicking the genetic cause found in patients. For example, mice over-expressing mutant forms of superoxide dismutase (SOD1) developed muscle atrophy, neurodegeneration, and death that is seen in human amyotrophic lateral sclerosis (ALS) cases (Gurney et al., 1994). Similarly, the cellular and molecular mechanisms of polyglutamine disorders, such as spinocerebellar ataxia, have been modeled and better understood by studying mouse models generated via transgenic expression of mutant proteins (Heintz and Zoghbi, 2000). In the case of Alzheimer’s disease, overexpression of mutant forms of amyloid precursor protein (APP) has been used to test hypotheses and generate powerful disease models (Box 8.2).

Adapted from Richardson A., Heydari A.R., Morgan W.W., Nelson J.F., Sharp Z.D., and Walter C.A. (1997). The use of transgenic mice in aging research. *Inst. Lab. Anim. Res. J.* 38:124–127.

which necessitates the creation and characterization of multiple founder mice to find lines with the desired expression patterns. This concern is mitigated by use of larger pieces of DNA as described next.

LARGE-CLONE TRANSGENICS AND DISEASE MODELS

Traditional transgenics are made with relatively small DNA constructs (3–25 kilobases) that can be generated through standard cloning techniques. While sufficient for many experiments, the complexity of gene regulation, and the large size of mammalian genes, often demands the use of larger fragments of DNA to effectively model gene regulation and disease states. Large-clone transgenics are made using bacterial artificial chromosomes (BACs) and yeast artificial chromosomes (YACs) (Heintz, 2001). BACs are large circular DNA plasmids that allow long stretches of DNA to be cloned and propagated in bacteria. BACs can be used to successfully propagate up to 300 kilobases (300,000 base pairs [bp]) of mammalian DNA in bacteria while YACs can propagate over 1,000 kilobases (1,000,000 base pairs) of mammalian DNA in yeast, allowing for transgenics to be made with entire genes and surrounding genomic regulatory sequences. Large-clone transgenics have been used to effectively model diseases that are caused by mutations in large genes. The accurate expression of the mutant form is likely to yield models that most closely mimic the human pathology. For example, YACs containing the entire human Huntingtin protein have been used to model Huntington’s disease (Hodgson et al., 1999). The YACs were modified to express the glutamine repeats that are found in individuals with the disease. Mice transgenic for these constructs developed the cellular, physiological, and behavioral characteristics similar to human Huntington’s patients, including selective striatal neurodegeneration. Transgenic approaches have also been useful in delineating the role of the amyloid precursor protein (APP) in Alzheimer’s disease (Box 8.2).

Large-clone transgenics have also used to determine the significance of gene dosage effects on behavior and disease states. For example, DNA around the Down syndrome candidate region was introduced via large-clone transgenics and mice were screened for learning abnormalities. This led to identification of the minibrain-related gene, *Dyrk-1*, as a candidate gene for Down syndrome (Smith et al., 1997). The large size of most mammalian genes necessitates the large-clone approach for these studies.

BAC TRANSGENICS AS REPORTER GENES

Another powerful application of large-scale clones has been the generation of reporter lines that express readily detectable marker proteins, such as green fluorescent protein (GFP). By using BACs surrounding specific genes, a series of mouse lines have been generated that allow researchers to detect, study, and isolate specific neuron populations that are otherwise difficult to detect (Heintz, 2004). These BAC reporter mice have been used to distinguish direct and indirect output neurons within the striatum, allowing for definitive characterization

BOX 8.2 TRANSGENICS AND ALZHEIMER'S DISEASE

Alzheimer's disease (AD) is a neurodegenerative disease characterized by a gradual decline in cognition and memory over a period of years. The neuropathology of AD is marked by the presence of extracellular senile plaques and intracellular neurofibrillary tangles. While the debate over the causative factor for AD remains controversial, growing evidence suggests plaques are required for the development of AD. Plaques are generated by accumulation of a 42-amino acid amyloid β protein ($A\beta$), which is derived from the amyloid precursor protein (APP). Genetic studies have identified mutations in the *APP* gene and in the presenilin genes (*PS1* and *PS2*) in familial forms of AD. Disorders that lead to the oversecretion of APP result in Alzheimer's disease-like syndromes.

Transgenic mice overexpressing APP and presenilin mutations have been used to model AD. The first successful attempt, using a platelet-derived growth factor promoter to drive expression of a familial APP mutation, resulted in mice with elevated levels of APP as well as increased amyloid deposits (Games et al., 1995; Masliah, 1996). More recently, transgenics have been generated that link the elevated APP to learning and memory deficits (Hsiao, 1996; Moran et al., 1995). Transgenic mice coexpressing the wild-type human *APP* gene and various *PS1* mutations exhibited high levels of $A\beta$ in the brain, suggesting the *PS1* mutations may influence $A\beta$ production and contribute to the pathology of the disease (Citron et al., 1997). This model has recently been used to test the effectiveness of immunomodulatory therapy (Janus et al., 2000; Morgan et al., 2000). The ability of transgenic mice to model aspects of AD represents a major advancement toward understanding the pathophysiology of this disease

Specific behaviors, such as certain paradigms in addiction, have been better studied in rat models, and transgenic rats have been used in recent work. For example, use of rats transgenic for a reporter gene that is activated in neurons (*cFos-lacZ*) allowed researchers to isolate and study neurons that are activated after exposure to cocaine, or a context associated with cocaine (Koya et al., 2009). Other investigators have generated rat lines that allow genetic or optogenetic manipulation of dopamine or acetylcholine neurons (Witten et al., 2011).

CONVENTIONAL KNOCKOUT MICE

Transgenic mice created via microinjection allow for efficient gain-of-function analysis or expression of exogenous molecules. Although this approach is powerful and can be used to model a subset of diseases, there was still a need to test the necessity of gene products via loss-of-function analysis. The goal of removing genes in a directed fashion motivated a number of approaches to modify the endogenous genes within the mouse genome. Ultimately, the knockout strategy depended upon modifying the genome of embryonic stem (ES) cell lines and subsequently generating a mouse from the modified cell lines.

Early research on cell lines derived from early embryos and embryonic carcinomas indicated that these lines could retain totipotency, or the ability to give rise to all differentiated cell types of the mouse. Cells derived from the inner cell mass of a mouse blastula were used to establish the first embryonic stem cell lines. Importantly, ES cell lines could be cultured and frozen, and they allowed recombination to occur between introduced DNA and homologous sequences in the cellular genome (Fig. 8.1). However, the rates of recombination that occur in ES cells are very low compared with random insertion events. To select for the rare recombination event, a "positive-negative" strategy was developed to select for inserts into the desired (homologous) position, while selecting against random insertions (Mansour et al., 1988). After a single copy (maternal or paternal) of the gene was modified, the cells were expanded and introduced into a developing mouse embryo. The cells became incorporated into the developing embryo, and the resulting founder mouse was a mosaic of wild-type cells and mutant cells. This founder must be bred to confirm the presence of the transgene in the progeny. Finally, progeny were mated to generate mice that were missing both copies of the gene (homozygous mutants).

Knockouts originally used a replacement strategy to exchange an endogenous gene with a neomycin-resistant gene cassette (PGK-neo^r). Later generation knockouts took advantage of the recombination event to replace the original gene with a reporter gene or a mutated version of an original gene. These "knock-in" studies yielded powerful data on gene expression and gene redundancy and are now standard practice in current gene analysis. This strategy could be used to misexpress a gene as with transgenic microinjections. Although more time-consuming than traditional transgenic approaches, no knowledge of regulatory elements is required since placing the

of different electrophysiological properties in these important neurons (Kreitzer and Malenka, 2007). Likewise, these same BACs can be used to express proteins, such as Cre recombinase, that allow investigators to target genetic manipulations to specific neuronal types. These Cre driver lines are critical in conditional knockout and transgenic mice, which are discussed in more detail later in the chapter.

RAT TRANSGENIC MODELS

While less common, transgenic rats have been made and are powerful tools for assessing physiology or behavior that is better characterized in rat models. For example, a transgenic model of Huntington's disease was generated in rats to allow for longitudinal imaging studies in a larger brain (von Hörsten et al., 2003). Working memory deficits have been characterized in transgenic rats overexpressing the adenosine receptor (A_{2A}) in the rat brain (Giménez-Llort et al., 2007). In addition, transgenic reporter rats have been generated for the study of circadian rhythms (Yamazaki et al., 2000). As the generation of transgenic rats becomes more efficient, including application of large-clone techniques, rat reporter and disease models will become more common and more powerful for behavioral and psychiatric research.

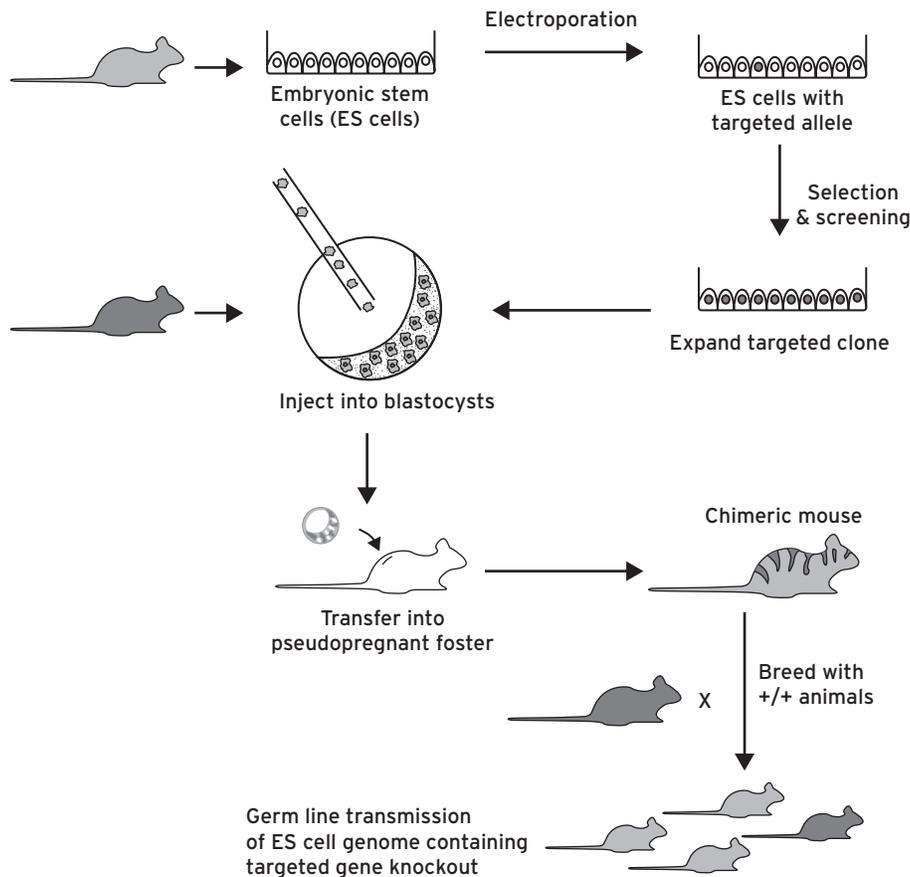

Figure 8.1 Knockout mouse production. Adapted from Joyner A. (2000). *Gene Targeting: A Practical Approach*. New York: Oxford University Press.

new gene into the same position of the genome should ensure correct expression.

KNOCKOUT DISEASE MODELS

Many human neurological and psychiatric diseases are likely to be due to loss of gene function that cannot be readily modeled with transgenics. For example, a subset of dominant human mutations is caused by loss of function of only one gene copy. This is known as *haplo-insufficiency* and is best modeled by evaluating heterozygote mice that are missing only one copy of a gene. This is particularly relevant and best studied in cancer models, where heterozygote mutant mice are more prone to tumor formation due to somatic loss of the normal copy. However, it is also possible that a loss of a single copy of a gene is sufficient to recapitulate aspects of psychiatric diseases in animal models. Recently, it was found that animals missing only one copy of the *Reeler* gene displayed gene expression changes as well as dendritic defects similar to those found in postmortem tissue from schizophrenic patients (Liu et al., 2001). It may be useful to conduct more widespread and thorough behavioral testing on heterozygous mice to evaluate the effects of reduced gene expression on behavior.

Like transgenic mice, knockout mice can be used to target specific genes in order to test a hypothesis or model a disease state. Box 8.3 and Table 8.1 highlight results obtained from knockout studies on molecules related to the dopamine

system, which have clearly helped to elucidate the specific role of receptors, enzymes, and proteins. Knockouts have also been useful in testing the specificity and effects of pharmacological agents. By completely removing a receptor, for example, knockout mice can be screened for the effects of various drugs. For example, mice missing the 5-HT_{2C} receptor have a paradoxical locomotor increase in response to the nonselective serotonin agonist *m*-chlorophenylpiperazine, which normally induces a locomotor decrease (Heisler and Tecott, 2000). It was subsequently discovered that the agonist was acting on 5-HT_{1B} receptors in the absence of 5-HT_{2C}, revealing the dependence of drug response on the genetic constitution of the individual.

While genetic knockout studies have traditionally focused on the use of mice, the completion of the rat genome project (Gibbs et al., 2004), and the extensive history and use of rats in studying behavior and modeling psychiatric disease, has motivated efforts for generating rat knockouts. There are mutagenesis strategies being used to systematically generate a large set of rat knockouts (Smits et al., 2006). This will undoubtedly lead to more use of rat knockouts for modeling behavior and psychiatric disease.

LIMITATIONS OF KNOCKOUT MICE

Early studies with knockout mice produced many surprises while also exposing a number of limitations. A drawback of knockout mice is that there can be functional redundancy of many gene products, leading to a lack of an appreciated phenotype.

BOX 8.3 KNOCKOUTS AND THE DOPAMINERGIC SYSTEM

Dopamine (DA) plays an important role in Parkinson's disease, drug addiction, and schizophrenia among other neuropsychiatric diseases. However, the role of individual components of the dopaminergic system in these disorders remains unknown. The ability to knock out specific genes involved in DA synthesis, release, signaling, and reuptake allows for a comparison of specific genetic alterations with pharmacological models of these disorders.

Dopamine (DA) is synthesized from tyrosine by tyrosine hydroxylase (TH) in the nerve cell cytoplasm and then loaded onto vesicles by vesicular monoamine transporters (VMATs). Once dopamine is released from the synapse, it can (1) activate either presynaptic (D2) or postsynaptic (D1–D5) dopamine receptors, (2) be degraded by catechol-O-methyl transferase (COMT) or monoamine oxidase (MAO), or (3) be taken up by a plasma membrane transporter (DAT).

Mice that lack TH die at birth, implicating catecholamines in fetal development (Zhou et al., 1995). The loss of VMAT disrupts the ability of dopamine to be loaded in the synaptic vesicles and results in mice that die shortly after birth (Takahashi et al., 1997; Wang et al., 1997). In contrast, knockouts of all of the dopamine receptor genes (D1–D5) are viable with mild alterations in locomotor activity (Accili et al., 1996; Baik et al., 1995; Clifford et al., 1998; Dulawa et al., 1999; Holmes et al., 2001; Kelly et al., 1998; Rubinstein et al., 1997; Xu et al., 1994, 1997). The loss of the DA degradative enzymes does not produce alterations in locomotor activity but does result in increased aggression and reactivity to stress (Gogos et al., 1998; Shih et al., 1999). The DAT knockouts have high extracellular DA concentration and display alterations in various behavioral abnormalities, including deficits in spatial cognitive function and sensorimotor gating (Giros et al., 1996; Jones et al., 1998). These knockouts of the dopaminergic system allow for a comparison of specific genetic alterations with pharmacological models of psychiatric and neurological disorders and may contribute to new therapeutic approaches in drug discovery.

Nevertheless, the use of knockout mice can also produce valuable information regarding the particular gene of interest as long as caveats of the model are appreciated. Recent genetic studies have identified several mutations, copy number variations, and other alterations associated with neuropsychiatric disorders with several reports focused in particular on autism and schizophrenia. The generation of animal models that mimic these abnormalities can have a strong impact on treatment advance, as they will enable detailed examination of neuronal circuit abnormalities derived from these genetic malformations. However, it is important to note that modeling complex genetic modifications in mice is difficult. For instance, alterations in methylation patterns, large gene deletions, or even single nucleotide polymorphisms may have distinct effects depending on the species in question. Moreover, chromosomal abnormalities such as those associated with Down syndrome are hard to replicate in mice. Nevertheless, these attempts will likely yield novel insight as

TABLE 8.1. Knockouts and the dopaminergic system

KNOCKOUT MICE	PHENOTYPES
Tyrosine hydroxylase (TH)	Lethal (Zhou and Palmiter, 1995)
VMAT2	Lethal (Takahashi et al., 1997; Wang et al., 1997)
D1 DA receptor	Hyperactivity, spatial learning deficit (Clifford et al., 1998; Xu et al., 1994)
D2 DA receptor	Hypoactive, some dysfunction of prepulse inhibition (PPI) sensorimotor gating (Baik et al., 1995; Kelly et al., 1998)
D3 DA receptor	Hyperactive (Accili et al., 1996; Xu et al., 1997)
D4 DA receptor	Hypoactive (Dulawa et al., 1999; Rubinstein et al., 1997)
D5 DA receptor	Normal (Holmes et al., 2001)
COMT	Normal activity; increased aggression, impairment of emotional reactivity (Gogos et al., 1998)
MAO-A	Normal activity; increased aggression, more reactive to stress (for review, see Shih et al., 1999)
MAO-B	Normal activity; more reactive to stress (for review, see Shih et al., 1999)
DAT	Hyperactive, deficits in PPI sensorimotor gating and spatial cognitive impairments (Giros et al., 1996; Jones et al., 1998)

long as they are well-executed studies done in a well-controlled manner by avoiding overinterpretation of the model.

Another limitation in studying constitutive knockout mice is the occurrence of lethality that can occur if a critical gene is deleted. Since developmental biologists did most of the early work, the early terminal phenotypes that were often observed were of interest. However, early lethality precludes studies of gene function in adult animals demanding use of conditional mutagenesis strategies that are outlined in the next section. Combining knockouts and transgenics can be used to overcome this limitation. For example, by generating a tyrosine hydroxylase (TH) knockout mouse that has been genetically engineered to express the *TH* gene only in noradrenergic cells, it is possible to generate a mouse that is missing dopamine and yet creates normal norepinephrine (Zhou and Palmiter, 1995). These dopamine-deficient mice survive until birth, indicating that the fetal lethality of constitutive tyrosine hydroxylase knockout mice was caused by the lack of norepinephrine. These mice can be kept alive via daily injections of L-DOPA and have been used extensively to better evaluate the function of dopamine in locomotion, nest building, and feeding. While this strategy was used successfully, it is not always possible to develop effective rescue experiments. More recent work has established strategies for better control of transgenic and knockout effects.

CONDITIONAL CONTROL OF GENE EXPRESSION

The ideal system to control gene expression would be a “genetic switch” that can be operated at will to turn genes on or off. Newer transgenic models are taking advantage of these inducible systems to clearly define the relationship between the transgene expression and the phenotype. In these models, the transgenic expression is regulated temporally by administration of an exogenous agent. Most approaches involve the use of a binary system, or two-gene system, in which one transgene controls the expression of a second. Binary systems that control gene expression can be classified into two groups: (1) transcriptional transactivator systems, to overexpress a gene of interest, and (2) site-specific recombination systems, to knock out a gene of interest (Fig. 8.2).

TRANSCRIPTIONAL TRANSACTIVATOR SYSTEMS

There are many different types of transcriptional transactivator systems; here we focus on the most commonly used system, the tetracycline gene regulation system (Gossen and Bujard, 1992). In this system, the first transgene encodes the tetracycline transactivator (tTA) under the control of enhancer sequences that dictate expression patterns. The second transgene encodes the gene of interest to be overexpressed under the control of a tetracycline responsive promoter (TetOp) (Fig. 8.2A). In this system, tTA binds to TetOp and results in transcription on the gene of interest unless tetracycline (or, doxycycline, a

tetracycline analogue that can cross the blood–brain barrier) is present. Tetracycline interferes with the ability of tTA to bind to TetOp and drive expression of the gene of interest and is referred to as the “tet-off” system. Thus, mice remain treated with doxycycline until the time the researcher wants to study the overexpression of the gene. This is an inducible system because the gene of interest is controlled by the presence or absence of doxycycline. It is also a cell-targeted system, since the transgene of interest will only be expressed in those cells that express tTA, which is controlled by the choice of promoter in the first transgene construct.

INDUCIBLE TRANSGENICS AND DISEASE MODELS

The tetracycline gene regulation system has been used to successfully overexpress genes in the central nervous system. The first published report overexpressed the calcium-calmodulin-dependent protein kinase II (CaMKII) selectively within the hippocampus of adult mice (Mayford et al., 1996). The resulting mice had cellular phenotypes including impaired functioning of place cells as well as decrements in long-term potentiation within the hippocampus. These mice also had a decrement in spatial learning, which is thought to be a hippocampal-dependent task. These findings suggest that CaMKII is an important step in cellular and behavioral forms of plasticity and highlight the functional importance of the gene in the hippocampus.

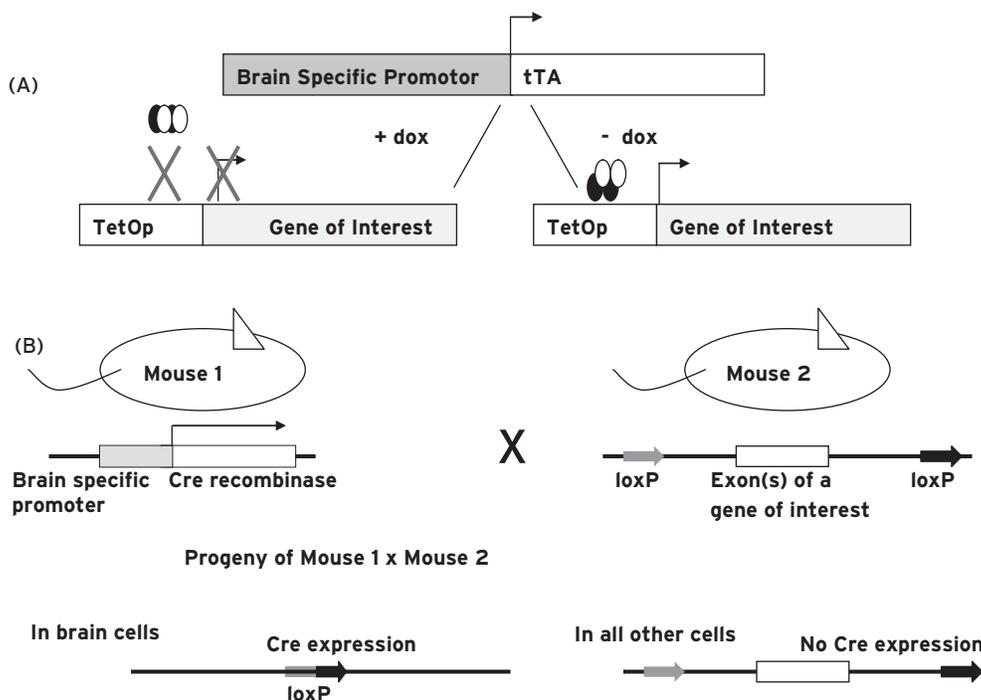

Figure 8.2 Binary systems for gene induction and removal. A, Schematic of the tetracycline transactivator system for the generation of double transgenic animals. In this system, a brain-specific promoter drives expression of the tetracycline transactivator (tTA) gene selectively to the brain. In the presence of doxycycline (dox), a tetracycline analogue, tTA cannot bind to its promoter (TetOp), and the gene of interest is not expressed. In the absence of dox, tTA binds to TetOp and results in transcription of the gene of interest selectively to the brain. B, Schematic of the Cre/loxP system for conditional knockouts: Genetic techniques are used to express Cre recombinase under the control of a brain-specific promoter. A second construct contains loxP sites flanking a critical region of the gene to be knocked out. The two lines of mice are crossed, and resulting bigenic mice show a loss of the gene of interest, which occurs at the time of development and selectively in those cells in the brain in which the brain-specific promoter is active. The gene of interest is expressed at wild-type levels in cells not expressing Cre recombinase.

Other studies have direct implications for better understanding of brain disease. For example, Yamamoto et al. (2000) found that the neuropathology and motor dysfunction caused by overexpression of huntingtin were reversible by simply turning off the transgene. This has important mechanistic implications that are relevant to the development of effective therapeutics. In contrast, the inducible transgenic strategy has been used to show that 5-HT_{1A} serotonin receptor function is required during development, and not in the adult, to produce normal anxiety responses in mice (Gross et al., 2002). Another use of inducible transgenic technology is to mimic molecular changes that may be seen in psychiatric disease states as exemplified in Box 8.4.

There are many advantages of the tetracycline gene-regulated system, including the reversibility of the system and the ability to target it to a specific cell type with the use of a cell type-specific enhancer/promoter. There are, however, also limitations to the system. First, the dynamics of gene induction is relatively slow (hours to days) since this system requires the mice to be removed from doxycycline to induce expression of the target gene of interest. Second, transgene expression can be influenced by the position that it has inserted into the genome and not just by the promoter that is driving its expression. While these concerns are of importance, the tetracycline gene-regulated system is still being used with remarkable

BOX 8.4 OVEREXPRESSION OF Δ FosB AND THE LINK TO DRUG ABUSE

Chronic exposure to many drugs of abuse (e.g., cocaine, amphetamine, morphine, and nicotine) results in the accumulation of the transcription factor Δ FosB in the striatum. Δ FosB is a protein that, once induced, persists for a very long time in the brain. The striatum regions are important for mediating many behavioral aspects of addiction. The molecular mechanisms that are responsible for the long-term induction of Δ FosB in the striatum may represent one biological basis underlying the transition from a nonaddicted to an addicted state.

The tetracycline gene-regulated system has been used to successfully overexpress the transcription factor Δ FosB to the striatum region of the brain (Chen et al., 1998). The resulting mice were more responsive to the rewarding effects of cocaine (Kelz et al., 1999). The use of additional genomic technologies (i.e., viral-mediated gene transfer) has provided evidence that Δ FosB-associated upregulation of GluR2 (an AMPA glutamate receptor) causes, at least in part, the increases in sensitivity to cocaine (Kelz et al., 1999) and other types of rewards (Todtenkopf et al., 2006) (See Fig. 8.3). Interestingly, in a parallel set of experiments with the tetracycline gene-regulated system, mice were generated that overexpress a dominant-negative inhibitor of Δ FosB in the striatum, and these mice were less responsive to cocaine (Peakman et al., 2003). These findings demonstrate a direct role for Δ FosB in the rewarding properties of cocaine and may suggest a role for this molecule in promoting a switch from casual drug use to addiction. By limiting overexpression of Δ FosB in adult mice, this molecular phenotype is mimicked without the potential developmental effects that might have been caused by more traditional transgenic analysis.

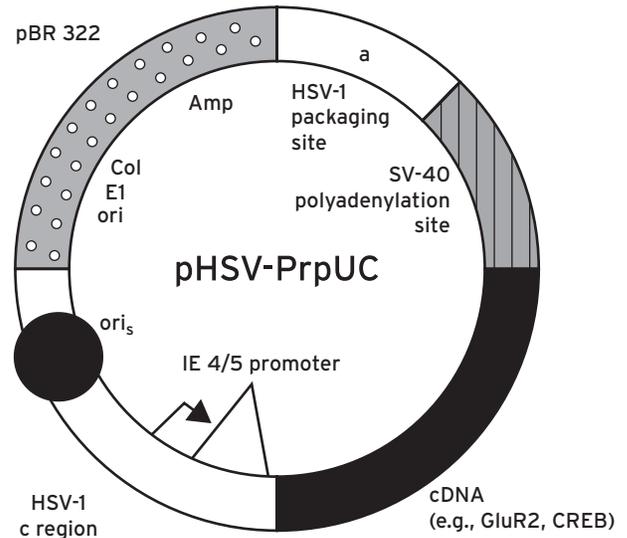

Figure 8.3 The amplicon (plasmid-based) vector HSV-PrpUC, into which foreign cDNA (e.g., that encoding GluR2, cAMP-responsive element binding protein [CREB]) is subcloned. The viral backbone contains minimal wild-type viral genes and relies upon specially engineered cell lines for propagation and helper virus to produce the proteins needed for packaging.

success to study the function of genes in the adult nervous system. These inducible transgenic systems are of particular use in psychiatry, where minor developmental disturbances could have subtle, but persistent repercussions.

SITE-SPECIFIC RECOMBINATION SYSTEMS

One way to target a genetic deletion in a regionally and temporally dependent manner is with site-specific recombination. Site-specific recombinases are enzymes that catalyze recombination between specific DNA sites. The Cre recombinase from P1 bacteriophage is the most widely used enzyme. Cre recognizes a 34-bp site (loxP, or locus of recombination) to catalyze recombination. If two loxP sites are placed in the same orientation on a piece of DNA, the region between the two sites will be excised by the recombinase (Nagy, 2000).

Recombinase sites are not normally found in the mammalian genome. The recombinase sites are inserted into the genome of ES cells by homologous recombination such that the sites flank an exon (or exons) of a gene of interest. The gene with flanking recombinase sites is referred to as a “floxed” gene. The recombinase sites should be placed in the genome so as not to interfere with the expression or function of the gene of interest before the recombination event. A selection strategy is employed to identify those ES cells containing the floxed gene in a similar manner to that used to generate a conventional knockout (see Fig. 8.1). The resulting floxed mice still have the functional endogenous gene because the Cre recombinase has not yet been introduced into the system. To obtain a knockout of the targeted gene, the floxed mouse is bred to a second mouse in which a regional or cell type-specific transcriptional promoter controls Cre recombinase expression (Fig. 8.2B). These mice are referred to as “conditional” knockouts, since the knockout occurs only in certain regions and is dependent on Cre recombinase expression

(Box 8.5). This approach has proved quite useful in the development of adult knockout mice where the traditional knockout of the gene is fatal and has moved us closer to understanding the function of specific genes (in the brain) and modeling human genetic diseases. Alternatively, viral vectors (see the following) expressing Cre recombinase can be used to ablate expression of floxed genes at various times during development or to selectively delete a gene of interest in a particular brain region. The use of a viral-mediated approach is often used when there is not a specific regional or cell type-specific transcriptional promoter that would target the brain region of interest and thus turn Cre recombinase on in the appropriate site. The viral-mediated approach can circumvent this problem but relies on a surgical approach for each animal to inject the viral vector into the selected region of interest.

BOX 8.5 CRE-DRIVEN LINES CAN INFLUENCE THE PHENOTYPE OF THE CONDITIONAL KNOCKOUT

Recently, conditional knockouts of neurotrophin 3 (NT-3) were generated to study the role of this growth factor in adult brain. Traditional knockouts of NT-3 die shortly after birth. Two independent groups have generated conditional NT-3 knockouts in which the loss of NT-3 is restricted to the brain and the conditional NT-3 knockouts survive into adulthood. The first group generated conditional NT-3 knockouts by crossing floxed NT-3 mice with animals expressing Cre recombinase under the control of the neural-specific promoter, synapsin 1 (Ma et al., 1999). The conditional knockouts had an ablation of NT-3 in many regions of the brain, including the hippocampus. These conditional knockouts were examined in several parameters of synaptic transmission and displayed no difference between wild-type controls, suggesting that NT-3 does not play a role in synaptic transmission and some forms of hippocampal-dependent learning. The second group used the neural-specific nestin promoter to drive Cre expression in floxed NT-3 mice (Akbarian et al., 2001). These nestin-Cre expressing mice caused a more widespread pattern of NT-3 loss in the brain than the synapsin 1-Cre expressing mice. In contrast to the synapsin-Cre results, the nestin-Cre NT-3 conditional knockouts established a role for this growth factor in modulating noradrenergic function and opiate withdrawal in the brain.

The conditional knockouts generated by the two different groups resulted in progeny with different patterns of NT-3 loss in the brain and different reported phenotypes. This example illustrates the importance of using different Cre-driven expression lines to elucidate “gene–function” relationships in conditional knockouts. However, there are many important limitations with the currently available Cre-driven expression lines. First, there are not many enhancer and promoter sequences that are successful in expressing Cre recombinase specifically to the brain, let alone to particular regions or cell types. Second, many of these promoters do not express the Cre recombinase in the predicted locations. One approach is to identify better regulatory sequences to drive recombinase expression. Alternatively, knocking the recombinase directly into a known genetic locus by homologous recombination may allow for better control of its expression.

The first successful attempt of a conditional brain-specific gene knockout was the ionotropic glutamate receptor *N*-methyl-D-aspartate (*NMDAR1*) gene. The *NMDAR1* gene is an obligatory subunit of NMDA receptors. A floxed *NMDAR1* mouse was crossed with a transgenic line expressing Cre under the control of the calcium-calmodulin-dependent kinase II (CaMKII) promoter. The CaMKII promoter turns on Cre recombinase in specific regions of the brain without any peripheral expression. The resulting mice displayed a relatively selective knockout of *NMDAR1* in the hippocampus that resulted in an impairment in hippocampal long-term potentiation and spatial memory. These cellular and behavioral phenotypes provided support for the view that endogenous *NMDAR1* is important in hippocampal-dependent tasks (McHugh et al., 1996; Shimizu et al., 2000; Tsien et al., 1996a, b).

CONDITIONAL KNOCKOUTS AND DISEASE MODELS

Conditional knockouts have also been used to model aspects of Rett syndrome (RTT), a childhood neurological disorder that occurs almost exclusively in females. An exciting recent discovery has been the identification of the gene responsible for RTT (Amir et al., 1999). The majority of Rett syndrome is caused by mutations in the methyl-CpG-binding protein (*MeCP2*) gene located on the X chromosome (Wan et al., 1999). The *MeCP2* gene encodes a protein that binds to methylated DNA. Original attempts to knock out the *MeCP2* gene by traditional knockout approaches resulted in early lethality of the mice. Conditional knockout techniques resulted in the generation of viable mice that have a neurological phenotype similar to human RTT (Chen et al., 2001; Guy et al., 2001). Behavioral characterization of the conditional *MeCP2* knockout mice showed that the loss of this gene in broad forebrain regions was sufficient to mediate behavioral aspects of the disorder and starts to provide a framework of the brain regions that may be important in mediating some of these behavioral components of the disease (Gemelli et al., 2006). A mouse model that recapitulates aspects of a human disorder is a major advancement in studying this disease and may provide a model in which pharmacological agents can be tested for prevention or possible reversal of the behavioral phenotypes. In an important extension of this work, recent work demonstrated that reintroduction of *MeCP2* in adult *MeCP2* constitutive knockout mice rescues the disease phenotype supporting an acute rather than a developmental role for *MeCP2* in neuronal function (Guy et al., 2007). In addition, in another set of experiments the deletion of *MeCP2* in distinct age windows uncovered a divergent requirement for *MeCP2* at distinct developmental stages (Cheval et al., 2012). Overall, these studies on *MeCP2* provide a road map on how to take advantage of the conditional expression/deletion mouse model to recapitulate disease phenotype in a developmentally specific manner.

Conditional knockouts are also showing great promise in elucidating the genetics of synaptic vesicle function. Synaptic vesicles influence neurotransmitter release and thus play important roles in mediating synaptic transmission. There are a vast number of synaptic vesicle proteins, of which the majority have been knocked out by traditional genetic approaches.

Traditional knockouts have provided support for the role of many of these proteins in neurotransmitter release, but their functional redundancy and lack of regional specificity make it difficult to assess their role in individual neurotransmitter systems. This limitation is particularly important in diseases that are thought to be due to imbalances of particular neurotransmitter systems such as schizophrenia that may be due to an elevated dopaminergic and reduced glutaminergic transmission. The ability to target a knockout to a particular brain region in delineating the role of these particular proteins to specific neurotransmitter systems may contribute to our understanding of particular molecular mechanisms of psychiatric illnesses (Fernandez-Chacón and Sudhof, 1999).

VIRAL-MEDIATED GENE TRANSFER

Another strategy for genetic intervention in the brain is to engineer viral vectors that carry a specific gene (or coding sequence) of interest. These constructs can then be microinjected directly into discrete brain regions. This technique exploits the natural ability of viruses to deliver genetic material to cells. When delivered to the brain, these vectors cause infected cells to express (or, in the case of endogenous genes, overexpress) transferred genes (transgenes) or sequences. Vectors can be used to increase the expression of endogenous genes, mutated genes (e.g., encoding dominant-negative proteins), or siRNA. As such, viral-mediated gene transfer complements the use of mutant (knockout or transgenic) mice in neuropsychiatric research and is particularly useful when the goal is to manipulate expression of a single gene (1) in a specific brain region (2) at a specific time (3) in animals that developed normally.

There are several types of viruses that can be adapted for use as viral vectors, including those based on herpes simplex virus (HSV-1), adenovirus (AV), adeno-associated virus (AAV), lentivirus (LV), and more recently, canine adenovirus (CAV). Considering that each type of vector has unique advantages and disadvantages (see Carlezon et al., 2000b; Neve et al., 2005), the selection of the most appropriate viral backbone depends upon the goals of the experiment. For example, HSV (Fig. 8.3) is an excellent vector when targeting neurons because it is naturally neurotropic and it accommodates relatively large foreign cDNA sequences, but it is associated with a short duration (~5 days) of transgene expression. AV, on the other hand, is associated with a longer duration of transgene expression (months), but it is not selective for neurons and can elicit immune responses in the host. AAV elicits less of an immune response, but it can accommodate only small foreign cDNA sequences, thereby restricting the genes that can be transferred. LV vectors—which belong to the same class of viruses as the human immunodeficiency virus (HIV)—integrate into the host DNA and cause permanent increases in transgene expression but are often associated with biosafety concerns. CAV is of interest because it is neurogenic and retrogradely transported (Soudais et al., 2001) and thus can be used to express or ablate genes within specific neuronal pathways.

Generally, viral vectors are replication deficient: they transfer the gene (or sequence) of interest into cells, but they lack the genes that enable the wild-type virus to replicate or cause a destructive (lytic) infection. Currently, there are two types of replication-deficient vectors. *Genomic* vectors can be conceptualized as “guttled” viruses; the starting point is a competent virus from which harmful (lytic) genes have been removed, and to which the foreign cDNA has been added (for review, see Fink et al., 1996). Conversely, *amplicon* vectors (see Fig. 8.3) can be conceptualized as “modular” viruses; the starting point is a plasmid (amplicon) carrying the exogenous gene, to which minimal viral sequences are added that allow it to be packaged into virus particles with the aid of a helper virus and specialized cell lines (for review, see Carlezon et al., 2000b; Neve et al., 2005).

Typically in neuropsychiatric research, small quantities of viral vectors (for a rat or mouse, 1–2 μ l) are microinjected directly into discrete brain regions during stereotaxic surgery. Following a period of time that allows transgene expression to increase (or to increase and then wane), the consequences of increased transgene expression are evaluated in biochemical or behavioral assays. For a viral vector to have utility for this type of research (or ultimately, for gene therapy), the consequences of increased transgene expression must be detectable against the damage caused by the delivery procedure and any cytopathic effects of the viral vector (Fig. 8.4). Theoretically, it is possible to engineer viral vectors that express any biological entity with a known sequence. For example, vectors have been used that encode enzymes (e.g., TH, Cre recombinase), transcription factors (e.g., CREB, NAC-1), receptors (e.g., dopamine D1), receptor subunits (e.g., GluRs), growth-associated proteins (e.g., GAP43), microRNAs (miRs; e.g., miR-212), and reporter proteins (β -galactosidase, green fluorescent protein). Moreover, vectors encoding antisense sequences, dominant-negative mutations (assuming that they exist), or siRNA for any of these entities can be engineered. There are some practical limitations, including the size of the foreign cDNA and the ease with which it can be subcloned into the viral backbone. The larger the cDNA construct, the less efficient the amplification will be during replication, which leads to less favorable amplicon-to-helper virus ratios and lower titers of the vector (see Carlezon et al., 2000b). Assuming that the sequence of the construct is known, the cDNA itself is available, and that no untoward complications are encountered during subcloning, new HSV vectors can be engineered and generated usually within a period of several weeks, and sometimes within days.

EARLY APPLICATIONS OF VIRAL-MEDIATED GENE TRANSFER

During et al. (1994) performed one of the first *in vivo* applications of viral-mediated gene transfer. The goal in this study was to use the vectors as gene therapy to elicit behavioral recovery in an animal model of Parkinson's disease. In this model, rats were given unilateral, intrastriatal microinjections of the neurotoxin 6-hydroxydopamine (6-OHDA) to deplete local concentrations of dopamine. Viral-mediated gene transfer (by stereotaxic microinjections of vector) was then used to convert

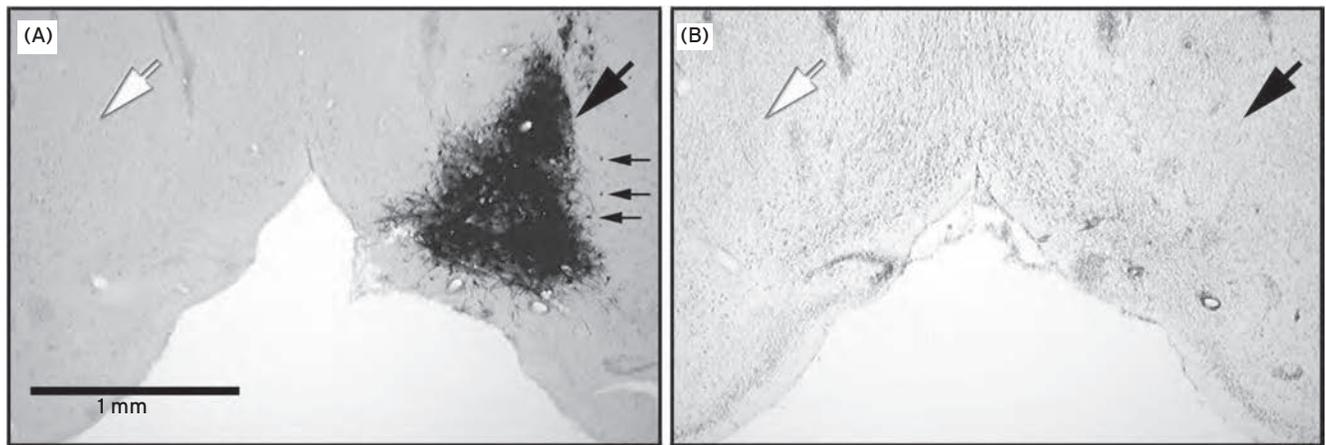

Figure 8.4 Histological examination of nucleus accumbens (NAc) tissue 3 days after gene transfer. A, Large solid arrow: brain site at which the viral vector HSV-LacZ was microinjected. This vector encodes the reporter protein *Escherichia coli* β -galactosidase, which causes a dark blue reaction product in the presence of substrate. Small solid arrows: individual cells expressing β -galactosidase. Open arrow: noninjected NAc. B, An adjacent, Nissl-stained slice from the same brain, showing minimal evidence of toxicity or damage despite strong transgene expression. Damage produces gliosis and darker Nissl staining.

the endogenous cells of the striatum (primarily GABAergic medium spiny neurons) into L-dopa-producing cells by delivering the gene for TH, the rate-limiting enzyme in the synthesis of dopamine. Hypothetically, increased expression of TH would lead to restored striatal dopamine levels and recovery of function. During et al. (1994) reported significant increases in the expression of TH within the striatum accompanied by partial behavioral recovery after viral-mediated gene transfer and concluded that TH gene therapy was effective in this model. Although other investigators (Isacson, 1995) who used the same viral vector preparations in their studies proposed alternative explanations for the behavioral data of During et al. (1994), this early work highlighted the theoretical potential of viral-mediated gene transfer to facilitate recovery from neurodegenerative processes and, more generally, the use of viral vectors to study how gene expression in discrete brain regions can influence behavior.

More recently, viral-mediated gene transfer has been used to study complex motivational states associated with neuropsychiatric disorders such as addiction and depression. The use of viral vectors is particularly well suited to the study of addiction because exposure to drugs of abuse causes many changes in gene expression within the brain (Nestler, 2005). Since viral vectors offer the capability to study individual changes in gene expression in discrete brain regions, it is possible to mimic certain aspects of the drug-exposed state without ever administering the drugs themselves. For example, repeated exposure to drugs of abuse can cause increases in sensitivity (“sensitization”) to the rewarding effects of drugs (Lett, 1989; Piazza et al., 1990), a phenomenon that may contribute to the addiction process (Robinson and Berridge, 2001). Because the dopamine projection from the ventral tegmental area (VTA) of the mid-brain to the nucleus accumbens (NAc) of the basal forebrain has been implicated in the habit-forming (rewarding) effects of virtually all abused drugs, many studies on the molecular basis of addiction have focused on this circuitry. Repeated intermittent exposure to morphine or cocaine can increase expression of the AMPA (glutamate) receptor subunit GluR1 within the

VTA and NAc (Churchill et al., 1999; Fitzgerald et al., 1996). To directly test the hypothesis that these drug-induced molecular adaptations *cause* drug-induced behavioral adaptations (including sensitization), viral vectors were used to elevate GluR1 levels within the VTA of rats not exposed previously to drugs. Rats with viral-mediated elevations in GluR1 expression within anterior portions of the VTA showed dramatic increases in sensitivity to the rewarding effects of morphine (Carlezon et al., 1997, 2000a). These data suggest that the behavioral consequences of repeated exposure to morphine are mimicked by gene transfer of GluR1 into the VTA, and support a causal relation between previously disparate drug-induced molecular and behavioral adaptations. Remarkably, elevated expression of GluR1 in the NAc appears to have the opposite effect—reduced sensitivity to reward (Todtenkopf et al., 2006)—highlighting the fact that altered expression of any given gene cannot be assumed to have uniform functional consequences from brain region to brain region (Carlezon et al., 2005).

Hints about the genes and intracellular mechanisms involved in depressive disorders have also evolved from this type of addiction research. Exposure to drugs of abuse increases the function of the transcription factor CREB (cAMP-responsive element binding protein) in striatal regions, including the NAc (Cole et al., 1995; Turgeon et al., 1997). CREB regulates the expression of many genes (Shaywitz and Greenberg, 1999), including that for dynorphin (Hurd et al., 1992), an opioid peptide implicated in dysphoric (aversive) states (Pfeiffer et al., 1986). Viral vector-mediated elevations of CREB in the NAc of rats make low doses of cocaine aversive, and higher doses of cocaine less rewarding (Carlezon et al., 1998). In addition to producing these signs of anhedonia—a hallmark symptom of depression characterized by a diminished ability to experience rewarding stimuli as rewarding—elevations of CREB in the NAc also produce other symptoms of depression in animal models (Pliakas et al., 2001). Antagonists of brain receptors for dynorphin (κ -opioid receptors) eliminate the signs of aversion and depression (Carlezon et al., 1998; Mague et al., 2003; Pliakas et al., 2001), suggesting that CREB-mediated induction

of dynorphin contributes directly to these complex behavioral states. Other investigators have used viral vectors to express miRs or “anti-miRs,” identifying novel intracellular mechanisms involved in regulation of CREB function and motivated behavior (Hollander et al., 2010).

Together, these types of “biobehavioral” studies demonstrate how viral-mediated gene transfer offers a unique methodology with which to examine how alterations in a single, localized gene product can lead to changes in behaviors that reflect complex motivational states. Moreover, they may help to identify intracellular pathways and alterations in gene expression that are potential targets for new generations of pharmacotherapies for addiction, depression, and possibly other neuropsychiatric disorders (see Box 8.6).

BOX 8.6 COMPLEMENTARY GENOMIC STRATEGIES TO STUDY Δ FosB AND GluR2

As described in Box 8.4, mice engineered to overexpress Δ FosB in the ventral striatum (NAc) are more sensitive to the stimulant and rewarding effects of cocaine (Kelz et al., 1999). Presumably, the proximal cause of heightened drug sensitivity is not increased expression of Δ FosB per se, but rather, increased expression of a target gene (or genes) regulated by this long-lasting transcription factor. Protein immunoblotting studies revealed that the Δ FosB-overexpressing mice also had large increases in GluR2 expression in the NAc, raising the possibility that local alterations in the expression of this AMPA receptor subunit contribute to increased drug sensitivity. To test the hypothesis that elevated GluR2 expression in the NAc is sufficient to cause increased sensitivity to the rewarding effects of cocaine, rats were given stereotaxic microinjections of an HSV vector encoding GluR2 (HSV-GluR2) into this brain region. Rats that received this manipulation showed dramatic increases in sensitivity to the rewarding effects of cocaine in place conditioning studies, mimicking the effects of increased expression of Δ FosB in mice (Kelz et al., 1999). They also showed heightened sensitivity to the rewarding effects of electrical stimulation of the medial forebrain bundle (Todtenkopf et al., 2006). These findings provide strong evidence that the increases in cocaine reward seen in Δ FosB transgenic mice are attributable, at least in part, to elevated expression of GluR2 in the NAc.

The use of additional viral vector constructs provided strong evidence that elevated expression of GluR2 in the NAc increases cocaine reward because of effects on calcium (Ca^{2+}) permeability of neurons within this region. There are numerous possible explanations for how local alterations in Ca^{2+} flux might influence drug reward, considering the role of Ca^{2+} in cellular functions including membrane depolarization, neurotransmitter release, signal transduction, and plasticity (Malinow and Malenka, 2002; Zucker, 1999). Regardless, the combined use of complementary genomic techniques allowed the testing of complex working hypotheses and led not only to the elucidation of drug reward mechanisms, but also to the identification of potential targets for new generations of medications for addiction.

OTHER DEVELOPMENTS IN VIRAL-MEDIATED GENE TRANSFER

TRANSGENE TAGGING

A general improvement to gene transfer methods has been the incorporation of “tags” onto the transgene product to facilitate its detection in the brain, and to differentiate between endogenous gene expression and viral-mediated transgene expression. One increasingly popular and powerful strategy is to incorporate the gene for the green fluorescent protein into the vectors. Coexpression of GFP enables researchers to visually detect cells infected by the vector against a background of endogenous gene expression. There are numerous engineering strategies that can be used to tag vector-infected cells (see Neve et al., 2005). The advantages of tagging proteins are obvious: for example, in cases where viral-mediated elevations in transgene expression have been found to have biobehavioral significance (e.g., GluR2 in the nucleus accumbens), electrophysiologists can visually identify infected neurons for study. An added advantage of the GFP tag is the ability to track the subcellular location of the transgene product, which may increase interest in the use of viral vectors for anatomical studies. Additionally, any of several nonfluorescent tags can be fused to the transgene product because they are not expressed in the brain endogenously, including -HA (hemagglutinin), -FLAG (Asp-Tyr-Lys-Asp-Asp-Asp-Lys), and -myc (an epitope of the avian myelocytomatosis oncogene). This type of work comes with an important caveat, however: it is imperative to demonstrate that the addition of the tag directly to the transgene product does not affect the native function of the protein.

NEURONAL SPECIFICITY AND DURATION OF EXPRESSION

Current limitations of many viral vectors include their lack of selectivity for neuronal subtypes (e.g., neurotransmitter-specific) and the transient nature of their effects. Reportedly, substitution of a viral transgene promoter with a neuronal promoter can solve both of these limitations. For example, HSV vectors that contain a fragment of the TH promoter cause increased transgene expression selectively in TH-positive (e.g., dopaminergic) neurons, and the expression has been observed for months after infection (Jin et al., 1996). However, the size of neuronal promoters can make packaging less efficient, thereby causing significant reductions in viral titers. Similar techniques have been utilized to restrict LV-mediated transgene expression to neurons (Jakobsson et al., 2006). While AAV can express products for extended periods of time, there is a stricter limit to how many base pairs of DNA the virus can carry.

These challenges have been overcome by combining transgenics and viral approaches to achieve specificity in neuronal expression. By combining transgenic mice that express Cre recombinase in specific neurons, with Cre-dependent viral vectors, expression is achieved in restricted types of cells (e.g., Cardin et al., 2010). This approach has been used extensively with optogenetics, where activated inhibition of specific types of neurons is highly desirable.

DEACTIVATION AND ACTIVATION OF GENES

One intriguing possibility is to use viral vectors in conjunction with other genomic technologies, such as mutant (knockout) mice. A current limitation of knockout mice (inducible knockouts notwithstanding) is that they lack the gene under study for their entire lives, raising the possibility of developmental adaptations that may complicate interpretation of results (Gingrich and Hen, 2000). However, the use of viral vectors that express the DNA-splicing enzyme Cre recombinase can eliminate this limitation. The general strategy is to engineer mutant mice such that the gene (or genes) to be knocked out is flanked by loxP sites (“floxed”), molecular targets for Cre recombinase (Nagy, 2000). Microinjection of a vector expressing Cre recombinase can then cut and fuse the DNA at the loxP sites, permanently knocking out the gene flanked by the sites. This approach enables regional and temporal selectivity to the genetic manipulation—two current limitations of mutant mouse technology, and two current advantages of viral-mediated gene transfer. Viral vector–induced excision of floxed genes has been used to demonstrate that expression of brain-derived neurotrophic factor (BDNF) in the mesolimbic system plays an essential role in stress-induced development of depressive-like behaviors (Berton et al., 2006) and self-administration of and relapse to drugs of abuse (Graham et al., 2007). Expression of Cre in CAV may offer unique opportunities to dissect complex circuitry: as one example, infusion of CAV-Cre into the nucleus accumbens would allow retrograde expression or ablation of genes specifically within ventral tegmental area (VTA) dopamine neurons that project to this region, while sparing VTA dopamine neurons that project to other areas (e.g., frontal cortex). Viral vectors have also been utilized together with siRNA to achieve gene knockdown with spatial and temporal specificity (Hommel et al., 2003). This approach has also applied to generate conditional knockdown rats with gene loss restricted to the midbrain region (Hommel et al., 2006). The use of viral vectors to deliver siRNA is not trivial, however, and often requires additional engineering of the viral backbone and siRNA oligonucleotide (Sandy et al., 2005; Saydam et al., 2005).

It may also be possible to design viral vectors that cause transgene expression that is subject to pharmacological regulation. For example, a vector has been created that expresses an RU486 (mifepristone)-inducible transactivator (Oligino et al., 1998). Transgenes under control of this transactivator are expressed only in the presence of RU486. Similarly, inducible LV vectors have been created that contain promoter elements that render transgene expression sensitive to doxycycline (Markusic et al., 2005). This strategy is analogous to the use of inducible promoters to regulate gene expression in mutant mice, which dramatically improves the temporal resolution of altered gene expression and facilitates the identification of causal relations between altered gene expression and altered behavior.

LIMITATIONS OF VIRAL-MEDIATED GENE TRANSFER

As an *in vivo* technique for neuropsychiatry research, viral-mediated gene transfer has two main limitations. First, the

vectors must be injected directly into the brain region of interest. This involves anesthesia, stereotaxic microinjections, damage to brain regions dorsal to the injection sites from the injection track, damage to the injection sites themselves from the hydraulic pressure of the microinjection, and several days recovery time for the animal. The size and shape of the targeted brain region can make the microinjection procedure difficult or prevent certain regions from being targeted with specificity. Many of these limitations are similar to those encountered with other brain manipulations (e.g., lesions), and their severity is often associated with the skill and experience of the researchers performing the *in vivo* procedures. Historically, cytotoxic effects of the viral vectors themselves or from an immune response from the host are also concerns, although improvements in vector engineering and purification (see Carlezon et al., 2000b) have greatly diminished their severity. The second limitation is that, in general, the vectors do not target specific types of cells. Whereas vectors such as HSV, AAV, and CAV target neurons, others such as AV and LV are not naturally selective for neurons or glia. More importantly, none of the current vectors can selectively target specific types of neurons (e.g., dynorphin-containing GABAergic medium spiny neurons). As previously noted, however, the use of Cre-dependent viruses in transgenic Cre driver lines has made neuronal specificity easier to achieve. As with any technique, these limitations of viral-mediated gene transfer must be weighed against its advantages and potential.

THE FUTURE OF VIRAL-MEDIATED GENE TRANSFER

Gene therapy is an obvious medical application for viral vectors. The use of viral vectors to transfer therapeutic genes or siRNA to treat neurological conditions (e.g., brain tumors) shows great promise (Saydam et al., 2005). However, gene therapy for neuropsychiatric disorders must overcome several technological challenges before it can become a reality (Neve et al., 2005). As previously emphasized, the ability to control the efficacy of the vectors will continue to be a critical consideration. In the past, most vectors have utilized strong or “promiscuous” promoters that tend to drive gene expression beyond physiological levels, raising the possibility of unwanted—and possibly detrimental—effects on cell function. An improved ability to target specific cell types while tightly regulating the timing and strength of gene expression will open up a wealth of opportunities for clinical applications. There are also conceptual hurdles. Aside from the fact that it seems unlikely that any neuropsychiatric disorder is due to alterations in a single gene, the brain is not particularly accessible or hospitable to genetic intervention. In addition, neuropsychiatric disorders such as schizophrenia may have their origins in molecular processes that occur transiently in small subsets of cells at very specific times during development. Once established, these molecular misadaptations may be difficult or impossible to correct with delayed interventions. Thus, while viral-mediated gene transfer is presently well suited for brain research in animals, a substantial amount of work is needed before it can be determined whether it has practical applications in evolving fields of molecular medicine.

DISCLOSURES

Dr. Carlezon discloses that he has a U.S. patent (assignee: McLean Hospital) covering the use of kappa-opioid antagonists for the treatment of depressive disorders.

Drs. Monteggia and Dileone declare no competing financial interests.

INTRODUCTION

How can the material substance of our brain become organized into a state that disturbs our very sense of self? What is the neural basis of hallucinatory or delusional perceptual experience that is dissociated from external triggers? And how do persistently maladaptive responses to stimuli manifest in the neural circuitry? Some of the most profound questions with respect to mental illness have been prohibitively difficult to address because of our limited ability to probe the human brain—to observe its development and deconstruct its systems into component parts. To circumvent this constraint, researchers have employed a variety of investigative approaches to make specific predictions about the processes underlying normal and pathological neural function in humans. Animal models have served as a viable and essential proxy for investigating mechanisms underlying clinically relevant pathophysiology in humans.

Conservation of gene function and pharmacological isomorphism provide correlative evidence to validate the use of these animals to model features of neurological disease. In patients, functional imaging, EEG (electroencephalography) and MEG (magnetoencephalography), genetic association studies, and postmortem analyses of brain tissue have all generated substantial and critical information regarding the pathology associated with psychiatric disorders. However, the molecular-, cellular-, and circuitry-level dynamics in the human brain that generate the symptomatology have been elusive because the system itself is not generally amenable to invasive studies.

The advent of stem cell technology has the potential to radically alter our investigative approach by opening a new window into the processes underlying human brain development and pathogenesis. Stem cells exhibit two hallmark properties, namely, unlimited self-renewal and the capacity to differentiate into different cell types (Gage, 2000). By harnessing the potential of stem cells to undergo unlimited self-renewal and specific differentiation, we are now able to generate a renewable source of living human neurons to study under controlled experimental conditions. This provides us with an exciting opportunity to expose human neural components to rigorous investigation and establish a translational bridge between animal studies and the diagnosis and treatment of disease. Although the human brain as a holistic system is still largely inaccessible to direct manipulation, investigating elemental units of neuronal communication and function may lead to a deeper understanding of the cellular mechanics that contribute to systemic dysregulation. Stem cell research will not supplant animal models or noninvasive studies of patients, but is a vital complement to these approaches and heralds a paradigm shift in our investigation of the neural substrates of mental disorders.

Cellular reprogramming is a method designed to convert differentiated somatic cells into different states, such as pluripotent stem cells, neural stem cells, or neurons, via forced expression of specific transcription factors. The prospective utility of cellular reprogramming for reducing the burden of neurological disease derives from two overarching goals—the ability to generate specific cell types to replace neural populations damaged by injury or disease and the generation of a renewable source of genetically tractable human neurons and glial cells to study the mechanisms underlying pathological development. The field is progressing at a rapid pace, and the number of reports using cellular reprogramming to investigate the mechanistic basis of neuropsychiatric disorders will likely

increase exponentially in the near future. At this nascent stage, the most striking advances in human reprogramming technology are driven by disease-specific questions as researchers begin to work on transforming some of the most vexing issues in the investigation of the human central nervous system into tractable research problems. Whether the focus is on identifying unknown etiology, engineering genetic rescue, or discovering a novel therapeutic compound, investigators are being challenged to find innovative solutions to unique problems, and the approaches they develop may be generalized to other domains. As the field matures, the cross-pollination of ideas from diverse research programs should facilitate generation of target cell populations and efficacious methods to characterize and rescue relevant phenotypes. In this chapter, we first introduce different types of stem cells used to investigate psychiatric disorders, then highlight some novel approaches in the field of cellular reprogramming and examples that use stem cells to understand psychiatric disorders, and conclude with discussion of some of the central challenges in the field. Because there are currently only a few published studies using patient-derived reprogrammed nerve cells to investigate cellular dysregulation in psychiatric disorders, we will include a discussion of prominent findings from other neurological diseases to illustrate salient issues that are applicable to all efforts to exploit the potential of cellular reprogramming (Table 9.1). Interested readers can consult other detailed review articles (Brennan et al., 2012; Dolmetsch and Geschwind, 2011; Vaccarino et al., 2011).

STEM CELLS FROM DIFFERENT SOURCES

EMBRYONIC STEM CELLS

Stem cells are defined by two essential characteristics—the capacity for self-renewal and the ability to generate multiple cell types (Gage, 2000). Although stem cells exist in many adult tissues, the number is limited, and fate choices are often constrained to a few cell types. Embryonic stem cells (ESCs) can be maintained in culture indefinitely and exhibit no restriction on fate specification. Early attempts to generate multiple neuronal subtypes to study in culture began with efforts to direct differentiation of mouse ESCs. Significant progress has been made in recent years to develop protocols to differentiate ESCs into different types of neurons in the CNS and PNS as well as glial cells (Gottlieb, 2002).

Human embryonic stem cell (hESC) lines derived from human blastocysts were first characterized in 1998 and exhibited the essential properties of self-renewal and pluripotency observed in mouse ESC lines (Thomson et al., 1998). The creation of these early hESC lines was invaluable to the study of early human development and offered the first real possibility of generating a renewable source of diverse cell types in the human nervous system. However, the ethical issues surrounding the acquisition of source material for hESCs has constrained the development of additional lines, which may limit applicability to a genetically diverse population.

INDUCED PLURIPOTENT STEM CELLS

One of the most significant technological advances in stem cell biology was the seminal study by Takahashi and Yamanaka demonstrating that both embryonic and adult fibroblasts of mice could be reprogrammed to a state of pluripotency through the retroviral-mediated introduction of four transcription factors—Oct3/4, Sox2, c-MYC, and Klf4 (Takahashi and Yamanaka, 2006). These induced pluripotent stem cells (iPSCs) exhibited all the classic hallmarks of stem cells, including self-renewal and the capability of differentiating into cells from all three embryonic germ layers. Critically, it was soon shown that this strategy was also effective for reprogramming of human fibroblasts and many other somatic cell types into pluripotent iPSCs (Park et al., 2008; Takahashi et al., 2007; Yu et al., 2007). Perhaps the most salient and exciting aspect of this technology is that differentiated cells arising from iPSCs retain the genetic information of the fibroblast donor, thus providing a renewable, genetically tractable resource for different types of human cells. This cardinal feature has a profound impact for investigating human disease in that it allows direct observation of neurons and glial cells that have a clinically relevant genetic profile. Efforts to validate pluripotency and stability of iPSC lines have converged on an array of standard assays to demonstrate fundamental properties of stem cells and similarity to ESCs (Fig. 9.1). Depending on the method of reprogramming, it may be necessary to show the silencing of viral-mediated introduction of transgenes. Karyotyping is typically performed to ensure that there are no gross chromosomal abnormalities. iPSC colonies should be positive for typical pluripotency markers, including Nanog, SSEA3, SSEA4, TRA-1-60, TRA-1-81, TRA-2-49, Sox2, OCT4, and alkaline phosphatase (Fig. 9.1A–C). Competency to generate all three embryonic germ layers can be demonstrated through expression of layer-specific markers for ectoderm (e.g., Tuj1), mesoderm (e.g., α SMA), and endoderm (e.g., AFP), following differentiation (Fig. 9.1D–F). Finally, the current *in vivo* benchmark for pluripotency is the teratoma assay in which undifferentiated iPSCs are intramuscularly injected into immunodeficient mice to induce formation of tumors that include all three germ layers. Once pluripotency has been achieved, the resultant iPSCs can be induced to differentiate toward specific lineages, including neural progenitors (Fig. 9.1G), which give rise to immature neurons (Fig. 9.1H), and finally, mature neurons expressing synaptic markers (Fig. 9.1H).

DIRECT PROGRAMMING INTO NEURONS OR NEURAL STEM CELLS

In the first iterations of cellular reprogramming, fibroblasts were converted to a state of pluripotency through the introduction of transcription factors delivered via a retrovirus (Takahashi and Yamanaka, 2006). Subsequently, additional induction methods were developed that were able to confer pluripotency while minimizing risk associated with viral-mediated transgene insertion. Although newer methods have minimized or eliminated the risk of residual expression of transgenes, the transient induction of pluripotency required for iPSC generation

TABLE 9.1. Patient-specific iPSC Studies of neurological disorders

DISEASE	MUTATION	REPROGRAMMING METHOD	DIFFERENTIATION	PHENOTYPE	RESCUE	REFERENCE
AD	APP duplication in two patients (APP ^{DP}); no identified mutations in two sporadic AD patients (sAD)	Retrovirus (Oct3/4, Sox2, Klf4, c-Myc)	Glutamatergic, GABAergic, and cholinergic neurons	Increased amyloid- β , p-tau, and aGSK-3 β expression in both APP ^{DP} lines and one of two sAD lines	Partial rescue of amyloid- β , p-tau, and aGSK-3 β expression with γ and β -secretase inhibitors	Israel et al. (2012)
AD	Three sporadic AD patients, three familial AD patients with mutations in either PSEN1 or PSEN2	Direct conversion to neurons via lentivirus (Ascl1, Brn2, Myt1l, Oligo2, Zic1)	Glutamatergic forebrain neurons	Familial AD-iPSCs show increased expression of A β ; dysregulated processing of amyloid precursor protein	WT PSEN1 expression rescues	Qiang et al. (2011)
FD	IKBKAP point mutation	Lentivirus (Oct3/4, Sox2, Klf4, c-Myc)	CNS and PNS precursors	Limited tissue-specific splicing; reduction in ASCL1 expression	Kinetin rescue of splicing and autonomic neuron generation	Lee et al. (2009)
FXS	FMR1 CGG repeat expansions (one mosaic patient, two with >600 repeats)	Retrovirus (Oct3/4, Sox2, Klf4, c-Myc)	Neurons, glia	Neuronal differentiation, process morphology	—	Sheridan et al. (2011)
FXS	FMR1 premutation –30, 94 CGG repeat	Retrovirus (Oct3/4, Sox2, Klf4, c-Myc)	Neurons	Reduced neurite length, synaptic puncta, PSD-95	—	Liu et al. (2012)
HD	HTT CAG expansion repeat mutations (50 CAG; 109 CAG)	Integration-free episomes	Neurons, astrocytes	CAG-repeat-associated presence of cytoplasmic vacuoles in astrocytes	—	Juopperi et al. (2012)
HD	HTT CAG expansion repeat mutations (72)	—	DAARP32 neurons	Cell death, mitochondrial bioenergetics, elevated stress response	BAC homologous recombination gene editing to reduce repeat length rescued mitochondrial and cell death vulnerability	An et al. (2012)
HD	HTT CAG expansion repeat mutations (60, 180)	Lentivirus (Oct4, Sox2, Klf4, cMyc, Nanog, Lin28)	DAARP32 neurons	Cell death, BDNF sensitivity, cytoskeleton, adhesion, cell energetics	—	HD iPSC Consortium (2012)
PD	LRRK2 dominant missense mutation	Retrovirus (Oct3/4, Sox2, Klf4)	Midbrain dopaminergic neurons	Differential gene expression; increased α -synuclein expression, increased susceptibility to H ₂ O ₂ , 6-OHDA, and MG-132	—	Nguyen et al. (2011)
PD	PINK1 nonsense or missense mutations	Retrovirus (Oct3/4, Sox2, Klf4, c-Myc)	Dopaminergic neurons	Impaired stress-induced translocation of Parkin to mitochondria; increased PGC-1 α and mtDNA following depolarization	Overexpression of WT PINK1 restored translocation capacity and prevented PGC-1 α increase	Seibler et al. (2011)

DISEASE	MUTATION	REPROGRAMMING METHOD	DIFFERENTIATION	PHENOTYPE	RESCUE	REFERENCE
PD	α synuclein point mutation	Tetracycline-inducible lentivirus (Oct3/4, Sox2, Klf4, c-Myc)	Dopaminergic neurons	—	ZFN gene editing; repair of point mutation in patient iPSCs; introduction of point mutation in hESCs	Soldner et al. (2011)
PD	PINK1, LRRK2	Retrovirus (Oct3/4, Sox2, Klf4, c-Myc)	Neurons	Mitochondrial dysfunction	Rescue via coenzyme Q ₁₀ , rapamycin, or the LRRK2 kinase inhibitor GW5074	Cooper et al. (2012)
PD	Parkin mutations	Lentivirus (Oct3/4, Sox2, Klf4, c-Myc, Nanog)	Midbrain dopaminergic neurons	Increased oxidative stress, spontaneous DA release, decreased DA uptake	Overexpression of WT-parkin rescued all phenotypes	Jiang et al. (2012)
RTT	MeCP2 missense, nonsense, and frameshift mutations	Retrovirus (Oct3/4, Sox2, Klf4, c-Myc)	GABAergic and glutamatergic neurons	Reduced soma size, number of spines, glutamatergic synapses; altered Ca ²⁺ transients, sEPSCs, sIPSCs	IGF1—partial increase in synapse number; gentamycin—restored MeCP2 expression in nonsense mutation	Marchetto et al. (2010)
RTT	MeCP2-null mutation	Retrovirus (Oct3/4, Sox2, Klf4, c-Myc)	Neurons	Soma size reduction	—	Cheung et al. (2011)
RTT	Domain-specific mutations (MBD, TRD, CTD)	Retrovirus (Oct3/4, Sox2, Klf4, c-Myc)	Neurons, glia	Decreased neuronal differentiation	—	Kim et al. (2011b)
SZ	4bp deletion in <i>DISC1</i> - frameshift	Integration-free episomes	—	—	—	Chiang et al. (2011)
SZ	Not known	Tetracycline-inducible lentivirus (Oct3/4, Sox2, Klf4, c-Myc)	Glutamatergic, GABAergic, and dopaminergic neurons	Decreased neuronal connectivity, increased <i>NRG1</i> expression	Loxapine rescue of neuronal connectivity deficits, <i>NRG1</i> expression	Brennan et al. (2011)
TS	<i>CACNA1C</i> point mutation	Retrovirus (Oct3/4, Sox2, Klf4, c-Myc)	Layer-specific cortical neurons	Differential gene expression; TH expression	—	Pasca et al. (2011)

ABBREVIATIONS: RTT, Rett syndrome; FD, familial dysautonomia; TS, Timothy syndrome; FXS, fragile X syndrome; HD, Huntington’s disease; SZ, schizophrenia; PD, Parkinson’s disease; AD, Alzheimer’s disease; TH, tyrosine hydroxylase; DA, dopamine; MAO-A, monoamine oxidase A; MAO-B, monoamine oxidase-B; ZFN, zinc finger nuclease; mtDNA, mitochondrial DNA; MBD, methyl-CpG binding domain; TRD, transcriptional repression domain; CTD, carboxyl terminal domain.

is still time consuming and labor intensive and poses a risk for tumor formation during transplantation. To address many of these issues, a rapidly evolving technology is the direct conversion of somatic cells to neuronal lineages (Chambers and Studer, 2011). An early study demonstrating the possibility of direct programming described direct conversion of murine adult somatic cells to functional neurons using a set of three neural-lineage-specific transcription factors, *Ascl1*, *Brn2*, and

Myt1l (Vierbuchen et al., 2010), a strategy that subsequently proved effective for human fibroblast conversion as well (Pang et al., 2011). Independent laboratories used a partially overlapping set of transcription factors in combination with specific microRNAs, such as miRNA-9 and miRNA-124, to achieve similar results (Ambasudhan et al., 2011; Yoo et al., 2011).

Nevertheless, direct programming of somatic cells to neurons has its own set of potential pitfalls and experimental

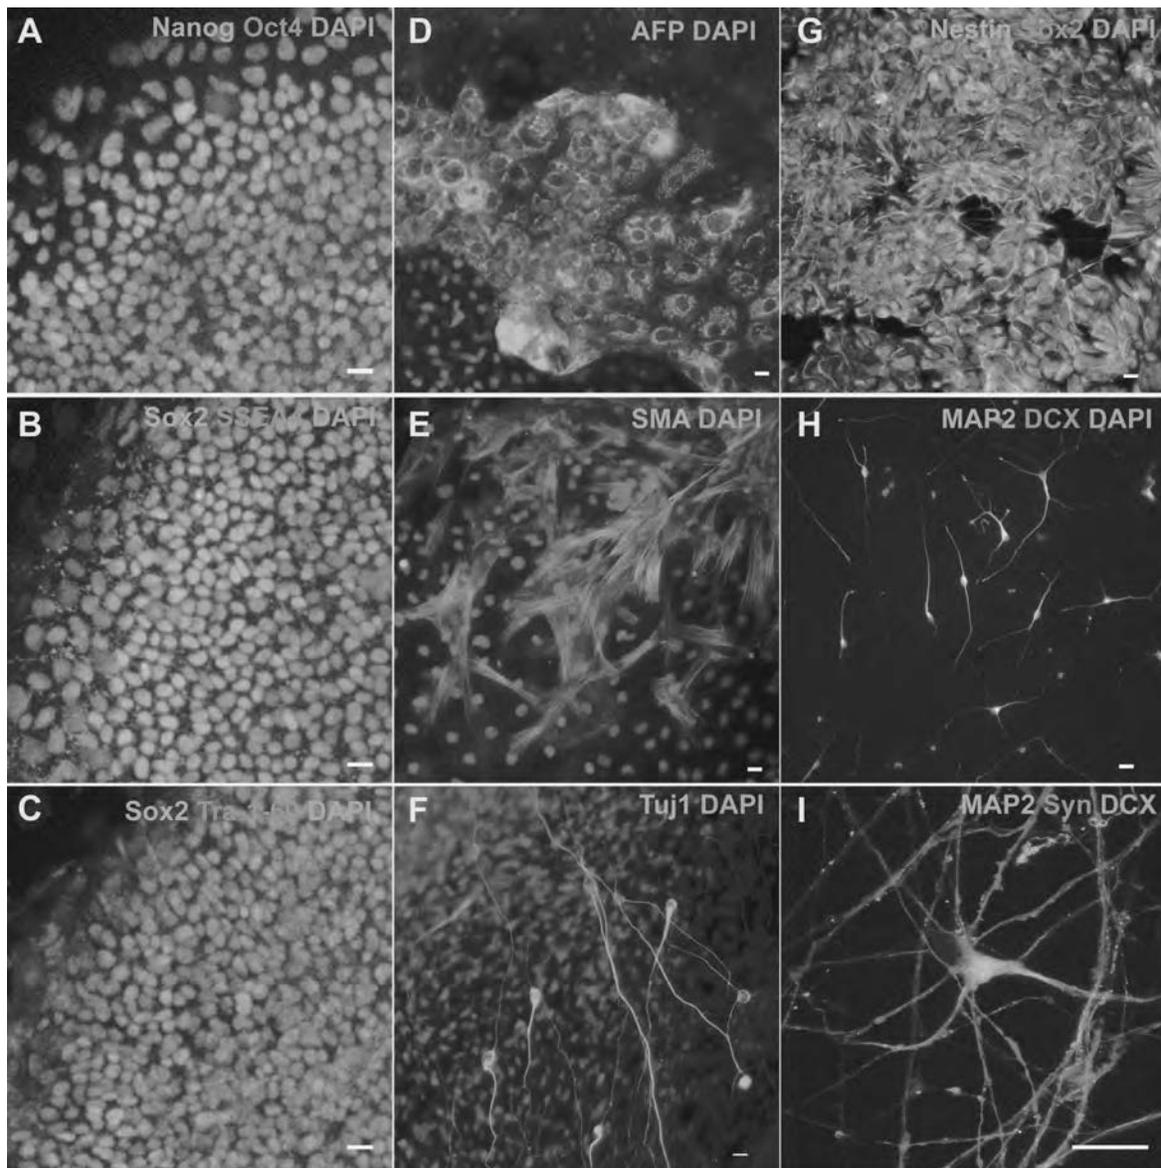

Figure 9.1 Generation of neurons from human iPSCs. challenges. While expedient, the process of direct conversion to neurons requires a large pool of source material and allows for the possibility of population-level variability. In addition, neurons generated as a result of direct programming exhibited little proliferative potential and limited ability for stable expansion. More recently, methods have been developed to generate multipotent neural stem cells and neural progenitors (Han et al., 2012; Kim et al., 2011a; Lujan et al., 2012; Thier et al., 2012). One approach relied on a slight modification of traditional methods for reprogramming by limiting the duration of Oct4 expression (Thier et al., 2012). The rationale of this approach was that sustained expression of the remaining transcription factors (Sox2, Klf4, and c-Myc) would create a selective pressure for neural-lineage induction while restricting

Oct4 expression to the first 5 days of reprogramming would limit the induction of pluripotency. As a result the induced neural stem cells were capable of differentiation into all three neural cell types—neurons, astrocytes, and oligodendrocytes—and, critically, this differentiation capacity remained stable over long-term expansion of more than 50 passages. A markedly different approach was used by two independent groups, which achieved generation of stable and expandable neural progenitor and stem cell pools in the absence of Oct4 (Han et al., 2012; Lujan et al., 2012). Interestingly, each group relied on a unique set of transcription factors in which Sox2 was the only common element, further supporting an integral role of Sox2 in neural induction. Sox2 has now been demonstrated to be capable of converting both mouse and human fibroblasts to

multipotent neural stem cells through single-factor conversion (Ring et al., 2012).

ENDOGENOUS NEURAL STEM CELLS

Although it was long believed to be devoid of postnatal proliferation, the adult central nervous system was shown to be capable of *de novo* cellular production in a pivotal series of studies in the 1960s, which were largely overlooked for the next several decades (Altman and Das, 1965). In the intervening years, it was conclusively demonstrated that two primary areas of the mature brain do exhibit ongoing neurogenesis throughout life in most species, including humans, and that specialized populations of neural stem cells occur endogenously in the mature mammalian brain (Gage, 2000). The subventricular zone gives rise to immature neurons that traverse the rostral migratory stream to populate the olfactory bulb. And in the hippocampus, neural stem cells in the subgranular zone are the source of newborn granule cells in the dentate gyrus. Because the hippocampus is an integrative site that supports many forms of learning and memory, much effort has been devoted to understanding the role of this site-specific generation of a select population of neurons (Aimone et al., 2011). Intriguingly, adult neurogenesis has been implicated in affective disorders, with the most striking evidence arising from a correlation between levels of neurogenesis and the efficacy of antidepressants in animal models (Samuels and Hen, 2011). These data suggest that adult neurogenesis may play an active role in mediating emotional behavior. Many mental disorders are associated with reduced hippocampal volume and correlate with decreased levels of neurogenesis in animal models, suggesting that depressed levels of cell proliferation may play a role in hippocampal atrophy and cognitive impairments, although there are limited data to demonstrate a casual influence of neurogenesis levels on disease etiology. Adult neurogenesis can also play a significant role as a model system to explore basic principles of how newborn neurons are integrated in the mature brain, which will be

critical to the development therapeutic cell replacement strategies (Christian et al., 2010). While mechanistic investigations of this phenomenon are limited to animal models, it provides a viable *in vivo* model that can be used to complement *in vitro* studies of human neurons. Furthermore, the presence of a robust neurogenic niche in the adult rodent brain provides a unique opportunity for transplantation studies of human neural stem cells to examine their development, maturation, and integration (Juopperi et al., 2012).

MODELING NEUROLOGICAL DISORDERS USING STEM CELLS

MONOGENIC DISEASES

Initially, the most approachable diseases to investigate mechanistically are those associated with highly or completely penetrant single gene mutations. This genetic determinism reduces complexity and narrows the investigative focus for characterization of the relevant pathology. To date, the most significant breakthroughs in terms of identifying potential strategies to reverse or prevent phenotypic disturbances have come from the study of monogenic diseases. Starting from a functional evaluation of a circumscribed genetic domain, two general approaches are being developed that show considerable promise in being able to rescue cellular phenotypes observed during the differentiation of neurons from patient-specific iPSCs—biochemical rescue and targeted gene editing (Fig. 9.2).

In diseases with a predominant psychiatric impact, there are few examples of monogenic diseases, but there is a subset of autism spectrum disorders (ASD) for which a causative genetic locus has been identified. Rett syndrome, Timothy syndrome, and fragile X syndrome are all associated with mutations in single genes and will be instructive in developing technologies for genetically mediated rescue or screening for biochemical compounds to ameliorate or reverse cellular phenotypes.

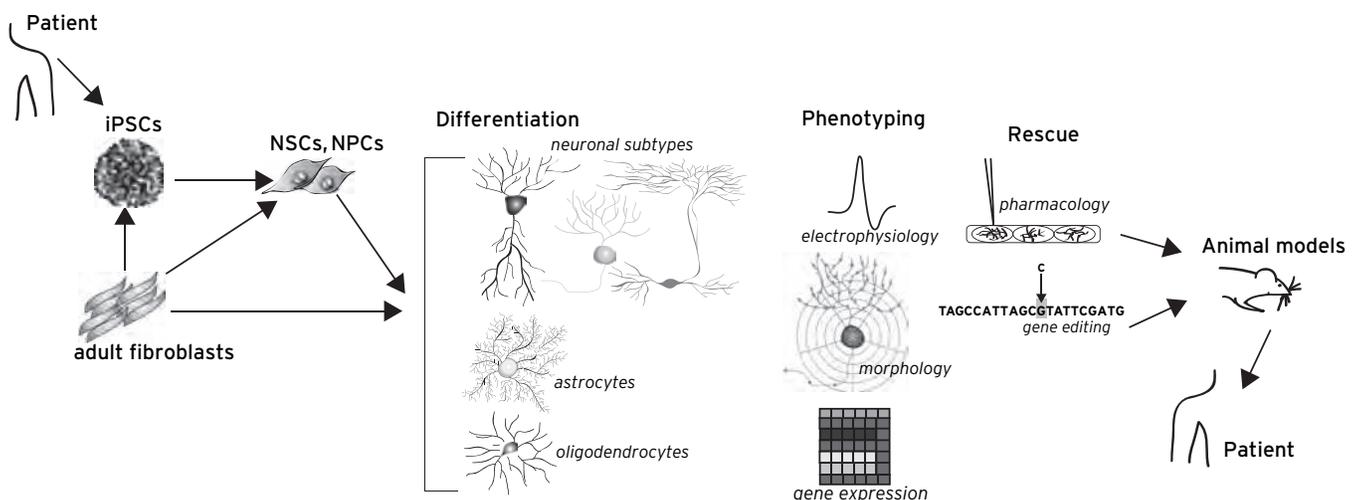

Figure 9.2 Flowchart for application of cellular reprogramming to neurological disorders. Schematic representing process from acquisition of fibroblasts from patients, reprogramming to iPSCs or directly to neural lineages, phenotypic screening of cellular properties, identification of strategies to rescue phenotypes, validation in animal models, and ultimately, the development of novel therapeutic strategies that can be tested in clinical trials.

RETT SYNDROME

Capitalizing on the opportunity to investigate a monogenic ASD developmental disorder marked by both cognitive and motor impairments, several laboratories have generated and begun to characterize neurons derived from Rett syndrome (RTT) patients. Caused by a mutation in the X-linked gene, methyl-CpG-binding protein 2 (*MeCP2*), symptoms of RTT emerge in females around 6–18 months of age, following a period of unremarkable and grossly normal development (Chahrour and Zoghbi, 2007). At the age of onset, developmental processes slow and often regress, resulting in decelerated head growth, movement stereotypy, and severe impairments of verbal and communicative skills. The first characterization of RTT patient-derived neurons revealed several morphological and electrophysiological phenotypes, including altered soma size, spine density, synapse number, calcium signaling, and evoked activity, compared with neurons derived from disease-free subjects (Marchetto et al., 2010). Partial rescue of the decrease in synapse number in RTT neurons was achieved through application of the nonspecific growth factor, IGF1, an effect previously observed in a mouse model of RTT (Tropea et al., 2009). Because the majority of causative *MECP2* variants are nonsense mutations, the authors then explored the possibility of using a pharmacological approach to impair ribosomal proofreading and allow read-through of the premature stop codon to restore *MECP2* expression. Low-dose application of the antibiotic gentamicin was able to enhance *MECP2* expression and showed a similar effect as IGF1 in increasing synapse number. Using two fundamentally different mechanisms for pharmacological rescue of phenotypes, this study demonstrated that at least some facets of cellular dysregulation could be reversed in human neurons. It is somewhat surprising that the enhanced *MECP2* expression did not rescue more of the morphological and electrophysiological deficits since it had been previously shown in a mouse model of RTT that introduction of *MECP2* could reverse behavioral deficits in adult mice (Guy et al., 2007). However, many parameters remain to be explored to determine the temporal requirements for pharmacological treatment in the restoration of cellular function. Following this initial study, independent laboratories confirmed several of the cellular phenotypes (Cheung et al., 2011; Kim et al., 2011b).

One procedural complication in the evaluation of female iPSC lines is the ability to accurately characterize the status of X-inactivation in clonal progeny, an issue that has been central to the investigation of RTT patient iPSCs. Initially, it was reported that reactivation of the silenced X chromosome occurred during reprogramming, resulting in a differentiated population of human neurons that exhibited random X-inactivation based on variable expression of an epigenetic silencing marker, trimethylated histone 3 lysine 27 (me3H3K27), and the loss of *Xist* RNA, a noncoding transcript involved in silencing the inactive X chromosome (Marchetto et al., 2010). Other studies, however, found that iPSCs retained the allelic X-inactivation from the founder somatic cell, which was transcriptionally maintained, despite the emergent loss of *Xist* over extended passaging of the iPSCs (Ananiev et al., 2011; Cheung et al., 2011; Tchieu et al., 2010). Still others have

shown that reprogramming does not alter X-inactivation status from the parent cell but that late-passage iPSCs can lose both *Xist* RNA and me3H3K27 markers, which is believed to signal transcriptional derepression of the inactive X chromosome (Mekhoubad et al., 2012). Yet another group suggested that neither reprogramming of a mosaic culture of fibroblasts nor extensive passaging of fibroblasts results in activation of both X chromosomes, but that there is an intrinsic bias toward a dominant X chromosome and that cells in which the unfavored X chromosome is active are more resistant to proliferation, potentially as a result of shortened telomeres (Pomp et al., 2011). Finally, a systematic study of cell culture conditions showed that spontaneous X reactivation during reprogramming does occur rarely but that the frequency is heavily influenced by feeder conditions (Tomoda et al., 2012). Collectively, the preponderance of current evidence suggests that, unlike reprogramming of murine cells, human cells do not typically undergo transient reactivation of both X chromosomes and that transcriptional assays may be more sensitive than *Xist* or me3H3K27 in detecting the presence of X-inactivation. Further, allelic skewing toward a dominant X-chromosome may impact the reprogramming, proliferative, and differentiation capacity of female iPSCs.

TIMOTHY SYNDROME

Caused by a single-point mutation in the *CACNA1C* gene, Timothy syndrome (TS) is a rare disorder that has a pervasive impact on the developing central nervous system and leads to autism or ASD, in conjunction with other deficits including cardiac arrhythmia and intermittent hypoglycemia. Because most TS patients meet the diagnostic criteria for ASD, this disease provides a useful entry point to investigate cellular phenotypes associated with a psychiatric disease with limited genetic complexity (Splawski et al., 2004). *CACNA1C* encodes the α_1 subunit of the L-type calcium channel, $Ca_v1.2$, and the missense mutation responsible for TS impairs voltage-dependent channel inactivation. To identify the functional impact of the single point mutation on human neurons, iPSCs from TS patients were generated and compared with neurons derived from control subjects without the disease (Pasca et al., 2011). Consistent with the proposed role of the point mutation in regulating $Ca_v1.2$ inactivation kinetics, action potentials recorded from TS neurons exhibited a broader profile, and there was an elevated increase in intracellular calcium following depolarization. This change in intracellular calcium had consequent effects on Ca^{2+} -mediated activity-dependent gene expression through the CREB pathway as evidenced by whole-genome expression profiles. Downstream targets of CREB include tyrosine hydroxylase (TH), the rate-limiting enzyme necessary for dopamine and norepinephrine production. In TS-derived neurons, baseline TH levels were higher, and in contrast to control neurons, there was no downregulation of TH following prolonged depolarization.

The differentiation protocol used in this study was designed to promote the generation of cortical neurons. One of the most striking phenotypes observed in the population-level analysis

of TS-derived neurons was a propensity for differentiation into upper-layer cortical neurons. This finding suggests a new investigative target for postmortem studies to determine whether patients have an imbalance in the composition of cortical neurons. A bias toward upper-layer neurons would effectively increase the proportion of neurons projecting to subcortical regions at the expense of callosal projections and could significantly alter signaling pathways among distributed neural systems. Finally, in an attempt to define the specificity of the mutation and role of the L-type calcium channels in the observed pathology, application of roscovitine, which increases inactivation of this channel subtype, was highly effective in ameliorating expression of TH in differentiated neurons. L-type calcium channels have been independently associated with other psychiatric disorders, including bipolar disorder and schizophrenia (Green et al., 2010; Nyegaard et al., 2010), and these results suggest a potential strategy to reduce abnormal expression of TH via enhanced channel inactivation.

FRAGILE X SYNDROME

Fragile X syndrome (FXS) is a genetically mediated ASD and the most common form of inherited intellectual disability. Caused by an expansion of a CGG repeat (>200 repeats) in the X chromosome-linked fragile X mental retardation gene 1 (*FMR1*) gene, the extent of cognitive deficits can range from mild to severe. The first published report of human iPSCs from FXS patients compared FXS-iPSC lines from three unrelated males with a clinical diagnosis of FXS and CGG repeat length in the full mutation range (Sheridan et al., 2011). Retroviral-mediated reprogramming resulted in several iPSC lines in which the CGG repeat length differed slightly from the donor fibroblast, but it was uncertain whether this change reflected an undetected mosaicism in the fibroblast population or was a consequence of the reprogramming itself. Initial characterization of the patient lines compared with unaffected control lines revealed no significant difference in the capacity to differentiate to a neuronal lineage but a distinct morphological phenotype in the neural progenitor cells in the form of shorter length and decreased complexity of neural processes. A subsequent study focused on premutation CGG repeat length and generated iPSCs from a female with both a normal repeat length (30) and a premutation repeat length (94) on separate X chromosome alleles (Liu et al., 2012). Functional characterization of differentiated neurons revealed several phenotypes, including decreased neurite length, decreased expression of the synaptic marker, PSD-95, elevated spontaneous calcium transients, and heightened responses to glutamate, while repeat length appeared stable throughout reprogramming and differentiation. Together, these studies provide initial evidence of morphological and synaptic abnormalities that are consistent between FXS patients and a carrier of a premutation length CGG repeat sequence and suggest the existence of a graded phenotype associated with repeat-level regulation of *FMR1* expression.

FAMILIAL DYSAUTONOMIA

One of the first studies to rely on hypothesis-driven investigation of neurological disease mechanisms using cellular

reprogramming focused on familial dysautonomia, a rare and lethal disease most commonly arising from a point mutation in the I-k-B kinase complex-associated protein (*IKBKAP*) gene (Lee et al., 2009). This mutation causes splicing defects and tissue-specific expression of the IKAP protein and a progressive loss of sensory and autonomic neurons, but it is unknown at what point during development these neurons become vulnerable to degeneration. Fibroblasts from FD patients and control subjects were obtained and used to generate viable iPSC lines. After targeting differentiation to five tissues spanning all three embryonic germ layers, the authors identified lower absolute levels of wild-type IKAP expression in neural crest precursors, the lineage most affected in FD. Transcriptome analysis of purified FD neural crest precursors revealed decreased transcripts of genes that regulate neurogenesis and differentiation compared with controls, which was reflected in a relative decrease of FD neural crest precursors to differentiate into neurons. Migration deficits were also observed in the neural crest precursors derived from patient iPSCs. All of these data suggest that at least some of the phenotypes associated with FD could result from early defects in neuronal development, as opposed to degeneration of a well-developed peripheral nervous system. Previous studies using lymphocytes from patients had identified the plant cytokinin, kinetin, as a bioactive compound capable of reducing expression of mutant *IKBKAP*. Acute application of kinetin to neural crest precursors increased the ratio of normal to mutant transcript of *IKBKAP*. Chronic application of kinetin beginning prior to differentiation reduced the deficits in neurogenic gene expression and increase in markers of peripheral neurons, although no rescue of migratory defects was observed. Although FD is not a predominantly psychiatric disorder, this early study was instrumental in illustrating the potential of using patient-derived iPSCs for initial screening of cellular phenotypes and the evaluation of candidate compounds for biochemically mediated rescue. In addition, it demonstrates how recapitulation of developmental processes can pinpoint the time of pathological onset and disambiguate between neurodevelopmental and neurodegenerative effects.

PARKINSON'S DISEASE

Parkinson's disease (PD) is a late-onset progressive neurodegenerative disorder that affects dopaminergic neurons in the substantia nigra of the basal ganglia. Primary symptoms of PD involve impairments in motor control and postural stability, although cognitive impairments and psychological disturbances are often associated with the disease. Several genetic loci have been associated with the rare cases of familial PD, including mutations in α -synuclein, *LRRK2*, *PTEN-induced putative kinase 1* (*PINK1*), *parkin*, and *DJ-1* (Martin et al., 2011). Risk for sporadic PD may be partially mediated by variation in these and other unidentified genes in combination with environmental risk factors that have yet to be fully understood. Although early studies showed successful generation of iPSCs from patients with sporadic forms of PD, more recent studies have focused on patients with a single known mutation

in an attempt to isolate specific genetic influences on cellular pathology and establish a baseline from which to investigate functional dysregulation. These studies targeting monogenic influences have revealed several characteristic phenotypes in differentiated dopaminergic or tyrosine hydroxylase-positive neurons. The G2019S missense mutation in the *LRRK2* gene, associated with both familial and sporadic PD cases, resulted in the increased expression α -synuclein, the protein that aggregates to form Lewy bodies, a signature of PD and other degenerative diseases (Nguyen et al., 2011). Also, in support of previous animal and cellular models, differentiated dopaminergic neurons from these *LRRK2*-mutated patient iPSCs showed a modest upregulation of select oxidative stress genes in basal conditions and enhanced vulnerability to neurotoxins and hydrogen peroxide-induced cell death. Investigation of a different genetic locus, the *PINK1* mutation, revealed deficits in depolarization-induced translocation of Parkin to mitochondria, which was restored through lentiviral-mediated expression of wild-type *PINK1* in the mutant iPSC lines (Seibler et al., 2011). Because Parkin is believed to act in a *PINK1*-dependent manner to degrade dysfunctional mitochondria, levels of mitochondrial DNA were quantified and shown to be higher in the mutant dopaminergic neurons, although increased levels of a mitochondrial biogenic protein were also observed, raising the possibility of enhanced mitochondrial production in the mutant neurons. In a separate study, direct investigation of Parkin mutations (affecting exons 3 and 5) did not reveal any differences in expression levels of mitochondrial DNA or α -synuclein (Jiang et al., 2012). However, mutant neurons showed increased spontaneous release of dopamine and decreased dopamine uptake due to misfolding of dopamine transporter proteins that impacted dopamine binding sites. Hypersensitivity to dopamine-induced oxidative stress was also observed in the patient-derived neurons, likely a result of the compromised Parkin-regulated expression of monamine oxidases A and B in mutant neurons.

Several of these initial studies to characterize the cellular phenotypes of disease-relevant mutations in PD-associated genes used expression of wild-type protein to effectively rescue deficits, suggesting the genetic specificity of the observed phenotypes. More recently, investigators have begun to explore alternative means of reversing cellular pathology through pharmacology. In a comprehensive study of several iPSC lines derived from patients with either a *PINK1* or one of two known *LRRK2* mutations, treatment of differentiated neural cells with the antioxidant coenzyme Q_{10} reduced vulnerability to low-dose exposure to the chemical toxins valinomycin and concanamycin A as measured by cellular release of lactate dehydrogenase (Cooper et al., 2012). Interestingly, the sensitivity to chemical stressors was enhanced in the derived neural cells when compared directly with the fibroblasts, suggesting that the observed pathology was selective to cell types that are more functionally similar to the affected neuronal populations in the patients.

In one of the first studies to employ targeted gene editing in the investigation of neurological disease, Soldner et al. took a counterbalanced approach to generate several isogenic iPSC lines that differed in two point mutations in the α -synuclein

gene associated with familial PD (Soldner et al., 2011). The distinct advantage of this approach is the virtual elimination of genetic variability that is introduced when comparing patient iPSCs with “control” iPSCs derived from disease-free individuals, who differ not only in disease status but genetic background. In complementary sets of experiments, the authors repaired the point mutations in patient-derived iPSCs to generate isogenic lines with either mutant or wild-type α -synuclein expression and introduced the point mutations to hESCs to express the mutant form of α -synuclein. The strategy used for the targeted manipulation of the base pair changes was a zinc finger nuclease (ZFN) gene-editing technique that employs a combination of DNA-binding domains specific to the target sequence with a generic cleavage domain. Nuclease-mediated introduction of double-strand breaks in the DNA are then repaired through either nonhomologous end joining or homology-directed repair end joining. Use of this strategy requires additional assays to verify the absence of off-target cleavage sites and genomic alterations. Although neuronal phenotypes in the edited iPSCs were not extensively characterized, this study provided an important proof of principle that selective gene editing is feasible, and this technique will be instrumental in identifying the specific role of restricted genetic variation in monogenic diseases.

HUNTINGTON'S DISEASE

Huntington's disease (HD) is another late-onset neurodegenerative disorder that initially impacts medium spiny neurons in the striatum, progresses to involve other brain regions, and induces pervasive motoric and cognitive impairments. HD is caused by an autosomal dominant mutation in the Huntingtin gene characterized by excessive polyglutamine (CAG) repeats, the number of which strongly correlates with the age of onset. In a collaborative study published by the Huntington's Disease iPSC Consortium, a total of 14 iPSC lines from HD patients and controls were extensively characterized. Interestingly, the CAG repeat length appeared to exhibit a graded phenotypic profile in only a subset of assays, including a measure of calcium homeostasis (The HD iPSC Consortium, 2012). In a separate study, gene editing through the use of bacterial artificial chromosome (BAC)-based homologous recombination was successful in reducing the number of CAG repeats in HD patient iPSCs (An et al., 2012), resulting in two corrected iPSC lines with 21 and 20 repeats, below the pathological threshold (36 CAG repeats). Strikingly, the genetic correction was able to protect neural stem cells against cell death following withdrawal of growth factors, restored levels of brain-derived neurotrophic factor (BDNF), and enhanced mitochondrial function. In one of the few studies to evaluate glial phenotypes in relation to neurological disease, astrocytic differentiation of HD iPSCs revealed distinct vacuoles in the somatic cytoplasm of cells derived from two genetically related HD patients, which was more pronounced in astrocytes generated from the patient with a longer CAG repeat length and early-onset HD (Juopperi et al., 2012). Initial characterization showed indistinguishable properties between patient and control iPSC-derived neurons. Interestingly, HD neural progenitors transplanted to

the neurogenic subventricular of the adult mouse brain were capable of generating immature neurons that migrate along the endogenous rostral migratory stream and differentiate into mature neurons in the olfactory bulb. *In vivo* transplantation of neural precursors was later shown to result in successful differentiation of GABAergic neurons and modest functional recovery in rats subjected to unilateral striatal lesions (Jeon et al., 2012). *In vivo* neuronal pathology following transplantation of patient-derived neural progenitors was only observed at remote time points. This observation suggests the possibility that latent phenotypes may emerge after an extended period of development and integration *in vivo* and, importantly, that the rodent brain may serve as viable model to evaluate age-dependent factors regulating neural pathology.

POLYGENIC DISEASES

For most psychiatric disorders, there is no single identified genetic cause. These complex polygenic diseases, which are known to include schizophrenia, affective disorders, and the vast majority of ASDs, are instead associated with several hundred “risk” genes that may increase the probability of disease onset to variable degrees but alone are not causally sufficient to induce the disease (Eichler et al., 2010). Because these genes confer only susceptibility, there are several other factors that can modify the net risk for a given individual. Any number of combinations of environmental influences, epigenetic mechanisms, and genetic interactions could enhance susceptibility for disease. Disentangling the individual contributions of each factor to the pathophysiology is extremely challenging. Using iPSCs to address this issue should proceed in a systematic fashion starting from known parameters. If the donor material is obtained from patients, the one certainty is that the genetic background is at least permissive for the disease state. Building upon that knowledge, it is then feasible to explore the impact of additional influences on cellular integrity.

SCHIZOPHRENIA

One such strategy was recently employed in a phenotypic screen of iPSCs derived from unrelated patients with sporadic schizophrenia (SZ) who had no identified genetic link (Brennand et al., 2011). This study was among the first to characterize the functional properties of human neurons from patients with a psychiatric disease and describes a comprehensive battery of assays designed to reveal pathological disturbances predicted to be relevant for SZ. Several prominent cellular phenotypes were identified, including a deficit in cellular connectivity among differentiated neurons, which was partially rescued through application of the antipsychotic drug loxapine. Markers of synaptic function, including PSD95 and glutamate receptor expression, were diminished in the patient-derived iPSCs but functional synaptic transmission appeared largely intact. In order to investigate changes in gene expression shared among lines derived from different patients, the authors analyzed RNA expression profiles and identified a subset of genes related to the cyclic AMP- and WNT-signaling

pathways that were common to all SZ-iPSC lines. Strikingly, only 25% of the genes that were differentially regulated in the SZ-iPSCs had been previously identified as putative risk genes, and many of these genes are involved in signaling pathways not previously associated with SZ.

These results illustrate both the potential utility of patient-derived iPSCs to identify novel gene interactions in complex genetic disorders and the constraints imposed by the technical challenges of generating multiple iPSC lines on a large enough scale to validate the role of these interactions in cellular phenotypes in diverse patient populations. Importantly, however, this study effectively demonstrates how a genetically complex disease can be probed mechanistically through patient-specific iPSCs and lead to the identification of novel cellular targets of pathology.

Although schizophrenia is a genetically complex disease, several genes have emerged as prominent risk factors. Originally identified at the breakpoint of a balanced (1;11)(q42;q14) chromosome translocation in a large Scottish family, mutations in *DISC1* have been shown to segregate with schizophrenia, schizoaffective disorders, and major depression in several studies (Porteous et al., 2011). Genetic mouse models have been developed to manipulate *DISC1* expression, and several phenotypes have been identified in behavioral assays such as prepulse inhibition, latent inhibition, working memory, and sociability that are reminiscent of symptoms in SZ patients (Johnstone et al., 2011). However, similar to the heterogeneity observed in the clinical profile of patients and family members with *DISC1* mutations, the behavioral deficits observed in the rodent models also varied across studies using different strategies to disrupt *DISC1* expression. Recently, an episomal-vector-based approach was used for integration-free reprogramming of fibroblasts from several family members who harbor a 4 bp mutation in the *DISC1* gene (Chiang et al., 2011). In this family, the *DISC1* mutation is associated with increased risk for schizophrenia, schizoaffective disorder, and major depression (Sachs et al., 2005). Reprogramming efficiency and differentiation capacity were similar to control iPSCs in the initial characterization assays. Together, these two studies, focused on generation of iPSCs from schizophrenia patients, represent complementary strategies to identify relevant pathology and etiological factors. Data generated from both approaches may eventually converge on a common set of developmental mechanisms that are vulnerable to dysregulation in individuals at risk for SZ.

ALZHEIMER'S DISEASE

Another strategy to begin to resolve the ambiguity in the etiology of diseases not fully explained by heritable mutations was described in a recent study that directly compared iPSCs from familial and sporadic Alzheimer's disease (AD) patients (Israel et al., 2012). A late-stage neurodegenerative disease, AD induces widespread cellular pathology in both cortical and subcortical regions and is associated with the presence of neurofibrillary tangles and amyloid plaques identified in postmortem analyses. Familial forms of AD can result from a duplication in the amyloid- β precursor protein gene (*APP*). In this study, patient-derived iPSCs were generated from two

patients with familial AD and two patients with sporadic AD. Interestingly, neurons generated from one of the sporadic AD patients showed a phenotypic similarity along a number of dimensions with both lines generated from the familial AD patient. All three lines exhibited increased levels of amyloid- β and phosphorylated tau, suggesting a mechanistic link between plaque and tangle formation. Strikingly, the line from the second sporadic AD patient exhibited none of these phenotypes and thus indicated the possibility of categorical discrimination of patients with sporadic AD based on a phenotypic profile. However, it remains an outstanding question whether the difference in cellular phenotypes from these two sporadic AD patients results from distinct mechanisms or instead a variable latency in the development of phenotypes in neurons differentiated from reprogrammed cells.

In relatively late-onset diseases such as AD and even SZ, a critical question is the nature and duration of the prodromal period. At what point is cellular or systems-level pathology discernible? And is there a critical window, before the onset of deterministic pathological development, when successful intervention is possible? This is a particularly salient issue with respect to newly differentiated human neurons as cellular pathology may not be present in cells that have not been sufficiently challenged by exogenous or endogenous demands. Although we are fully capturing the static genetic background of patients, culturing derived human neurons in a dish cannot recapitulate the dynamic conditions of a mature human brain, either in terms of acute environmental demands or the trajectory of its past history. It is an open and important question how the developmental timeline in cultured human neurons maps onto the endogenous state of *in vivo* neuronal development. In this respect, one of the potential advantages of direct programming to neurons or neural stem cells is that differentiated neurons may, in fact, retain age-specific features of the donor material (Saha and Jaenisch, 2009), while differentiation of iPSCs may most closely recapitulate embryonic development due to a complete resetting of the cellular clock. Although a comparison between iPSCs and direct induction of neurons from fibroblasts of a single patient has yet to be tested in a late-onset disease model, direct conversion of skin fibroblasts from sporadic and familial AD patients was recently reported (Qiang et al., 2011). Familial AD-induced neurons revealed deficits in the processing of the amyloid precursor protein and increased production of amyloid- β , caused by a dominant mutation in the *Presenilin-1* gene, characteristic features associated with AD pathology. It remains to be seen whether direct conversion will have any advantage in modeling age-dependent disease mechanisms, but this is a rapidly developing area of research and one of the many strategies being pursued to optimize cellular reprogramming.

MODELING PSYCHIATRIC DISORDERS IN NONHUMAN ANIMALS

Moving forward, reprogramming technology should be integrated with *in vivo* animal experimentation to build dynamic models of disease etiology and a platform to evaluate the

efficacy of proposed treatment. To maximize the potential of stem cells to inform our understanding of disease mechanisms, we should work to apply knowledge gained from cellular analyses toward a systems-level inquiry of how pathology in neural components can affect global brain function. And conversely, we will need to identify how to engineer targeted rescue of disease phenotypes, while leaving normally functioning systems intact. Nonhuman animal models will be vital to this effort and can provide a means to evaluate basic properties of neural stem cells and progenitors in the mature brain.

IN VIVO TRANSPLANTATION

One of the most often discussed benefits of patient-specific cellular reprogramming is the potential for cellular replacement with minimal risk of immune rejection. Undoubtedly, this holds great promise for any number of human diseases that affect tissues with relatively homogenous cellular distribution and function. For disorders of the central nervous system, however, the vast heterogeneity of cell type and widespread anatomical distribution of deeply integrated functional systems may preclude the straightforward replacement of affected neural populations. For many predominantly psychiatric diseases, we do not yet know the extent of the causally relevant pathology, nor do we have a strategy for directing integration of exogenous populations to distributed loci within the brain.

But *in vivo* transplantation of derived human neurons in animal models is an important step in the full characterization of neuronal function. The ability of stem cells and progenitors to differentiate and integrate *in situ* not only will be critical for cell engineering in therapeutic applications but also will provide another level of analysis to identify disease-relevant phenotypes. By introducing patient-specific neural precursors to the developing or mature brains of rodents or nonhuman primates, we may be able to observe latent phenotypes that were not readily apparent in cell culture conditions. Further, we will be able to expose transplanted neurons to physiological stressors in an intact animal model to investigate the impact of environmental conditions on genetically mediated disease risk. To date, several studies have provided proof of principle to demonstrate that transplanted neural stem cells and progenitors are capable of differentiation into mature neurons with signature properties of effective synaptic signaling and targeting. In a stroke model, neuroepithelial-like stem cells derived from adult human iPSCs were transplanted to either the cortex or striatum and the grafted cells differentiated into several neuronal subtypes including GABAergic interneurons and projection neurons (Oki et al., 2012). Neural precursors from HD patient iPSCs have also been successfully grafted into adult mice and rat brains, and initial characterizations showed immunohistological evidence of mature neurons (Jeon et al., 2012; Juopperi et al., 2012).

ENDOGENOUS NEUROGENESIS AS A MODEL SYSTEM

In addition to providing a host system to interrogate *in vivo* functionality of human neurons, nonhuman animals also provide an

empirically tractable system in which to explore the basic properties of endogenous neurogenesis. Because adult neurogenesis mirrors embryonic neurodevelopment on a dilated timescale, it is more amenable to systematic investigation of intracellular and niche signaling pathways. As an *in vivo* cellular model, adult neurogenesis has been effectively used to explore neurodevelopmental mechanisms of psychiatric disease. This model has been most extensively characterized with respect to the schizophrenia risk gene, *DISC1*. Accruing evidence implicates *DISC1* in a wide range of neurodevelopmental processes. During embryonic neuronal development, knockdown of *DISC1* can lead to premature exit from cell cycle and early differentiation, reducing the proliferative capacity of neural progenitors (Mao et al., 2009) and disorganization of dendritic arbors in the developing cerebral cortex (Kamiya et al., 2005). In adult hippocampal neurogenesis, *DISC1* interacts with several binding partners to regulate several aspects of neuronal development. Effects on proliferation of neural progenitors are mediated through the GSK3 β -signaling pathway (Mao et al., 2009). Interaction with KIAA1212/Girdin impacts several morphological phenotypes, including soma size, primary dendrite formation, dendritic length, and migration patterns (Enomoto et al., 2009; Kim et al., 2009). Direct interactions of *DISC1* with NDEL1 and FEZ1 each lead to a complementary, nonoverlapping subset of phenotypes (Duan et al., 2007; Kang et al., 2011). Globally, *DISC1* acts as a negative regulator of neuronal and dendritic development during the temporally extended time course of adult neurogenesis. Knockdown of *DISC1* in proliferating cells results in the acceleration and overshoot of neuronal development *in vivo*, an effect that is at least partially mediated by concomitant levels of GABAergic signaling (Kim et al., 2012). Systematic investigation of the *DISC1*-signaling pathways during adult neurogenesis provides important mechanistic information about the potential role of this gene in risk for disease pathology that can subsequently be probed in human neurons derived from patients and “at-risk” family members. Further, it is possible to identify novel synergistic or epistatic genetic interactions within a single signal transduction pathway that may begin to explain the variable penetrance of many risk genes and “missing heritability” observed in many genome-wide association studies (Eichler et al., 2010).

CHALLENGES FOR MODELING PSYCHIATRIC DISORDERS

Tremendous progress has been made in the effort to generate renewable sources of human neurons for mechanistic investigation of psychiatric disease, but many significant challenges remain. With the publication of each new study, the field evolves, and new information emerges about critical variables that may influence effective reprogramming, neuronal generation, and the variability in iPSCs, all of which could impact the investigation of disease-specific and patient-invariant phenotypes necessary for the development of widely applicable therapeutic approaches.

During embryonic development, epigenetic mechanisms constrain and direct cell fate, transforming totipotent stem cells

into lineage-specific progenitors and, ultimately, terminally differentiated cell types. A goal of cellular reprogramming is to erase the epigenetic signature of the source tissue, creating a cellular tabula rasa from which researchers can direct fate specification to the desired cell type. However, several studies have shown that iPSCs can retain DNA methylation signatures similar to the tissue of fibroblast origin, indicating incomplete reprogramming (Plath and Lowry, 2011). ESCs remain the standard against which iPSCs are measured to evaluate pluripotency and unbiased potential for differentiation. Characterizing the extent of residual genetic and epigenetic somatic memory in iPSCs remains an ongoing challenge, but efforts are being made to directly compare those generated from different somatic tissues and across independent laboratories to isolate sources of variability (Boulting et al., 2011).

While differentiation capacity may be largely impacted by the extent of reprogramming, the optimization of specific protocols to direct targeted differentiation is also still very much a work in progress. Researchers are just beginning to refine differentiation protocols to enrich specific cell populations and have demonstrated successful generation of GABAergic, glutamatergic, dopaminergic, and layer-specific cortical neurons as well as astrocytes and oligodendrocytes (Hansen et al., 2011). However, many of these studies have only been able to bias differentiation toward the desired fate, resulting in a mixed population that could still require an additional step to isolate homogenous populations for studies of cell-autonomous phenotypes. But in the investigation of psychiatric disease, identification of genetically mediated, cell-autonomous pathology should be countered by an equally vigorous attempt to understand dysfunction within integrated neural networks. One approach will be to pursue *in vivo* transplantation strategies, but another would be to develop small-scale models of neuronal interactions *in vitro*. By modeling features of endogenous cell distributions in a given brain region, it may be possible to isolate discrete signaling defects between specific neural subtypes and begin to approximate physiological conditions.

Certainly, this represents one of the most significant challenges looking forward—how to ask the right questions so that we can observe signatures of neuronal dysfunction *in vitro* that may be relevant to disease etiology. Newly differentiated human neurons *in vitro* exist in an environment that is temporally and spatially distinct from the system we are trying to understand. Many of the specific phenotypes observed thus far in patient-derived iPSCs are remarkably congruent with data from animal models or postmortem studies and support current working hypotheses. However, many of the patient-derived neurons exhibit minimal or unexpected phenotypes when compared with controls. But our current methodological tools may not have the resolution and sensitivity to detect all the environmental influences on cellular function, which properties are specific to neurons in a dish versus neurons in a brain, and how the history and age of the neuron affects its function. In addition to the procedural challenges facing all researchers invested in cellular reprogramming, investigators of psychiatric disorders are additionally challenged in using *de novo* human neurons to investigate a biological system that can store and retrieve information for decades, a system in which function is

often measured by the capacity for both constitutive plasticity and long-term memory.

CONCLUSION

Both conceptually and empirically, there is a huge chasm between traditional animal models of psychiatric illness and the limited range of information we have been able to garner from studies of patients and postmortem analysis of human brains. Cellular reprogramming has enabled us to partially fill this gap by establishing a new intermediate level of investigation. Physicians often lament that for many neuropsychiatric disorders, their only option is to treat the symptoms of disease, as opposed to its underlying cause. Stem cell technology has the potential to transform this palliative approach to one in which novel therapies are generated from rational design based on causal mechanisms. It remains to be seen whether this field will live up to its promise and whether some of the most troubling issues can be resolved in order to enable revolutionary new therapies for patients. Also uncertain is the extent to which fundamental principles that evolve from a focus on the most prominent psychiatric disorders, namely, affective disorders, schizophrenia, and ASD, can be successfully applied to other disorders such as compulsive and dissociative disorders. In principle, generalization is possible, but for many of these less well-studied disorders, there is a paucity of data on putative risk genes, postmortem analyses, and validated behavioral correlates in animals, all of which are critical to the generation of testable hypotheses using patient-derived human neurons.

But what is appealing about the use of iPSCs and investigations of patient-specific human neurons is the possibility to redefine diagnostic criteria of disease based on a mechanistic understanding of the features underlying relevant pathology. Identification of etiological factors can inform the discussion over whether a categorical or dimensional approach to the diagnosis and treatment of patients is most efficacious. What has been missing in this debate over the years is a mechanistic understanding of symptomatology that may transcend traditional boundaries of behavioral categorization. And it is likely that the granularity of analysis will change the more we understand the mechanisms. For example, positive and negative symptoms of schizophrenia may have different neural substrates, but the negative symptoms may be mechanistically similar to features of depressive disorders. Stem cell researchers should build upon this diagnostic framework to test discrete hypotheses regarding neural structure and function while adopting an agnostic stance toward the possibility of shared mechanisms among categorically distinct diseases.

De novo generation of human neurons that are isogenic to patients reflects a remarkable achievement and a putative turning point in our attempt to understand human neurological diseases. But mental illness is humbling in its complexity, and we are a long way from being able to answer the questions posed at the outset of this chapter. Nor can we expect that iPSCs will provide the consummate solution. We will not be able to delineate the phenomenology of mental illness by investigating neurons in a dish. Psychiatric disorders are often characterized

by complex deficits such as an impairment in exerting volitional control over behavior, the persistence of aberrant sensory processing, or maladaptive responses to external demands. We cannot expect that investigations of dissociated human neurons will be able to provide a comprehensive explanation for what is ultimately an embodied phenomenon, and it is a mistake to presume that a cell-based reductionist strategy will be able to capture all the relevant features of psychiatric disease. Our brains are composed of neurons and glia and a rich milieu of chemical neurotransmitters and modulators. What cellular reprogramming has given us is a means to examine the building blocks of the human brain to search for patient-invariant phenotypes and molecular mechanisms associated with complex diseases. For the first time, we can generate and manipulate human neurons that have confirmed disease-relevant genetic profiles. While the majority of psychiatric diseases may not be immediately amenable to cell-replacement strategies, there is a wealth of information to be gleaned from an understanding of the basic mechanisms. The promise of this technology is nearly boundless, and it is our sincere hope that the excitement, innovation, and productivity expressed by researchers thus far will continue to grow and contribute to a better understanding of how dysfunction of neural components and processes can lead to some of the most devastating ailments. Most importantly, we may learn how to reverse or prevent dysfunction to alleviate the suffering of people who have limited information about why or how their symptoms emerge. A better mechanistic understanding of mental illness will not only enable the development of new therapeutic approaches but will also help affirm that these diseases are the consequence of specific neural pathology and dysregulation of discrete neural processes.

DISCLOSURES

10 | OPTOGENETIC TECHNOLOGIES FOR PSYCHIATRIC DISEASE RESEARCH: CURRENT STATUS AND CHALLENGES

LIEF E. FENNO AND KARL DEISSEROTH

INTRODUCTION

Studying intact systems with simultaneous local precision and global scope is a fundamental challenge in biology. This familiar tradeoff leads to important conceptual and experimental difficulties in psychiatric disease research and, indeed, throughout the study of complex biological systems. Part of a solution may arise from the technology of optogenetics: the combination of genetic and optical methods to achieve gain- or loss-of-function of temporally defined events in specific cells embedded within intact living tissue or organisms (Deisseroth, 2010; Deisseroth et al., 2006, 2011, 2012; Fenno et al., 2011; Scanziani and Häuser, 2009). Such precise causal control within the functioning intact system can be achieved via introduction of genes that confer to cells both light detection capability and specific effector function. For example, microbial opsin genes can be expressed in mammalian neurons to mediate millisecond precision and reliable elicitation or inhibition of action potential firing in response to light pulses, while hybrid opsin receptor proteins called optoXRs can recruit defined biochemical signaling pathways in response to light (Fig. 10.1; recent primers on this methodology have been published [Yizhar et al., 2011a; Zhang et al., 2011]).

This approach has now been used to control neuronal activity in a wide range of animals, resulting in insights into fundamental aspects of circuit function, as well as circuit dysfunction and treatment in pathological states (Deisseroth, 2012; Tye et al., 2012). Here we review the current state of optogenetics for neuroscience and psychiatry and address the evolving challenges and future opportunities. Despite both rapid growth and wide scope of applications, fundamental challenges remain to be addressed.

BACKGROUND: CURRENT FUNCTIONALITY OF TOOLS

Diverse and elegant mechanisms have evolved to enable organisms to harvest light for survival functions. For example, opsin genes encode 7-transmembrane (TM) proteins that (when bound to the small organic chromophore all-*trans* retinal) constitute light-sensitive rhodopsins, which are found across all kingdoms of life (Fenno et al., 2011). Many prokaryotes

employ these proteins to control proton gradients and to maintain membrane potential and ionic homeostasis, and many motile microorganisms have evolved opsin-based photoreceptors to modulate flagellar motors and thereby direct phototaxis toward environments with optimal light intensities for photosynthesis. Owing to their structural simplicity (both light-sensing and effector domains are encoded within a single gene) and fast kinetics, microbial opsins can be treated as precise and modular photosensitization components for introduction into non-light sensitive cells to enable rapid optical control of specific cellular processes. For example, channel-rhodopsins (Fig. 10.1, left) such as ChR2 induce nonselective cationic photocurrents in response to illumination, resulting in a net depolarization and spike firing in neurons, first demonstrated in 2005 (Boyden et al., 2005). Halorhodopsins (Fig. 10.1, middle; NpHR) conduct chloride, and bacteriorhodopsin and related opsins conduct protons (not shown) in response to illumination, both hyperpolarizing neurons (Chow et al., 2010; Zhang et al., 2007, 2011) reviewed in Mattis et al., 2012; Yizhar et al., 2011a). Many other nonopsin classes of naturally occurring protein have been explored as well, including flavin chromophore-utilizing light-activated adenylyl cyclases, as well as artificially engineered systems in which light sensation modules become physically linked to effector modules (Airan et al., 2009; Gulyani et al., 2012; Möglich and Moffat, 2007; Stierl et al., 2011; Wu et al., 2009).

The relatively small number of initial genomically identified opsins has now been dwarfed by an ever-increasing portfolio of derivatives designed to manipulate peak wavelength, current magnitude, and inactivation time constant (τ_{off}). τ_{off} is an intrinsic property that describes the time taken for an opsin to spontaneously relax from the conducting state to the non-conducting state after the cessation of light. The τ_{off} of ChR2 is ~12 ms whereas (e.g.) that of the mutant ChR2-H134R is approximately doubled (Mattis et al., 2012; Fig. 10.2); this property in part determines the maximum frequency at which a neuron may produce precisely timed light-initiated action potentials (Gunaydin et al., 2010; Mattis et al., 2012). Indeed, an opportunity was seen to speed up optogenetic control function by modulating τ_{off} ; destabilizing the open state of the channel could lead to a more rapid spontaneous reversion to the nonconducting state of ChR2 following light cessation, thereby increasing the frequency ceiling for driving

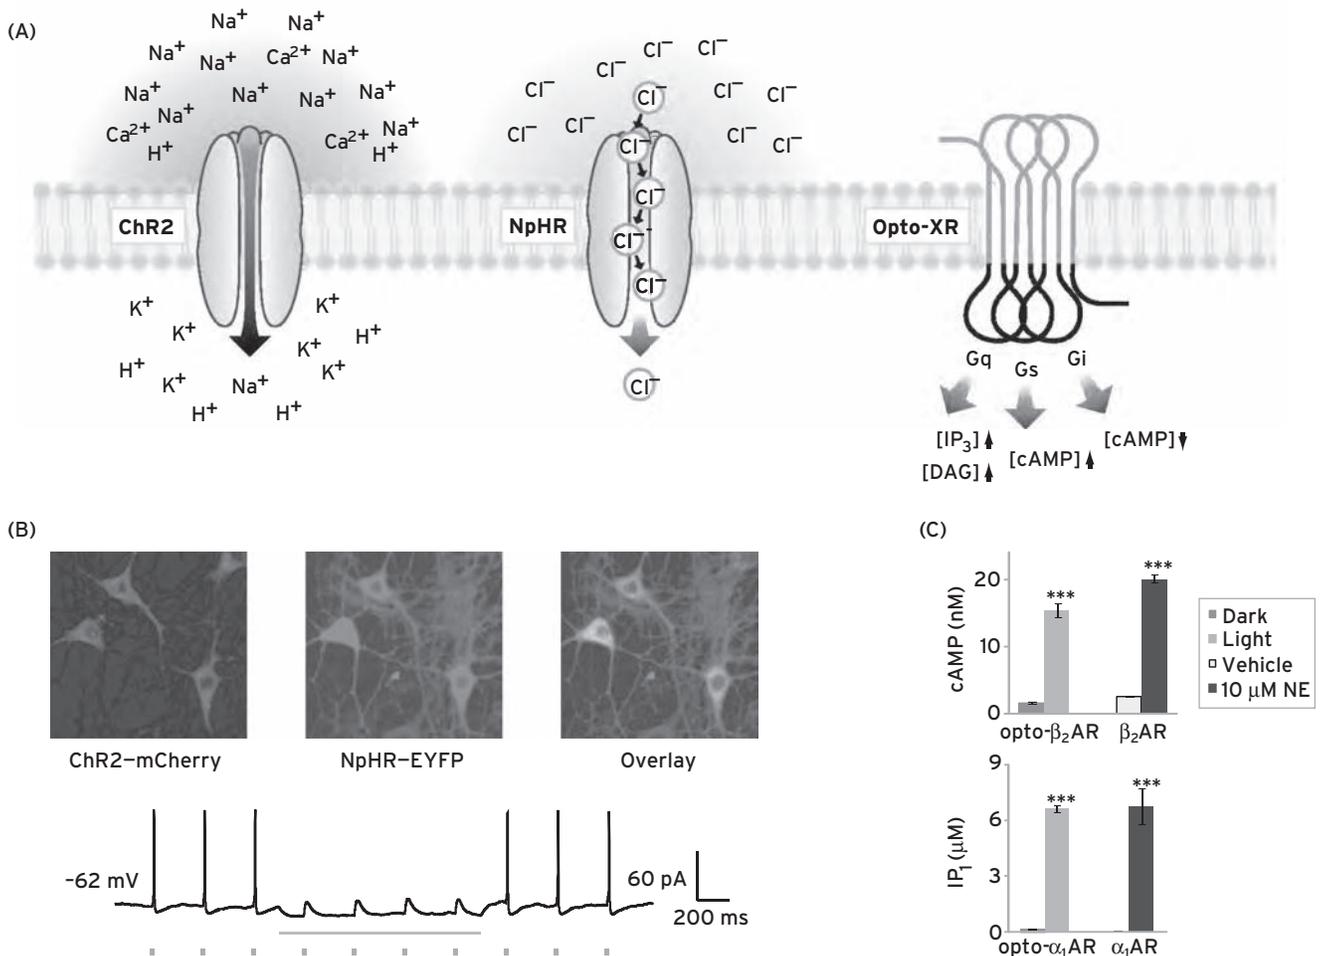

Figure 10.1 Optogenetic tool families. (A) Channelrhodopsins (left), such as ChR2, induce nonselective cationic photocurrents in response to illumination, resulting in a net depolarization and spike firing in neurons. Halorhodopsins (middle; NpHR) conduct chloride, and bacteriorhodopsin and related opsins conduct protons (not shown) in response to illumination, both hyperpolarizing neurons. The optoXRs (right) are chimeric proteins that elicit biochemical signal cascades in response to illumination. The specific biochemical cascade is determined by the source of the intracellular loops. (B) Whole-cell patch clamp response of a neuron expressing both ChR2 and NpHR. Pulses of dark gray light activate ChR2 and induce sufficient depolarizing photocurrent to produce action potentials whereas dark gray light induces an inward chloride current that hyperpolarizes the neuron and prevents firing. (C) Response of HEK cells expressing opto β_2 or native β_2 adrenergic receptor (top), or opto α_1 or native α_1 adrenergic receptor (bottom). Production of downstream biochemical effectors is similar in magnitude from optical stimulation of optoXRs (left) and agonist-induced response in native receptors (right). (Panel A adapted from Fenno et al., 2011; panel B adapted from Zhang et al., 2007; panel C adapted from Airan et al., 2009.)

neurons—an especially important consideration for some classes of fast-spiking inhibitory interneurons, including those expressing parvalbumin (PV). By applying observations in the bacteriorhodopsin literature to ChR2 based on the high degree of homology among Type I rhodopsins, it was found that shifting a single amino acid residue was sufficient to approximately halve the τ_{off} (ChETA; Gunaydin et al., 2010; Mattis et al., 2012), thereby increasing the top high-fidelity frequency to at least 200 Hz and increasing overall performance. A separate creative approach to creating a channelrhodopsin with a rapid τ_{off} arose from chimeras of ChR1 and ChR2 (ChEF/ChIEF) (Lin et al., 2009; Mattis et al., 2012) (Fig. 10.2).

Opsins optimized for rapid closure and high-frequency stimulation are complemented by ChR2 variants designed to induce prolonged depolarization after light cessation. The engineering approach to design these proteins also took advantage of homology between ChR2 and BR to produce variants

that stabilize, as opposed to destabilize, the active retinal conformer. These “step function opsins” (SFO) allow precise induction and inactivation of a depolarizing current “step” into the population of neurons, the duration of which is dependent upon the particular mutation (C128S: 100s, Berndt et al., 2008; D156A: 6.9 min, Bamann et al., 2008; C128S/D156A: 29 min [stabilized step function opsins/SSFOs], Yizhar et al., 2011b) (Fig. 10.2). As these are derivatives of ChR2, they are activated by blue (470 nm) light. This depolarizing step can then be terminated with yellow light (590 nm), which drives the opsin to its resting state. In the case of SSFO, the most stable of the SFOs, the depolarization step occurs without crossing the sodium channel activation threshold, which has the useful effect of modestly sensitizing a population of neurons to incoming excitatory input.

One additional benefit of an extended τ_{off} is that the cell expressing the protein may effectively act as a photon

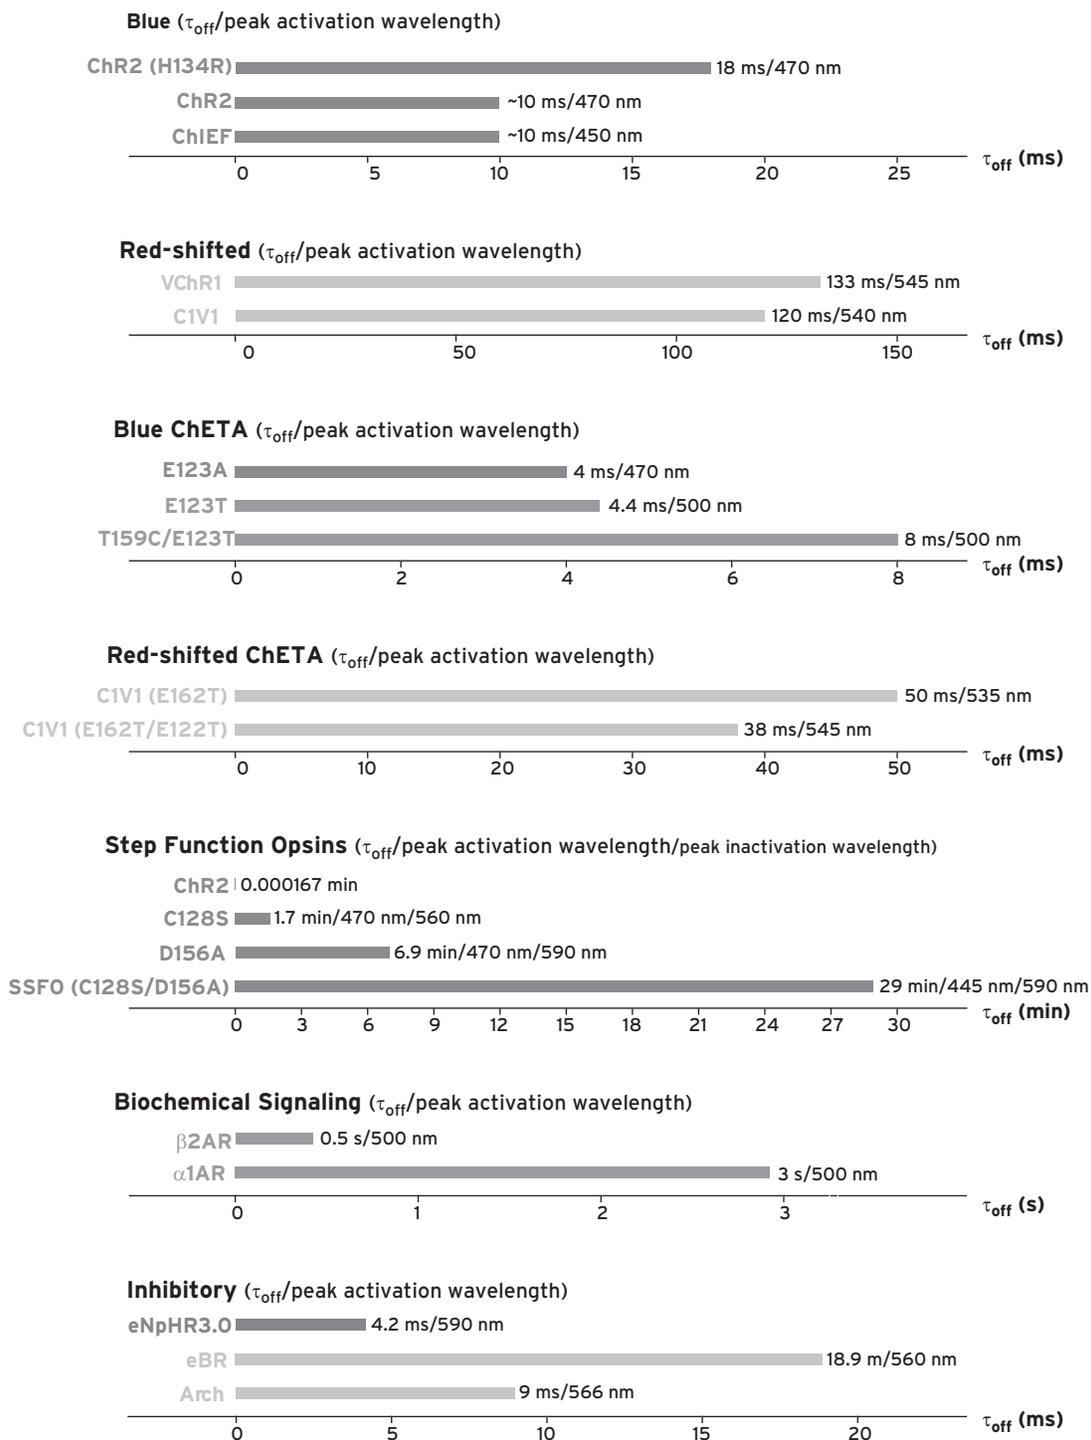

Figure 10.2 Properties of optogenetic tools. Deactivation time constants (τ_{off}) and activation/inactivation wavelengths are illustrated for comparison purposes and as a look-up table. ChR2 is grouped with step function opsins for scale purposes. Decay kinetics were measured where precise published values were not available. Values from room temperature except for optoXRs (37°C). (Adapted from Fenno et al., 2011.)

integrator: in the case of SSFO, once a channel has been activated, it remains open for a period approximately 150,000 times longer than native ChR2 (Yizhar et al., 2011b). The implication of cellular photon integration is that the total number of photons needed to induce a maximal photocurrent in the cell may be spread over a longer period of time (in contrast to stimulation parameters of ChR2 that require a high density of photons in order to activate enough channels to move the neuron

beyond action potential threshold). In the context of behavioral neuroscience, this property has been exploited to allow for extracerebral light delivery, obviating the need to implant fiber optic light delivery devices into animals for behavioral trials at depths of at least 2.8 mm (Yizhar et al., 2011b).

A second dimension into which considerable engineering resources have been invested is “red-shifting” the maximum excitation wavelength of channelrhodopsins. A tool that is

sufficiently red activated might be able to be modulated independently of ChR2, thus allowing for the manipulation of multiple, independent populations of neurons within the same space (Yizhar et al., 2011b; Zhang et al., 2008). While both VChR1 and the recently described MChR1 are significantly red shifted relative to ChR2, VChR1 does not produce sufficient photocurrents to reliably drive suprathreshold events in neural populations, and the function of MChR1 in neurons has yet to be described (although data from other heterologous systems suggests that its currents will be similar in magnitude to VChR1; Govorunova et al., 2011). The most potent red-shifted channelrhodopsins currently available are not derived from any one organism but are chimaeras between ChR1 and VChR1 (C1V1); resulting currents are significantly larger than ChR2 (Mattis et al., 2012; Yizhar et al., 2011b), and action potentials may be elicited by even 630 nm red light (Yizhar et al., 2011b). In a recent series of experiments, C1V1 was shown to independently modulate cell bodies and terminals in the same tissue as neurons expressing ChR2 (experiments conducted in brain slice, in anesthetized (“optrode”) recordings *in vivo*, and in awake, behaving animals (Yizhar et al., 2011b). Independent modulation of multiple populations is of immediate utility in understanding the dynamics of circuits and, indeed, has been used to examine independent inputs into thalamus as well as the interplay between pyramidal neurons and parvalbumin-expressing, fast-spiking interneurons in medial prefrontal cortex (mPFC; Yizhar et al., 2011b).

In summary, the explosion of channelrhodopsins, mutational variants, and chimaeras since the original introduction of ChRs into neurons in 2005 has included the engineering of tools differently specialized for increased photocurrent, for driving action potentials at high frequencies, for depolarizing neurons for extended periods in the absence of direct action potential generation, and for combinatorial control via red-shifting of excitation wavelength. However, while using channelrhodopsins to control the excitability of a population of neurons with fine temporal resolution allows neuroscientists to ask if the activity of a genetically and/or anatomically specified population of neurons is sufficient to cause a given outcome, the reverse side of this experimental coin is to ask if the activity of these elements is necessary for the outcome. To obtain direct evidence of necessity, a tool is required that is able to silence the activity of a targeted population of neurons while leaving others unaffected. The light-activated halorhodopsin (HR) is an electrogenic pump producing inward chloride flux that can hyperpolarize and thereby inhibit neurons (e.g., the HR from *Natronomonas pharaonis*, or NpHR; reviewed in Zhang et al., 2011). Optogenetic function of proton efflux pumps that can hyperpolarize neurons have since also been described (reviewed in Mattis et al., 2012; Zhang et al., 2011). Local environmental acidification can result from proton efflux; the consequence to neighboring neurons will require further investigation.

In addition to optically modulated mediators of neuronal membrane potential, a class of tools for optical control of biochemical signaling cascades (the optoXRs) now exist for temporally precise manipulation of G-Protein Coupled Receptor (GPCR) signaling cascades (Fig. 10.1). These chimeric proteins

are composed of the light-sensing extracellular domain of the Type II mammalian rhodopsin and the intracellular domain of a given GPCR, for instance, $\alpha 1$ and $\beta 2$ adrenergic receptors (G_q - and G_s -coupled, respectively; Airan et al., 2009; Kim et al., 2005), and 5-HT_{1a} ($G_{i/o}$ -coupled; Oh et al., 2010), and activate native signaling pathways in response to light. These receptors are activated by 500-nm light and are useful for control of biochemical signaling both *in vivo* (Airan et al., 2009) and *in vitro* (Airan et al., 2009; Kim et al., 2005; Oh et al., 2010).

As these examples show, the experimental potential of optogenetics has triggered a surge of genome prospecting and molecular engineering to expand the repertoire of tools and generate new functionality, in turn catalyzing further mechanistic studies of microbial proteins. High-resolution crystal structures are now available for all the major opsin classes (e.g., Kolbe et al., 2000), including most recently channelrhodopsin (ChR; Kato et al., 2012); this information has been of enormous value, not only for enhancing understanding of microbial opsin-based channels, but also for guiding optogenetics in the generation of variants with novel function related to spectrum, selectivity, and kinetics. The high-resolution, crystal-structural insights have also been used to help guide the assembly of light-sensitive modules together with effector modules into artificial proteins, thereby creating parallel information streams capable of carrying optogenetic control signals for modulation purposes (Gulyani et al., 2012; Möglich and Moffat, 2007).

CURRENT NEUROSCIENCE APPLICATIONS AND DISEASE MODELS

This diversity of optogenetic tool function will be important for making significant headway in our understanding both of normal brain function and of dysfunctional processes in neuropsychiatric disease (e.g., many disease states may relate to impaired interaction of multiple distinct cell- or projection types, pointing to the experimental value of achieving multiple-color excitation and multiple-color inhibition optogenetically within the same living mammalian brain) (Deisseroth, 2012; Tye et al., 2012). Indeed, recent years have already seen a swiftly growing wave of applications of optogenetics to questions in neuropsychiatric disease, with the deployment of millisecond precision optical excitation or inhibition of specific circuit elements within behaving mammals. Overall this line of work is very timely at the societal level; psychiatric disease represents the leading cause of disability worldwide, but major pharmaceutical companies are withdrawing from developing new treatments, and many are shutting down psychiatry programs—a situation with major medical, social, and economic implications. Reasons cited include the lack of neural circuit-level understanding of symptom states, which impairs identification of final common pathways for treatment and hobbles development of predictive animal models. Identification of simplifying hypotheses and unifying theories by optogenetic or other means is one of the most pressing needs and exciting avenues of research into neurological and psychiatric disease.

Optogenetic technology now exists in a special relationship with psychiatry because one of the unique and most versatile features of optogenetics (modulation of defined neural projections by fiberoptic-based “projection-targeting,” in which cells are transduced with opsin in region A but illumination is delivered in region B where only a subset of the expressing cells from A send axonal projections; (Fig. 10.3; Gradinaru et al, 2007, 2009, 2010; Petreanu et al., 2007; Stuber et al., 2011; Tye et al., 2011; Yizhar et al., 2011a) is well aligned with what may be a core feature of psychiatric disease (altered function along pathways of neural communication). The fiberoptic neural interface not only allows this selective recruitment of cells defined by projection target, but also overcomes the depth limitations caused by light scattering, and allowed access to (and optogenetic control of) any brain region even in freely moving mammals. This device debuted in 2007 (Aravanis et al., 2007) and was first applied that year (Adamantidis et al., 2007) to address questions relevant to narcolepsy and sleep–wake transitions. Specific activity patterns were played into hypocretin neurons (genetically targeted by use of a cell type–specific promoter that was functional in an injected opsin-bearing viral vector) in the lateral hypothalamus in freely moving mice; certain patterns but not others were found to favor sleep–wake transitions, providing the first causal understanding of specific activity patterns in well-defined cells underlying mammalian behaviors.

Memory deficits (notably in working memory but also in aspects of long-term episodic or declarative memory) are seen in autism and schizophrenia but more prominently in cognitive impairment and dementia. The persistence of episodic memories is also highly relevant to posttraumatic stress disorder (PTSD) and other anxiety disorders, in which the memory can be a contextual fear memory. Recent work using optogenetics has now found that long-term contextual fear memories surprisingly involve both hippocampus and neocortex, even in the remote phase (Goshen et al., 2011); this work may help inform our understanding of PTSD and attempts to ameliorate the debilitating consequences of this disease. Other optogenetics-based studies have explored diverse aspects of fear memory formation and expression in amygdala, hippocampus, neocortex, and other neural circuits, in freely moving mammals (Ciocchi et al., 2010; Haubensak et al., 2010; Liu et al., 2012). Optogenetic methods have also been used to probe unconditioned anxiety, and a specific intra-amygdala pathway has been optogenetically resolved that appears to bidirectionally set anxiety expression level in real time as mammals behave (Tye et al., 2011).

An even more versatile cell type–targeting approach involves mouse Cre-driver lines in which the enzyme Cre-recombinase is expressed across generations as a transgene, only in targeted cells. Cre-dependent viruses are constructed and injected that will therefore express opsin only in the targeted (Cre-expressing) cells. This technique led to the first control of specific recombinase-targeted populations in freely moving mice (Tsai et al., 2009) via selective opsin expression in tyrosine hydroxylase–expressing (dopaminergic) neurons in the ventral tegmental area, to probe reward and conditioning. Cre targeting was also (in separate studies)

used to control the cholinergic cells of the nucleus accumbens to identify a role for these neurons in cocaine conditioning (Witten et al., 2010), and to modulate the intriguing parvalbumin or fast-spiking inhibitory neurons (Sohal et al., 2009); prior pioneering work had shown that the parvalbumin neurons are altered in schizophrenia and had long been suggested to be involved in modulating certain kinds of brain rhythmicity such as gamma oscillations, which are also known to be abnormal in schizophrenia. Optogenetic studies were able to define a causal role of these neurons in the modulation of gamma oscillations, which in turn were found to modulate information flow within neocortical circuitry (Sohal et al., 2009).

Altered gamma oscillations are also seen in autism, another disorder (like schizophrenia) in which information processing and social function deficits are seen, although with a markedly different quality. A long-standing hypothesis in the field had been that elevated excitation–inhibition imbalance could give rise to social dysfunction of the kind seen in autism, but the physiology (unlike the genetics) had been difficult to test in a causal fashion. Optogenetic interventions were able to directly and causally implicate excitation–inhibition balance changes in setting up abnormal social function as well as giving rise to abnormal information processing and gamma oscillations (Yizhar et al., 2011b) of the kind seen in autism and schizophrenia.

While the above neocortical interventions did not discriminate among neocortical layers, it is presumed that pyramidal neurons of different layers play different roles in the circuit. To address this caveat, multiple studies have described the introduction of optogenetic tools using *in utero* electroporation (IUE), and IUE takes advantage of distinct temporal windows during which the pyramidal neurons of different cortical layers are born. With knowledge of when the neurons of a layer are produced, one may introduce an expression construct with a given optogenetic tool to target only that layer. This has been used with success in rodents (Adesnik and Scanziani, 2010; Gradinaru et al., 2007; Petreanu et al., 2009) to analyze the contribution of layer-specific pyramidal populations to neocortical information processing. Similar to transgenic mouse lines, constructs electroporated *in utero* are expressed at birth, allowing for acute slice preparation of young animals. One drawback of this strategy is lower expression level of the opsin, possibly due to reduced expression construct copy number.

IUE-introduced ChR2, in a recent study from Adesnik and Scanziani (2010), was integral to a description of the role of excitatory/inhibitory (E/I) interactions in layer-specific communication between and across cortical columns. Their approach to examining cortical circuitry involved introduction of ChR2 into layer 2/3 as well as use of a stimulating light ramp that increased in intensity over time. Driving excitation in layer 2/3 pyramidal neurons in this way with ChR2 was sufficient to induce gamma-band oscillations in nonexpressing cells from both inhibitory and excitatory classes, assessed by patch clamp. Using a simultaneous four-cell patch clamp, this group found that transmission of ChR2-driven excitation and inhibition across layers (vertically) in cortex was clearest from layer 2/3 to 5, and less so to 4 or 6.

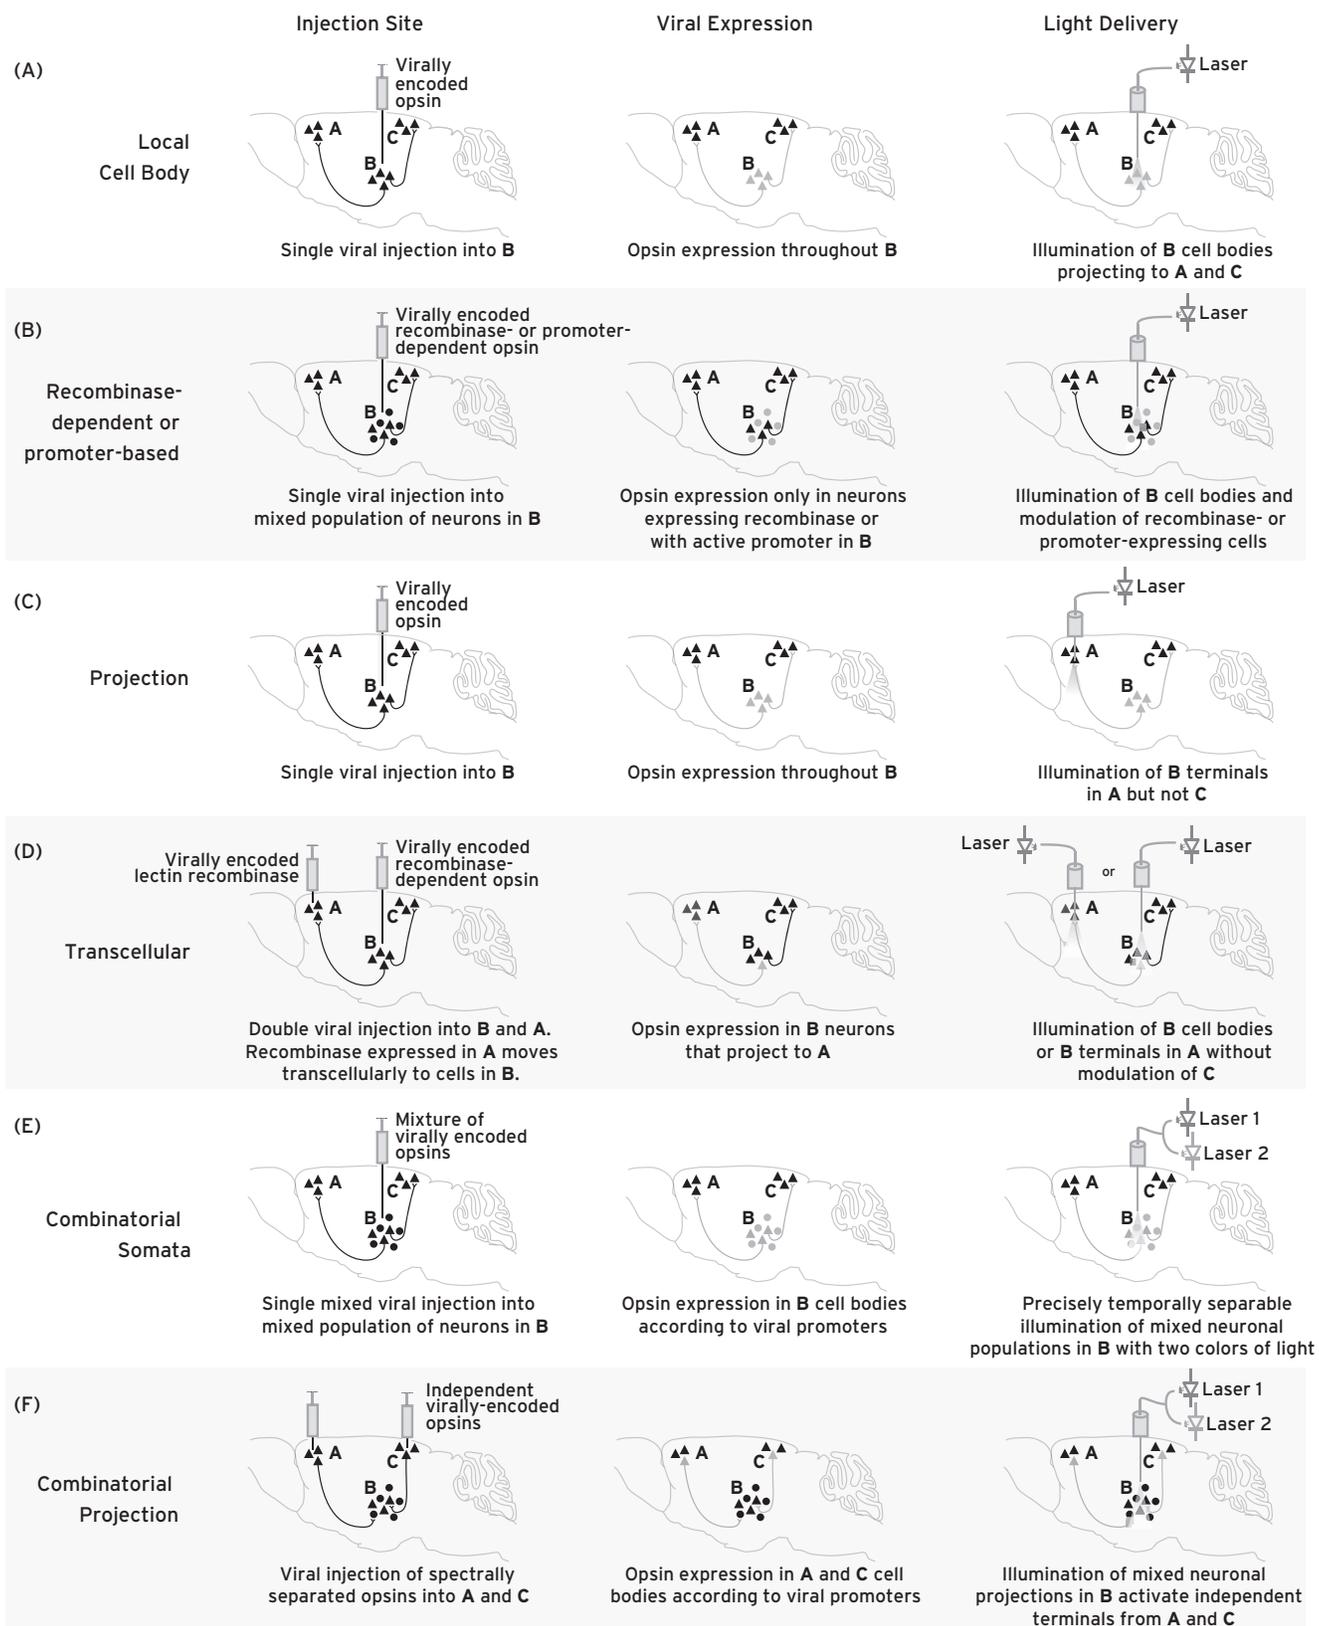

Figure 10.3 In vivo optogenetic targeting strategies. (A) Viral targeting of a neuron population based on promoter specificity followed by stimulation of the same area as the injection. (B) Viral targeting of a neuron population based on expression of Cre-recombinase followed by stimulation of the same area as the viral injection. (C) Viral targeting of a neuron population followed by stimulation of a downstream target region; note that this will likely be a subset of the total population of neurons expressing opsin. (D) Dual viral targeting of a downstream population with lectin-recombinase (e.g., WGA-CRE) and upstream injection of cre-dependent DIO virus followed by stimulation of either the somata or axons of opsin-expressing population. (E) Injection of multiple opsins expressed in separate populations within the same space based on promoter or recombinase-mediated specificity followed by multiwavelength stimulation at the somata. (F) Trans-synaptic or retrograde targeting of axons in two separate locations followed by central multiwavelength stimulation location to differentially modulate somata of neurons based on their projections. (Adapted from Yizhar et al., 2011.)

Additionally, checks and balances involving inhibition and excitation were found to be operative when spatially distinct subsets of cells expressing ChR2 were stimulated. Strikingly, when single cells in layer 2/3 were stimulated with current injection, photostimulation of nearby layer 2/3 cortical columns decreased induced spiking activity of the patched cell. In contrast, cells in layer 5 induced to spike with current injection saw a significant increase in firing rate during layer 2/3 photostimulation, which was reduced by lateral 2/3 excitation. In combination, it was found that layer 2/3 cells compete with layer 2/3 neighbors to drive cortical output via layer 5. These experiments utilized optogenetics to ask questions that could not be answered with other available neuroscience tools lacking this spatial and temporal specificity.

A distinct direct examination of the excitation/inhibition ratio imbalance in neocortex developed and employed novel ChR variants, including the “stabilized step function opsin” modified to remain in the activated state for >30 min after the introduction of blue light (but still inactivated using yellow light) (Yizhar et al., 2011a, b). Like other SFOs, the photocurrent generated by SSFO is subthreshold and thus does not directly generate action potentials by driving a neuron above threshold. Yizhar et al. combined the novel opsin variants and viral delivery to manipulate E/I cortical balance through expression of SSFO in either pyramidal neurons (via the specific promoter CaMKII α to increase E) or in parvalbumin expressing inhibitory interneurons (using a DIO-SSFO virus in combination with PV::Cre transgenic mouse to increase I). It was found that baseline gamma-band activity was increased in response to E/I elevation, even in freely moving mice (Yizhar et al., 2011b); moreover, both social behaviors and episodic learning (but not anxiety, locomotion, or novel object exploration) were nearly abolished in response to E/I elevation but not reduction (Yizhar et al., 2011b).

Further investigation in slice to examine potential mechanisms underlying this deficit revealed that information processing by pyramidal neurons became saturated at a much lower input frequency during SSFO activation of pyramidal neurons, whereas activation of PV neurons decreased the gain of the transfer curve, but without changing the slope; indeed, E/I balance elevation but not reduction was found to actually reduce information throughput in neocortical pyramidal neurons, assessed in bits per second (Yizhar et al., 2011b). Last, combinatorial optogenetics (discussed below) was employed to examine the effect of simultaneously increasing excitation and inhibition (with a resultant E/I more similar to baseline than during manipulation of either E or I in isolation); partial restoration of social function was observed (Yizhar et al., 2011b).

In summary, the expanding optogenetic toolbox is beginning to pay dividends in addressing mysteries and challenges in psychiatric disease research that have long been out of reach (including in the above studies and many others, e.g., Abbott et al., 2009; Busskamp and Roska, 2011; Covington et al., 2010; Ivanova and Pan, 2009; Lobo et al., 2010; Paz et al., 2011; Tan et al., 2008, 2012; Tonnesen et al., 2009). Optogenetic work has even begun to provide clues to treatment mechanisms and refinement; for example, in the case of the deep brain

stimulation (DBS) mechanism, optogenetic studies have suggested that the likely direct initial target of DBS (at least in the case of Parkinson’s disease) is not local cell bodies but afferent axons to the region (in this case, to the subthalamic nucleus), which may arise from globally distributed brain regions (Gradinaru et al., 2009). However, major areas of optogenetic tool advancement are nevertheless required in the future, as detailed next.

UNSOLVED PROBLEMS AND OPEN QUESTIONS: TECHNOLOGY FROM CELL BIOLOGY, OPTICS, AND BEHAVIOR

One group of technological challenges to be addressed in optogenetics lies within the natural domain of mammalian biology. First, the development of improved subcellular trafficking will be important. Membrane trafficking strategies have improved the expression of opsins at the membrane (Gradinaru et al., 2008, 2010; Zhao et al., 2008), but further exploration in this area may produce targeting strategies that allow selective opsin expression in subcellular compartments such as dendrites, soma, or axon terminals. Indeed, while efforts have been made in this regard, achieving truly robust (near 100%) exclusion of heterologously expressed optogenetic proteins from axons would prevent undesired optical drive of axons of passage during illumination of an opsin-expressing brain region. While the expression of opsins in axons is one of the most useful features of this approach in allowing “projection targeting”-based recruitment of cells defined only by selective illumination and projection pattern, this effect also confounds certain kinds of functional mapping procedures that employ optogenetics (Petreanu et al., 2009).

Second, it would be valuable to develop a robust and versatile optical (nonpharmacological) strategy to (when desired) prevent the propagation of optogenetically elicited action potentials in the antidromic direction or along axon collaterals during projection-targeting experiments. Again, sometimes this antidromic drive is desired, but in other cases it is not (wherein the experimenter seeks to allow generalizable selective excitation only of spatially defined projections, and wishes to not take advantage of the existing capability to recruit cells defined by projection).

Third, improved high-speed volumetric (3D) light delivery strategies with single-cell resolution would be of great value, so that populations of cells even within intact mammalian brain tissue could be recruited optogenetically with any required extent of synchrony or asynchrony. Optogenetics applications *in vivo* to questions in mammalian circuit dynamics and behavior have typically involved synchronous optogenetic control of entire genetically targeted cell populations over millimeter scale spatial domains, for example, in studies of sleep-wake transitions, Parkinsonian circuitry, gamma rhythms, feeding behavior, olfaction, aggression, and memory consolidation. Yet methods for guiding spatial delivery of light excitation itself in 3D volumes could allow much improved precision and complexity in optogenetic modulation, taking the next step beyond the single-photon, guided-light strategies which have already

been used in mammalian tissue for applications such as refined optogenetic circuit mapping and dissection of anxiety circuitry (Tye et al., 2011). Improved optogenetic two-photon illumination theoretically could provide a distinct means to manipulate single or multiple genetically and spatially targeted cells with high temporal resolution over sustained intervals and within intact tissue volumes, in order to delineate and define components that work in concert to generate circuit dynamics or behavior.

Fourth, it would be immensely valuable to develop methods to rapidly and efficiently extract brainwide wiring (connectomic) patterns, or at least projection patterns, from optogenetically driven cells that had been shown to have a known and quantified impact on behavior in the very same animal (Deisseroth, 2012).

Fifth, robust extension of optogenetic tool-targeting strategies to non-genetically tractable species or cell types will be enormously helpful. The generation of Cre-driver rats has been important (Witten et al., 2011), and projection targeting provides an independent step forward. But improved intersectional targeting strategies will also be crucial since few relevant cell types can be specified by only a single descriptor such as cell body location, projection target, or activity of one promoter/enhancer region. Design and validation of opsin-carrying viruses that depend on multiple recombinases (e.g., with Boolean AND or other logical gates) will be essential, and improved methods to selectively *exclude* optogenetic tool expression in cells with a given genetic identity will also be useful. Finally, true retrograde and anterograde wiring-based strategies (i.e., targeting cells that project to a particular region, or cells that receive projections from a particular region) would greatly enhance the flexibility of optogenetic control, both in mice and in other species; such strategies exist but are not always robust or well tolerated.

Sixth, it would be of great value to rapidly and efficiently extract the brainwide elicited-activity patterns arising from optogenetic control of a targeted population. This can be achieved to some extent with ofMRI (optogenetic functional magnetic resonance imaging; Lee et al., 2010), an optogenetic method that enables unbiased global assessment of the neural circuits upstream and downstream of focal stimulation. However, fMRI methods in general suffer from poor spatial and temporal resolution. Whether the optimal method to obtain brainwide activity records in freely moving animals would be through activity imaging compatible with optogenetics, or with deposition of some recoverable permanent activity trace (Deisseroth, 2012) in the cellular population of interest (since light-based imaging methods encounter fundamental limitations of resolution arising from scattering in mammalian brain tissue), remains to be seen. In general, improved integration of optogenetic control with readouts will be important—whether behavioral, electrophysiological (e.g., Anikeeva et al., 2011), or imaging. Moreover, closing the loop so that neural activity or behavioral readouts can feed back and control the inputs played in via optogenetics will be of great interest—as will the development of computational methods to begin “reverse engineering” the studied circuitry by identifying the underlying transformations of information carried out in the tissue.

Addressing the above technological challenges, all squarely in the domain of modern neuroscience, will help provide experimental leverage that may lead to key insights into neural circuit function and dysfunction that would be difficult or impossible to establish by other means.

UNSOLVED PROBLEMS AND OPEN QUESTIONS: GENOMICS AND BIOPHYSICS

Another group of technological challenges to be addressed in optogenetics falls more into the natural domain of microbial biologists and biophysicists (although, of course, many laboratories and investigators span the mammalian and the microbial realms).

First, the ongoing identification of additional genomically identified tools (via searching databases, broad-based sequencing efforts, and ecological genome mining) will profoundly improve our ability to perturb and understand biological systems. Many thousands of new opsin genes alone, to say nothing of other classes of light-sensitive modules, will be accessible in this way. For example, even though known opsins already span most of the visual spectrum and a very broad kinetics space (Fenno et al., 2011; Yizhar et al., 2011), it is very likely that new kinds of light sensitivity, kinetic properties, and even ion selectivity will emerge. One important goal is moving into the infrared, which will achieve (1) deeper light penetration at a given irradiance value, (2) reduced scattering for improved resolution, and (3) provision of an additional control channel; infrared actuation has already been achieved for certain non-opsin-based optogenetic approaches but possibly pushes against certain physics-based limitations for retinal-based photoreceptors.

Second, engineering of these known or new tools for a narrowed (as well as shifted) action spectrum would enable more clean separation of control channels. For example, engineering of blue-shifted hyperpolarizing opsins with narrower activation wavelength spectra could ultimately allow for enhanced combinatorial neuronal inhibition experiments within scattering mammalian tissues. While action spectrum peaks for existing tools span the visible spectrum and beyond, the broad shoulders of relevant action spectra may prevent use of more than two or three channels of control at once, unless spectra can be narrowed. Such efforts might involve mutations that prevent access of the photocycle to specific states or intermediates that have shifted absorbance properties. This class of opsin engineering will be facilitated by structure-based insights into the photocycle; to understand the ChR photocycle in more detail, further structural studies beyond the current closed-state structure (Kato et al., 2012), including of open and intermediate photocycle states, are clearly needed. These efforts may also lead to the generation of mutants with novel kinetic properties.

Third, engineering the light sensors of optogenetics for higher quantum efficiency, greater light sensitivity, and/or increased current elicited per optogenetic-protein molecule, would be of substantial value in allowing the use of lower

irradiances for targeting a given tissue volume or depth, which may be important in minimizing photodamage, heating, or power use/deposition constraints. While for opsins many orders-of-magnitude-increased light sensitivity can be achieved with the bistable or step-function approach, this comes at a kinetic cost (slowing down the deactivation after light-off; Berndt et al., 2009).

Fourth, developing an electrically inhibitory optogenetic channel (rather than a pump) would be of immense value. Current hyperpolarizing tools are all pumps rather than channels and therefore do not provide shunting or input resistance changes (and also can only move one ion per photon); as a result these optogenetic tools are not nearly as effective as the channels or native inhibitory receptors, especially in projection-targeting experiments wherein the goal is to intercept action potentials in axons. Achieving this goal would also rapidly enable the generation of a hyperpolarizing SFO or bistable optogenetic tool that would allow sustained inhibition of neurons without requiring constant illumination. New structural knowledge of the ChR cation-conducting pathway (Kato et al., 2012) and pore vestibules may facilitate construction of ChR variants with potassium selectivity for this purpose, as well as improved photocurrents, light sensitivity, and kinetic properties.

Fifth, “dead” optogenetic tool mutants with expression and targeting properties comparable to active tools, but with no light-induced effector function, would be useful as controls. Currently, controls for optogenetic experiments often include XFP-expressing organisms or viruses, but this approach may not fully account for potential side effects of expressing the optogenetic tools themselves on parameters such as membrane capacitance and endogenous protein trafficking. Again, knowledge of pore structure (and pump mechanisms) may facilitate the generation of such tools.

Sixth, in addition to light-sensitive pumps and channels, continued expansion of optically recruited biochemical signaling will be important, with increasing attention to strategies for modular and easily programmable pathway recruitment, improved specificity, expanded spectral responsivity bands, and adaptation to additional classes of native chromophores (such as flavins, biliverdins, and the like). The optoXR family of light-activated 7TM neurotransmitter/neuromodulator receptors will see addition of novel tools based on chimeras between vertebrate rhodopsins and both well-known and orphan GPCRs. And light-sensitive domains are being added to an increasing number of receptor and even intracellular signaling proteins, so that optogenetics will expand to occupy the full breadth of cell signaling, far beyond the study of neural activity.

CONCLUSION

In summary, continued investigation from the microbial and biophysical side into ecological diversity, high-resolution structures, photocycle properties, and functional phylogenetics of light-sensitive protein modules will enable the discovery and engineering of new and improved classes of optogenetic

control. Moreover, investigation from the neuroscience side into targeting, trafficking, selective spatiotemporal properties of illumination, precise circuit element recruitment, and diverse compatible readout engineering will fundamentally advance the scope and precision of resulting insights into complex, intact biological systems. Existing methods represent only the tip of the iceberg in terms of what could be ultimately achieved for neuroscience and neuropsychiatry disease research, in maximally enabling the principled design and application of optogenetics.

DISCLOSURES

Dr. Fenno has no conflicts of interest to disclose.

Dr. Deisseroth has disclosed his optogenetic research findings to the Stanford Office of Technology Licensing, which has filed patent applications for the possible use of the findings and methods in identifying new treatments for neuropsychiatric disease; Dr. Deisseroth is also co-founder and scientific advisor to a company, Circuit Therapeutics, which employs related methods to develop new treatments for neuropsychiatric disease. All materials, methods and reagents remain freely available for academic and non-profit research in perpetuity through the Deisseroth optogenetics website (<http://www.optogenetics.org>).

11 | BLOOD–BRAIN BARRIER OPENING AND DRUG DELIVERY USING FOCUSED ULTRASOUND AND MICROBUBBLES

ELISA E. KONOFAGOU

INTRODUCTION

Current treatments of neurological and neurodegenerative diseases are limited due to the lack of a truly noninvasive, transient, and regionally selective brain drug delivery method (Pardridge, 2005). The brain is particularly difficult to deliver drugs to because of the blood–brain barrier (BBB). The impermeability of the BBB is due to tight junctions connecting adjacent endothelial cells and highly regulatory transport systems of the endothelial cell membranes (Abbott et al., 2006). The main function of the BBB is ion and volume regulation in order to ensure conditions necessary for proper synaptic and axonal signaling (Stewart and Tuor, 1994). However, the same impermeability properties that keep the brain healthy are the reason for the difficulties in its efficient pharmacological treatment. The BBB prevents most neurologically active drugs from entering the brain, and, as a result, has been determined as the rate-limiting factor in brain drug delivery (Pardridge, 2005). Until a solution to the trans-BBB delivery problem is found, treatments of neurological diseases will remain impeded.

BBB PHYSIOLOGY: STRUCTURE AND FUNCTION

The BBB is a specialized substructure of the vascular system, consisting of endothelial cells connected together by tight junctions. The luminal and abluminal membranes line the inner wall of the vessel and act as the permeability barrier. The combination of tight junctions and these two membranes characterizes the BBB as having low permeability to large and ionic substances. However, certain molecules such as glucose and amino acids are exceptions because they are actively transported. It has also been shown that lymphocytes can traverse the BBB by going through temporarily opened tight junctions of the endothelial walls. The astrocytes have been proven to offer a protective mechanism of the neurons to any mechanical effect (Abbott et al., 2006).

BBB AND NEUROTHERAPEUTICS

Several neurological disorders remain intractable to treatment by therapeutic agents because of the BBB, the brain's natural defense. By acting as a permeability barrier, the BBB

impedes entry from blood to the brain of virtually all molecules with higher than 400 Da of molecular weight, thus rendering many potent neurologically active substances and drugs ineffective simply because they cannot be delivered to where they are needed. As a result, traversing the BBB remains the rate-limiting factor in brain drug delivery development (Pardridge, 2005, 2006).

FOCUSED ULTRASOUND

Focused ultrasound (FUS) utilizes the same concept of acoustic wave propagation as the more widely known diagnostic ultrasound applications. However, instead of acquiring and displaying echoes generated at several tissue interfaces for imaging, FUS employs concave transducers that usually have a single geometric focus, at which most of the power is delivered during sonication in order to induce mechanical effects, thermal effects, or both. Note that the more widely used “high-intensity focused ultrasound (HIFU)” name of the method is not used here for BBB opening since the intensities used are low, that is, on the level of what is used in diagnostic ultrasound.

BBB OPENING USING FUS AND MICROBUBBLES

Blood–brain barrier opening induced by ultrasound at or near ablation intensities was first observed while accompanied by neuronal damage (Bakay et al., 1956; Ballantine et al., 1960; Patrick et al., 1990; Vykhodtseva et al., 1995). After reducing the acoustic intensity and duty cycle (the time the power is on relative to the time the power is off), BBB opening was still observed, but without the macroscopic damage detected as lesions (Mesiwala et al., 2002). With the addition of intravenously (IV) injected microbubbles prior to sonication, BBB opening was determined to be transient (Hynynen et al., 2001) in the presence of Optison™ (Optison™; Mallinckrodt Inc., St. Louis, MO), which are albumin-coated, octafluoropropane-filled microbubbles of 3–4.5 μm in diameter and are usually used to enhance blood vessels on clinical ultrasound images through opacification. The BBB opening procedure could also be monitored with MRI and MR contrast agents (Hynynen et al., 2001). This showed the potential of opening the BBB without damaging parenchymal

cells, such as neurons. Further investigation entailed study of this phenomenon with Optison™ to search for a difference in threshold of BBB opening and neuronal damage and understand the mechanism of the opening in rabbits, with (Hynynen et al., 2003; McDannold et al., 2004; Sheikov et al., 2004) or without (Hynynen et al., 2005) a craniotomy. The advantage of having microbubbles present in the blood supply is that it allows for the reduction of the ultrasound intensity, the containment of most of the disruption within the vasculature, and the reduction of the likelihood of irreversible neuronal damage (Choi et al., 2005, 2006, 2007a, 2007b; Hynynen et al., 2003, 2005, 2006; McDannold et al., 2004, 2005, 2006; Sheikov et al., 2004, 2006). Although there are many indications that damage can be contained to minimal hemorrhage (Hynynen et al., 2006), the complete safety profile remains to be assessed. In addition, indications to various mechanisms such as the dilation of vessels, temporary ischemia, mechanically induced opening of the tight junctions, and the activation of various transport mechanisms have been reported (Mesiwala et al., 2002; Sheikov et al., 2004, 2006).

Our group has demonstrated feasibility of BBB opening through intact skull and skin and successful imaging of the BBB opening in the area of the hippocampus at sub-millimeter imaging resolution using a 9.4T MR scanner in both wild-type (Choi et al., 2005, 2007a, 2007b; Konofagou et al., 2009) and Alzheimer's mice (Choi et al., 2008). Our group also concentrates on a specific brain region (e.g., the hippocampus), which is key in neurodegenerative disease, such as Alzheimer's, and can be successfully and reproducibly targeted (Konofagou and Choi, 2008). Delivery of molecules of up to 2,000 kDa in molecular weight was also demonstrated (Choi et al., 2010). Preliminary histology indicated no structural damage in the area of the hippocampus (Baseri et al., 2010). Finally, it is important to note that the microbubbles used for BBB opening have been approved by the Food and Drug Administration (FDA) for human use in contrast echocardiography, for example, for the detection of myocardial infarction (Kaufmann et al., 2007). It is equally important to specify that the pressure amplitudes used for BBB opening are of similar range to ultrasound diagnostic levels (<1.5–2 MPa) and, therefore, assumed safe for human use (Christensen, 1988) while the pulse duration is by orders of magnitude longer.

MICROBUBBLES IN CONTRAST ULTRASOUND AND ASSOCIATED BIOEFFECTS

Currently, in the United States, microbubbles are only FDA approved for echocardiography in patients with suboptimal images of the cardiac chambers. However, microbubbles have shown promise for imaging myocardial perfusion using intermittent contrast destruction pulses. Therefore, most *in vivo* bioeffects studies have focused on the heart (Miller, 2007). For a given frequency, separate pressure thresholds exist for microbubble destruction and the onset of bioeffects (Chen et al., 2002; Li et al., 2003, 2004). Safe cardiac perfusion imaging would then be done with the microbubble clearance pulse being between these thresholds. Extravascular drug delivery to the brain would then be performed near the threshold for transient opening, but well below the conditions for permanent damage. Human doses for commercially available microbubbles used in contrast echocardiography could provide a useful benchmark for therapy trials. However, the human dose for imaging purposes varies widely (Table 11.1). A typical dose ranges between 6 and 12 × 10⁷ microbubbles per kg (60–120 microbubbles per mg). Mean diameters are given, but detailed information of the polydispersed size distributions is lacking. Thus, the effects of microbubble size and concentration on safety are difficult to decouple from previous studies using these commercial agents. Our ability to generate and isolate microbubbles of distinct and narrow size distributions with well-defined concentrations will allow us to probe these effects in the proposed study.

Several studies have shown an increase in bioeffects with increasing microbubble dose. For Definity and Optison, increases in rat cardiomyocyte cell death and premature heartbeats and microvessel leakage were found after exposure to ultrasound, also called sonication (Li et al., 2003; Miller et al., 2005). Similar dose–response relationships have been observed for BBB opening (Kaps et al., 2001; Yang et al., 2007). Miller et al. (2005) compared insonation of Optison, Definity, and Imagent in the rat heart and found that microvascular effects were similar when expressed as the number of microbubbles injected. They concluded that shell type and encapsulated gas have little effect on bioeffects. Given the polydispersed size distribution of the different formulations, however, the effects

TABLE 11.1. Clinically used contrast agents and their specifications

FORMULATION (MANUFACTURER)	SHELL/GAS	CONCENTRATION (ml ⁻¹)	MEAN DIAMETER (μm)	GAS VOLUME FRACTION ^a	DOSE (ml/kg)
Optison (GE Healthcare)	Albumin/C ₃ F ₈	8 × 10 ⁸	3.0–4.5	1.1%–3.8%	0.006–0.1 ^b

Sonovue (Bracco)	Lipid/SF ₆	2 × 10 ⁸	2.5	0.2%	0.003–0.3 ^c

^aDetermined from concentration and mean diameter.

^bData obtained from Optison package insert.

^cData from NIH Molecular Imaging and Contrast Agent Database (MIDAC).

of size are difficult to glean from that study. However, little is known about the effects of microbubble size on bioeffects. Christiansen et al. (2003) found that intra-arterial injection was more effective than intravenous injection for gene transfection through sonoporation. This result was attributed to the difference in microbubble sizes delivered to the insonified region. Several biophysical studies have shown remarkable size dependence for microbubble oscillation and destruction (Borden et al., 2005; Chomas et al., 2001).

CLINICAL RELEVANCE OF BBB DISRUPTION

NEURODEGENERATIVE DISEASE

Over 4 million U.S. men and women suffer from Alzheimer’s disease: 1 million from Parkinson’s disease, 350,000 from multiple sclerosis, and 20,000 from ALS (amyotrophic lateral sclerosis). Worldwide, these four diseases account for more than 20 million patients. Although great progress has been made in recent years toward the understanding of neurodegenerative diseases like Alzheimer’s, Parkinson’s, multiple sclerosis, ALS, and others, few effective treatments and no cures are currently available. Aging greatly increases the risk of neurodegenerative disease, and the average age of Americans is steadily increasing. Today, over 35 million Americans are over the age of 65. Within the next 30 years, this number is likely to double, putting more and more people at increased risk of neurodegenerative disease. Alzheimer’s disease, which has emerged as one of the most common brain disorders, begins in the hippocampal formation and gradually spreads to the remaining brain at its most advanced stages, and it is characterized partly by deposition of amyloid plaques in the brain tissue but also in the blood vessels themselves (Iadecola, 2004). For the purpose of this study, we will focus on the treatment of Alzheimer’s disease through the FUS-induced BBB opening, and therefore, the targeted region in the brain will be the hippocampus.

DRUG DELIVERY IN NEURODEGENERATIVE DISEASE

Over the past decade, numerous small- and large-molecule products have been developed for treatment of neurodegenerative diseases with mixed success. When administered systemically *in vivo*, the BBB inhibits their delivery to the regions affected by those diseases. A review of the Comprehensive Medicinal Chemistry database indicates that only 5% of the more than 7,000 small-molecule drugs treat the central nervous system (CNS) (Pardridge, 2006). With these, only four CNS disorders can be treated: depression, schizophrenia, epilepsy, and chronic pain (Ghose et al., 1999; Lipinski, 2000). Despite the availability of pharmacological agents, potentially devastating CNS disorders and age-related neurodegenerative diseases, such as Alzheimer’s disease, Parkinson’s disease, Huntington’s disease, multiple sclerosis, and amyotrophic lateral sclerosis, remain undertreated mainly because of the impermeability of the BBB (Pardridge, 2005, 2006). The goal of this proposal is thus to optimize the FUS method and elucidate its mechanism in order to ultimately deliver therapeutics to the brain and significantly facilitate treatment of currently intractable and devastating neurodegenerative diseases.

A successful drug delivery system requires transient, localized, and noninvasive targeting of a specific tissue region. None of the current techniques clinically used, or currently under research, address these issues within the scope of the treatment of neurodegenerative diseases. As a result, the present situation in neurotherapeutics enjoys few successful treatments for most CNS disorders. Some of those routes of administration are listed in Table 11.2. Several pharmaceutical companies use the technique known as “lipidization,” which is the addition of lipid groups to the polar ends of molecules to increase the permeability of the agent (Fischer et al., 1998). However, the effect is not localized as the permeability of the drug increases not only in the targeted region, but also over the entire brain and body. There can thus be a limit to the amount absorbed before the side effects become deleterious (Fischer et al., 1998).

TABLE 11.2. Techniques shown to induce trans-BBB transport or BBB disruption

METHOD	DESCRIPTION	PROBLEMS	NONINVASIVE?	LOCALIZED?
<i>Lipidization</i>	“Lipidizes” the drug. Allows uptake in the BBB.	Increases penetration across <i>all</i> biological membranes.	Yes	No
<i>Transcranial brain drug delivery (Fig. 11.2)</i>	Neurosurgically based drug delivery method. Diffusion-based method.	Invasive. Diffusion reduces the initial concentration by 90% when traveling only 0.5 mm.	No	Yes
<i>Solvent/adjuvant-mediated BBB disruption</i>	Solvent and adjuvants disrupt the BBB using dilation, contraction, and other methods.	Disrupts the BBB in all of the brain. Potentially toxic.	Yes	No
<i>Delivery through endogenous transporters</i>	Uses endogenous transporters to traverse the BBB.	Requires medicinal chemistry to modify drugs and knowledge of the endogenous transporters.	Yes	No
<i>Ultrasound</i>	Focused ultrasound (FUS) with microbubbles	Possible irreversible damage may be induced.	Yes	Yes

A second set of techniques under study are neurosurgically based drug delivery methods, which involve the invasive implantation of drugs into a region by a needle (Blasberg et al., 1975; Fung et al., 1996). The drug spreads through diffusion and is localized to the targeted region, but diffusion does not allow for molecules to travel far from their point of release. In addition to this, invasive procedures traverse untargeted brain tissue, causing unnecessary damage. As a result, effective drugs have recently been shelved after reports of adverse effects. Other techniques utilize solvents mixed with drugs or adjuvants (pharmacological agents) attached to drugs to disrupt the BBB through dilation and contraction of the blood vessels [Pardridge, 2005, 2006, 2007]). However, this disruption is not localized within the brain, and the solvents and adjuvants used are potentially toxic. This technique may constitute a delivery method specific to the brain, but it requires special attention to each type of drug molecule and a specific transport system resulting in a time-consuming and costly process while still not being completely localized to the targeted region. FUS in combination with microbubbles constitutes thus the only truly transient, localized, and noninvasive technique for opening the BBB. Due to these unique advantages over other existent techniques (Table 11.2), FUS may facilitate the delivery of already developed pharmacological agents and could significantly impact how devastating CNS diseases are treated.

However, despite the fact that FUS is currently the only technique that can open the BBB locally and noninvasively, several key aspects of this phenomenon remain unexplored. A clear correlation of BBB opening with microbubbles has been shown (Choi et al., 2005; Hynynen et al., 2001; McDannold et al., 2004). Although the presence of microbubbles allows for a reduction in the necessary acoustic pressure for BBB opening, it also allows for the possibility of disrupting the microbubble through inertial cavitation (Leighton, 1994; Neppiras, 1980; Pardridge, 2007). The resulting effects not only can open the tight junctions but also could induce irreversible damage to the blood vessels and their surrounding cells (Baseri et al., 2010). Recent studies have indicated that BBB opening may occur without necessarily incurring inertial cavitation, without (Hynynen et al., 2003) or with (McDannold et al., 2006) craniotomy. However, it is not clear how the different types of mechanical effects lead to BBB opening and how the role of the microbubble can be optimized. Given the strong coupling of microbubble size and concentration to the response to sonication, a mechanistic study to BBB opening by contrast-assisted focused ultrasound must include these parameters. Control over both ultrasound and microbubble parameters is essential for the proper optimization and understanding of the FUS technique. However, to our knowledge no study to date has included a thorough investigation of both of these components.

FUS-FACILITATED BBB OPENING IN DRUG DELIVERY FOR TREATMENT OF NEURODEGENERATIVE DISEASE

Realizing the strong premise of this technique for facilitation of drug delivery to specific brain regions, we showed that the BBB can be opened reliably and reproducibly in the hippocampal region in mice (Choi et al., 2005, 2006, 2007a, 2007b, 2007c, 2008,

2009, 2010; Konofagou et al., 2008, 2009). By developing a better understanding of the underlying physical parameters that are responsible for the opening of the BBB, namely, the ultrasound and microbubble parameters, we will be in a position to fully exploit this methodology and to do so safely. The feasibility of the technique at optimized ultrasound and microbubble parameters for reversible BBB opening, as determined *in vivo*, has been tested on wild-type mice as a first step to identify the potential of this technique in the treatment of neurodegenerative diseases (Choi et al., 2008). The MR imaging methods developed allow for high sensitivity, high spatial resolution, and high temporal resolution. The latter is achieved through the slow diffusion of intraperitoneally injected gadolinium. The added potential of combining this ultrasound technique with any therapeutic agent may renew possibilities in potentially employing available pharmacological agents, whose development has currently been abandoned because of poor BBB penetration. This may thus result in the novel and effective treatment of several potentially devastating neurological and neurodegenerative diseases. As previously indicated, we will concentrate on the feasibility of noninvasive and localized treatment of Alzheimer's disease by specifically targeting the hippocampus. However, the FUS technique can, in principle, be combined and applied in the case of any neurological disease. Therefore, findings of this study may impact not only treatment of a specific disease but also the entire field of brain diseases. In summary, FUS stands to make a very important impact in the brain drug delivery, and the proposed study aims at its optimization through understanding of the type of interaction between the microbubble, the tissue, and the FUS beam.

DRUG DELIVERY THROUGH THE OPENED BBB

The delivery of many large agents using focused ultrasound and microbubbles has been demonstrated in previous studies by our group and others: MRI contrast agents such as Omniscan (573 Da) (Choi et al., 2007b) and Magnevist® (938 Da) (Choi et al., 2007), Evans Blue (Kinoshita et al., 2006), Trypan Blue (Raymond et al., 2008), Herceptin (148 kDa) (Kinoshita et al., 2006), horseradish peroxidase (40 kDa) (Sheikov et al., 2008), doxorubicin (544 Da) (Treat et al., 2007), multisized Dextran (Choi et al., 2010), and rabbit anti-A β antibodies (Raymond et al., 2008). Despite the promise shown by the delivery of such a variety of compounds, several questions about the effectiveness of the delivery remain. In particular, it is still not known whether therapeutic molecules can cross through the BBB opening into the intracellular neuronal space so that they can trigger the required downstream effects for neuronal regeneration.

METHODS FOR INDUCING AND ASSESSING BBB OPENING

FUS AND MICROBUBBLES

The experimental setup is shown in Figure 11.1. The FUS transducer (center frequency: 1.5 MHz; focal depth: 60 mm;

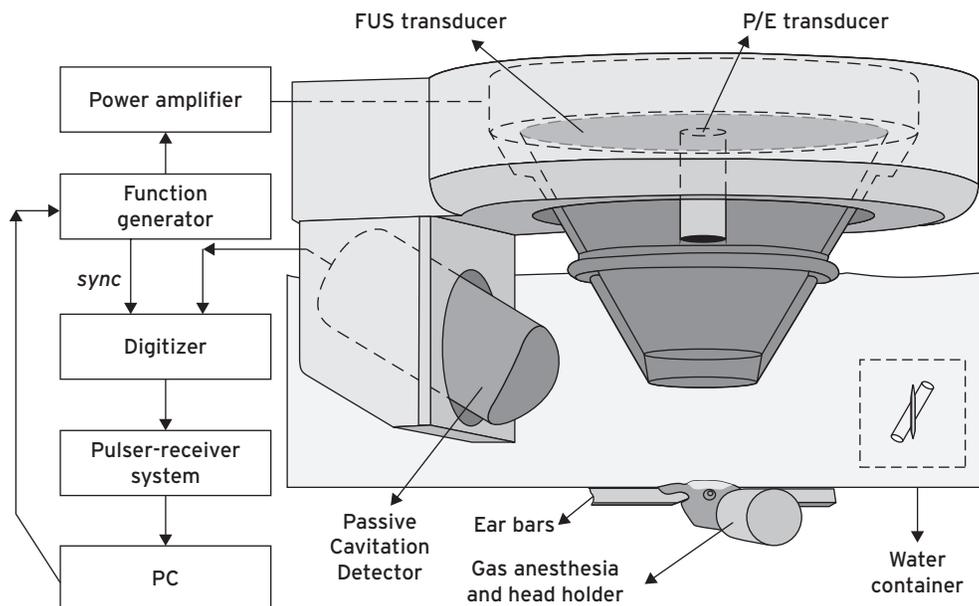

Figure 11.1 Block diagram and illustration of the experimental setup. The PCD was positioned at 60° relative to the longitudinal axis of the FUS beam. The overlap between the focal regions of PCD and FUS occurring inside the murine brain is illustrated in the inset.

outer radius: 30 mm; inner radius: 11.2 mm, model cdc7411-3, Imasonic, Besançon, France) is used to perform sonication immediately following bubble administration. The transducer is driven by a function generator (Agilent Technologies, Palo Alto, CA) through a 50-dB power amplifier (ENI Inc., Rochester, NY). A cone filled with degassed and distilled water is attached to the transducer system. The transducer is attached to a computer-controlled positioner (Velmex Inc., Bloomfield, NY). The PCD, a 5-cm cylindrically focused broadband hydrophone (Sonic Concepts, Bothell, WA), with a cylindrical focal region (height 19 mm, diameter 3.64 mm) is placed at 60° from the longitudinal axis of the FUS beam. The PCD and the FUS transducer are confocally aligned. The acoustic emissions from the microbubbles are captured with the PCD and collected using a digitizer (model 14200, Gage Applied Technologies, Inc., Lachine, QC, Canada) through a 20 dB amplifier (model 5800, Olympus NDT, Waltham, MA). Microbubbles (Definity®: mean diameter range: 1.1–3.3 μm, Lantheus Medical Imaging, MA, or lipid-shelled microbubbles manufactured in-house and size isolated using differential centrifugation [57]) are activated and used within 24 hr after activation. Following activation, a 1:20 dilution solution is prepared using 1× phosphate-buffered saline (PBS) and slowly injected into the tail vein (1 μl per gram of mouse body weight). Both transducers use pulsed-wave FUS (burst rate: 10 Hz; burst duration: 20 ms; duty cycle: 20%) in two 30-s sonication intervals with a 30-s intermittent delay. Peak-rarefactional acoustic pressures of 0.15, 0.30, 0.45, and 0.60 MPa are typically used as they have been shown to provide the best tradeoff between safety and BBB opening (Baseri et al., 2010). One side of the hippocampus in the horizontal orientation is sonicated in each mouse. Acoustic parameters other than the pressure have also been studied with respect to their role in BBB disruption. One of those is the pulse length (Choi et al., 2011). In that study, mouse brains were pulse sonicated

(center frequency: 1.5 MHz, peak-negative pressure: 0.3 MPa, pulse length [PL]: 2.3 μs, pulse repetition frequency [PRF]: 6.25, 25, 100 kHz) continuously or with a burst length of 1,000 pulses (burst repetition frequency [BRF]: 0.1, 1, 2, or 5 Hz) for 11 min. One minute after the start of sonication, fluorescence-tagged dextran (60 μg/g, molecular weight: 3 kDa) and Definity® microbubbles (0.05 μl/g) were intravenously injected. After 20 min of circulation, the mice were transcardially perfused, and the brains were sectioned and imaged using fluorescence microscopy. In order to determine the microbubble size dependence, mice have been injected intravenously with lipid-shelled bubbles of either 1–2, 4–5, or 6–8 μm in diameter while the concentration was 10⁷ numbers/mL (Choi et al., 2009).

CONFIRMATION OF BBB OPENING BY MAGNETIC RESONANCE IMAGING

A vertical-bore 9.4 T MR system (Buker Biospin, Billerica, MA) was used to confirm the blood–brain barrier opening in the murine hippocampus. Each mouse was anesthetized using 1%–2% of isoflurane gas and was positioned inside a single resonator. The respiration rate was monitored throughout the procedure using a monitoring or gating system (SA Instruments Inc., Stony Brook, NY). Prior to introducing the mouse into the scanner, intraperitoneal (IP) catheterization was performed. Two different protocols were used for MR imaging. The first protocol was a three-dimensional (3D), T1-weighted SNAP gradient echo pulse sequence, which acquired horizontal images using TR/TE = 20/4 ms, a flip angle of 25°, NEX of 5, a total acquisition time of 6 min and 49 s, a matrix size of 256 × 256 × 16 pixels and a field of view (FOV) of 1.92 × 1.92 × 0.5 cm³, resulting in a resolution of 75 × 75 × 312.5 μm³. The second protocol was a 3D T2*-weighted GEFC gradient

echo pulse sequence, which acquired horizontal images using TR/TE = 20/5.2 ms, a flip angle of 10°, NEX of 8, a total acquisition time of 8 min and 12 s, a matrix size of 256 × 192 × 16 pixels, and a FOV of 2.25 × 1.69 × 0.7 cm³, resulting in a resolution of 88 × 88 × 437.5 μm³. Both protocols were applied approximately 30 min after IP injection of 0.30 ml of gadodiamide (590 Da, Omniscan®, GE Healthcare, Princeton, NJ), which allowed sufficient time for the gadodiamide to diffuse into the sonicated region.

ACOUSTIC EMISSION SIGNAL ACQUISITION AND ANALYSIS

The acoustic emission signals acquired by the PCD are sampled at 25 MHz to accommodate the highest memory limit of the digitizer involved in each case. A customized spectrogram function (30 cycles, i.e., 20 μs, Chebyshev window; 95% overlap; 4096-point FFT) in MATLAB® (2007b, Mathworks, Natick, MA) is used to generate a time–frequency map, which provided the spectral amplitude in time. The spectrogram can then clearly indicate how the frequency content of a signal changes over time. Therefore, the onset of the broadband response and its duration could be clearly demonstrated on the spectrogram.

The acoustic emissions are quantified *in vivo*. A high-pass, Chebyshev type 1, filter with a cutoff of 4 MHz was first applied to the acquired PCD signal. The acoustic emission collected by the focused hydrophone was used in the quantification of the ICD; the harmonic (nf , $n = 1, 2, \dots, 6$), subharmonic ($f/2$) and

ultraharmonics ($nf/2$, $n = 3, 5, 7, 9$) frequencies produced by stable cavitation (Farny et al., 2009) were filtered out by excluding 300-kHz bandwidths around each harmonic and 100-kHz bandwidths around each sub- and ultraharmonic frequency. These bandwidths were designed to filter for the broadband response and to ensure that the stable cavitation response was not included in the ICD calculation. The root mean square (RMS) of the spectral amplitude (V_{RMS}) could then be obtained from the spectrogram after filtering. To maximize the broadband response compared to the sonication without microbubbles, only the first 50 μs of sonication were considered in the ICD calculation, which was performed by integrating the V_{RMS} variation within an interval of 0.75 μs (i.e., calculating the area below the V_{RMS} curve between 0.095 ms and 0.145 ms). In order to remove the effect of the skull in the ICD calculation, the V_{RMS} in the case without microbubbles was also calculated and was subtracted from the results with the microbubbles to obtain the net bubble response. A Student's *t*-test was used to determine whether the ICD was statistically different between different pressure amplitudes. A *p*-value of $p < 0.05$ was considered to denote a significant difference in all comparisons.

ACOUSTIC PARAMETER DEPENDENCE AND MECHANISM OF BBB OPENING

The BBB opening pressure threshold is identified to fall between 0.30 and 0.45 MPa in the case of the 1-to-2-μm bubbles and between 0.15 and 0.30 MPa in the 4- to-5- and 6- to-8-μm cases

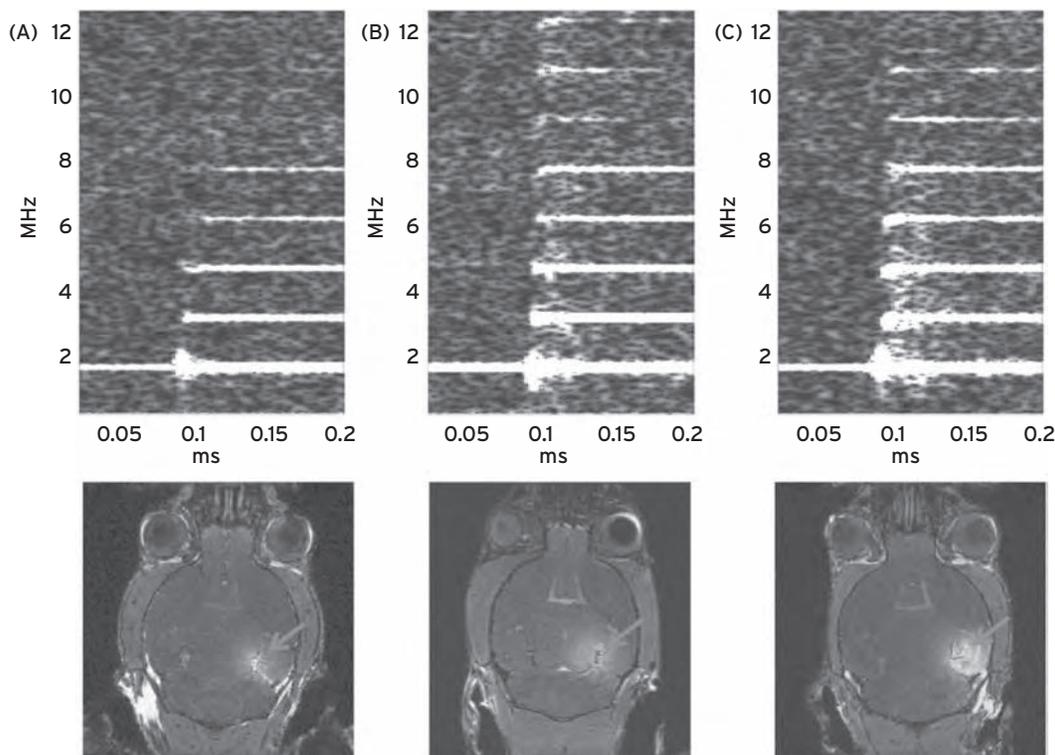

Figure 11.2 Spectrogram during the first 0.2 ms sonication. Broadband acoustic emissions were detected at (B) 0.45 MPa and (C) 0.60 MPa but not at (A) 0.30 MPa. Corresponding MRI images confirm that the blood–brain barrier could be opened at 0.30 MPa, that is, without inertial cavitation [60,64]. The arrows indicate the location of BBB opening.

(Choi et al., 2009; Tung et al., 2010). At every acoustic pressure, both the region of contrast enhancement in the MRI imaging and the amplitude of broadband emissions increased with the bubble diameter. The IC threshold is found to be bubble independent and to lie between 0.30 and 0.45 MPa for all bubble sizes (Fig. 11.2). In fluorescence imaging, the PL of 2.3 μ s was found to be sufficient for BBB opening and Dextran delivery (Choi et al., 2011).

MOLECULAR DELIVERY THROUGH THE BBB OPENING

A molecular delivery study (Choi et al., 2007c, 2010) indicated that the range of molecular size for trans-BBB delivery spreads to well beyond the 574 Da (Gadolinium; Fig. 11.2) to 67 kDa (Albumin; Fig. 11.3[v]) and 2,000 kDa (Dextrans; Fig. 11.3[iii]). As expected, at 2,000 kDa (or, \sim 20 nm), the fluorescent region is the smallest (since the molecule is the largest and thus diffusion the slowest) and mostly outside of the hippocampus. Therefore, FUS-induced BBB opening was shown feasible for noninvasive, local, and transient opening of the BBB for drug delivery of agents of several tens of kDa, providing thus the opportunity of delivering available pharmacological agents to specific brain regions for treatment of neurological disease.

SAFETY AND REVERSIBILITY OF BBB OPENING

In order to determine the safety window of the FUS technique, through histological and immunohistological techniques (Baseri et al., 2010), we have identified the safe operating parameters of ultrasound exposure for neurons, astrocytes, and endothelial cells (Fig. 11.4). In summary, BBB opening starts occurring at around 0.2–0.3 MPa rarefactional pressure amplitude and beyond. At pressures under 0.6 MPa (Fig. 11.4[i]), no extravasation of red blood cells (RBC) or neuronal damage was observed in the regions of the hippocampus exhibiting the most pronounced BBB opening. Beyond 0.6 MPa (Fig. 11.4[ii]), RBC extravasation was detected, and beyond 0.9 MPa neuronal damage was observed. These preliminary findings suggest that there is overlap between the feasibility and safety windows within the pressure range of 0.3–0.6 MPa; that is, the BBB can be opened throughout the entire hippocampus without endothelial or neuronal damage at those pressures (Fig. 11.4; Baseri et al., 2010; Konofagou and Choi, 2008). FUS-induced BBB opening was reported to close within 72 hours in rabbits (Hynynen et al., 2001). The blood-brain barrier closure occurs within the first 24 hours after BBB opening at low pressures and within 2–3 days at higher pressures and monodispersed bubbles (Samiotaki et al., 2012).

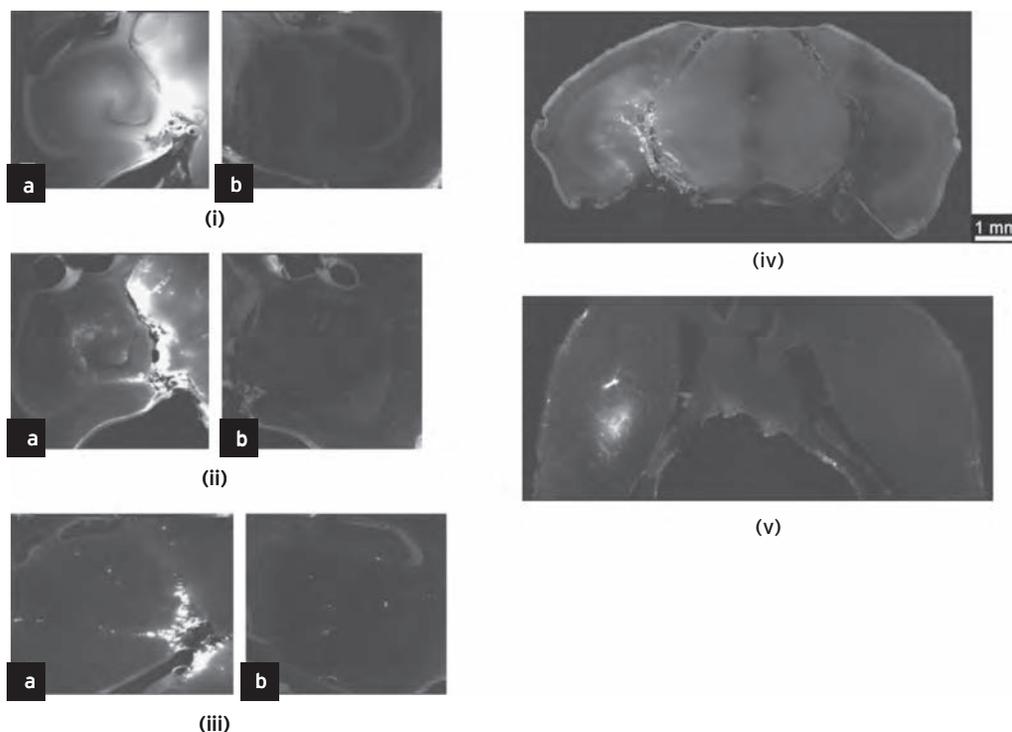

Figure 11.3 Study of the molecular size through the bbb opening using dextrans and fluorescence imaging. Horizontal slice of Dextran of molecular weight equal to (i) 3, (ii) 70, and (iii) 2000 kDa on the (a) left (targeted) and (b) right (not targeted) hippocampus; (iv) coronal slice of the entire brain at 70 kDa Dextran showing the fluorescent left hippocampus (crescent shaped); (v) fluorescent albumin (67 kDa) permeated in the putamen through the opened BBB.

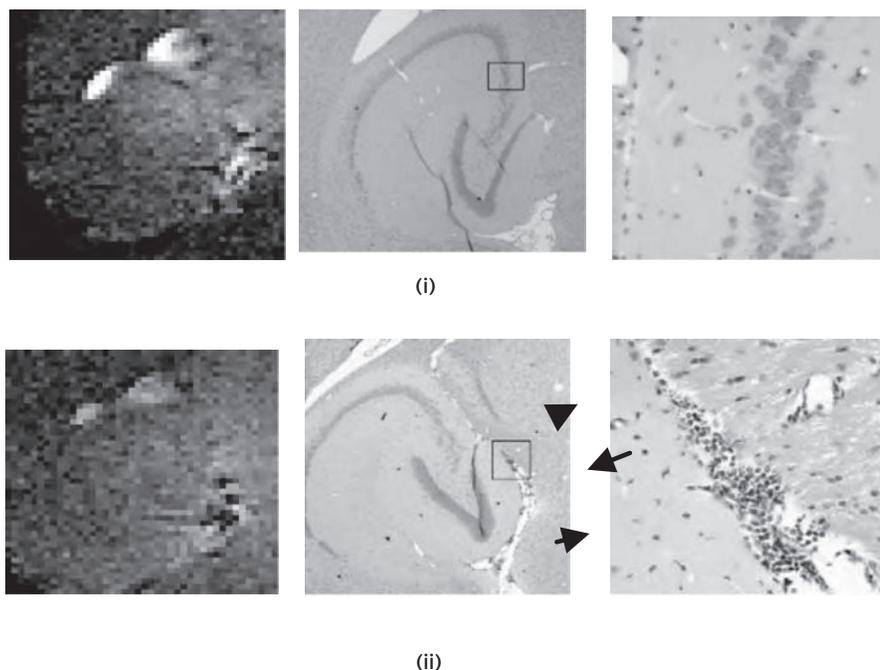

Figure 11.4 Comparison between MRI (left) and histology (center [1×] and right [200×]) near the region of most enhanced BBB opening according to the MRI after FUS-induced BBB opening on the left hippocampus at (i) 0.45 and (ii) 0.75 MPa peak rarefactional pressure. It shows that at lower pressures (i) the endothelial and neurons are intact while at higher pressures (ii) there is extravasation of red blood cells (indicated by arrowhead) and neuronal death (indicated by arrow). This indicates the safety window of the FUS technique in BBB opening.

PROPERTIES OF BBB OPENING

Dynamic contrast-enhanced (DCE) MRI has been performed before and after the intraperitoneal injection of gadodiamide over 60 min (Vlachos et al., 2010). The general kinetic model (GKM) and reference region model (RRM) were used to estimate the permeability in the entire brain (Vlachos et al., 2010). At 0.3 MPa and 4- to 5- μm bubbles (Feshitan et al., 2009), the permeability were found to equal $0.02 \pm 0.0123 \text{ min}^{-1}$ and increase by at least 100 times in the region of BBB opening compared with the control side (Fig. 11.5). Cavitation (Fig. 11.2) and permeability (Fig. 11.5) findings demonstrated that the inertial cavitation threshold is independent of the bubble size while both the ICD and MR amplitude increased at larger bubble sizes, also indicating a correlation between the cavitation and permeability increase (Tung et al., 2010). The fact that the permeability increased with the pressure and microbubble size indicated that the BBB opening occurs at multiple sites within the capillary tree and that the BBB opening is larger with larger microbubbles, most likely due to the larger area of contact between the bubble and the capillary wall.

BBB OPENING IN LARGE ANIMALS

A 500-kHz FUS transducer was used transcranially in Macaca Mulatta monkeys (Marquet et al., 2011). This transducer was mounted on a stereotaxic frame, enabling treatment planning using the brain atlas. *In vivo* experiments were conducted in six monkeys (30 sonications) using Definity or 4–5 μm ,

custom-made, lipid-shelled microbubbles. The BBB opening was confirmed using T1-weighted, spoiled gradient pulse-echo MR sequence at 3 T and gadodiamide IV injection. Damage was assessed using a T2 sequence with the same system. To obtain the BBB closing time line, the T1-weighted MR sequence was repeated along with gadodiamide IV injection over 4 days. MR images were registered to a monkey brain atlas allowing targeting quality assessment. Postprocessing was performed on combined pre- and postcontrast agent T1 images to quantify BBB disruption at the targeted regions, that is, caudate, hippocampus (Fig. 11.6), and visual cortex.

The blood-brain barrier opening was achieved in six different animals using peak negative pressures ranging from 0.2 to 0.6 MPa. No damage was detected at pressures below 0.45 MPa. The actual BBB-opened location was found to be in very good agreement with the targeted one under close to normal incidence angles with the absolute targeting error being less than 1 mm laterally and less than 4 mm axially. The maximum opening-volume-to-target overlap was 85% with an average of 52% depending on the brain region targeted (Deffieux and Konofagou, 2010; Marquet et al., 2011). Initial findings on the closing time line showed that the BBB was fully restored within 2 days after treatment.

THERAPEUTIC DELIVERY THROUGH THE BBB OPENING

Neurotrophic delivery to the brain has been proven essential in reversing the neuronal degeneration process but so far has been hindered by the blood–brain barrier. In a recent study

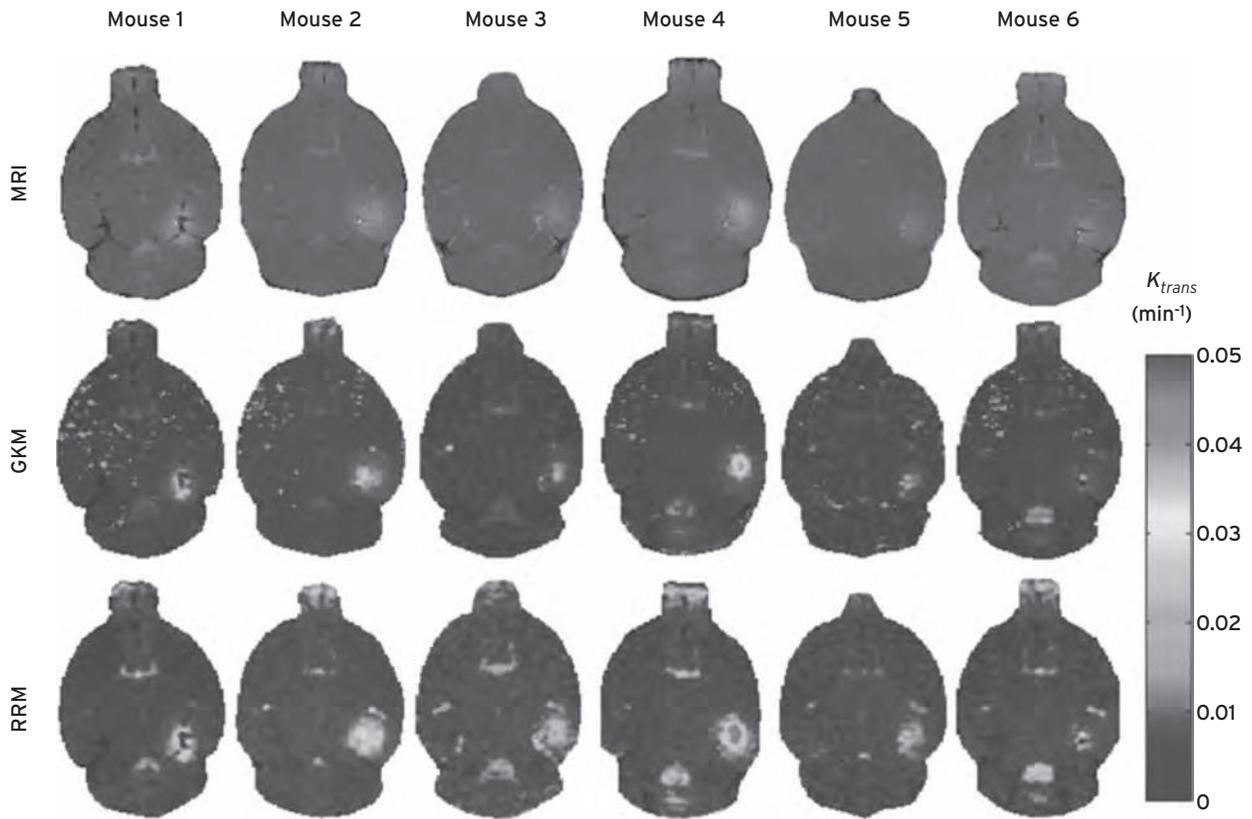

Figure 11.5 T1 images (first row) and their corresponding permeability maps generated from GKM (second row) and RRM (third row) for all mice. The transverse slice with maximum T1 signal enhancement is selected. The K_{trans} values are indicated in the color bar. The maps have been superimposed over the corresponding DCE-MR images. In the case of Mouse 1, the last acquired DCE-MR image is presented instead of a regular T1[61]. (See color insert).

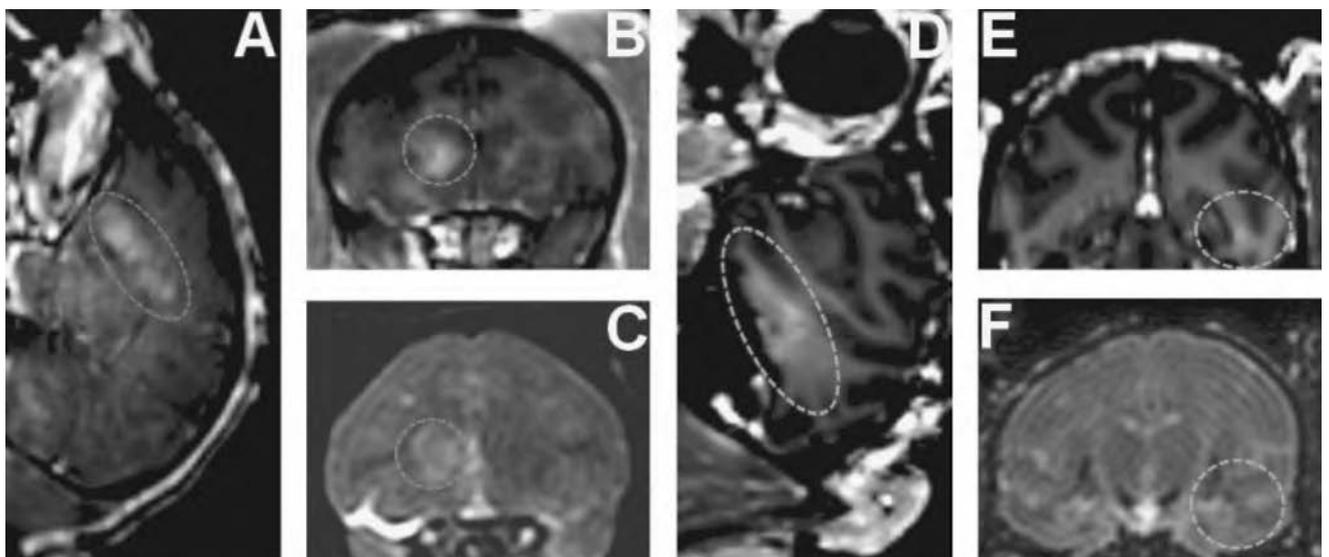

Figure 11.6 In vivo BBB opening in monkeys. (A, C) BBB opening experiment targeting the caudate using custom-made microbubbles and applying 0.6 MPa (dashed line shows region of interest). (D, F) BBB opening experiment targeting hippocampus using Definity® microbubbles and applying 0.6 MPa (dashed line shows region of interest). (A, B, D, E) 3D Spoiled Gradient-Echo (SPGR) T1-weighted sequence was applied after intravenous (IV) injection of gadodiamide 1 hr after sonication. (A, D) Sagittal slices at the region of interest. (B, E) Corresponding coronal slices. (C, F) 3D T2-weighted sequence. An edema was visible using custom-made microbubbles while no damage was detected using Definity® microbubbles.

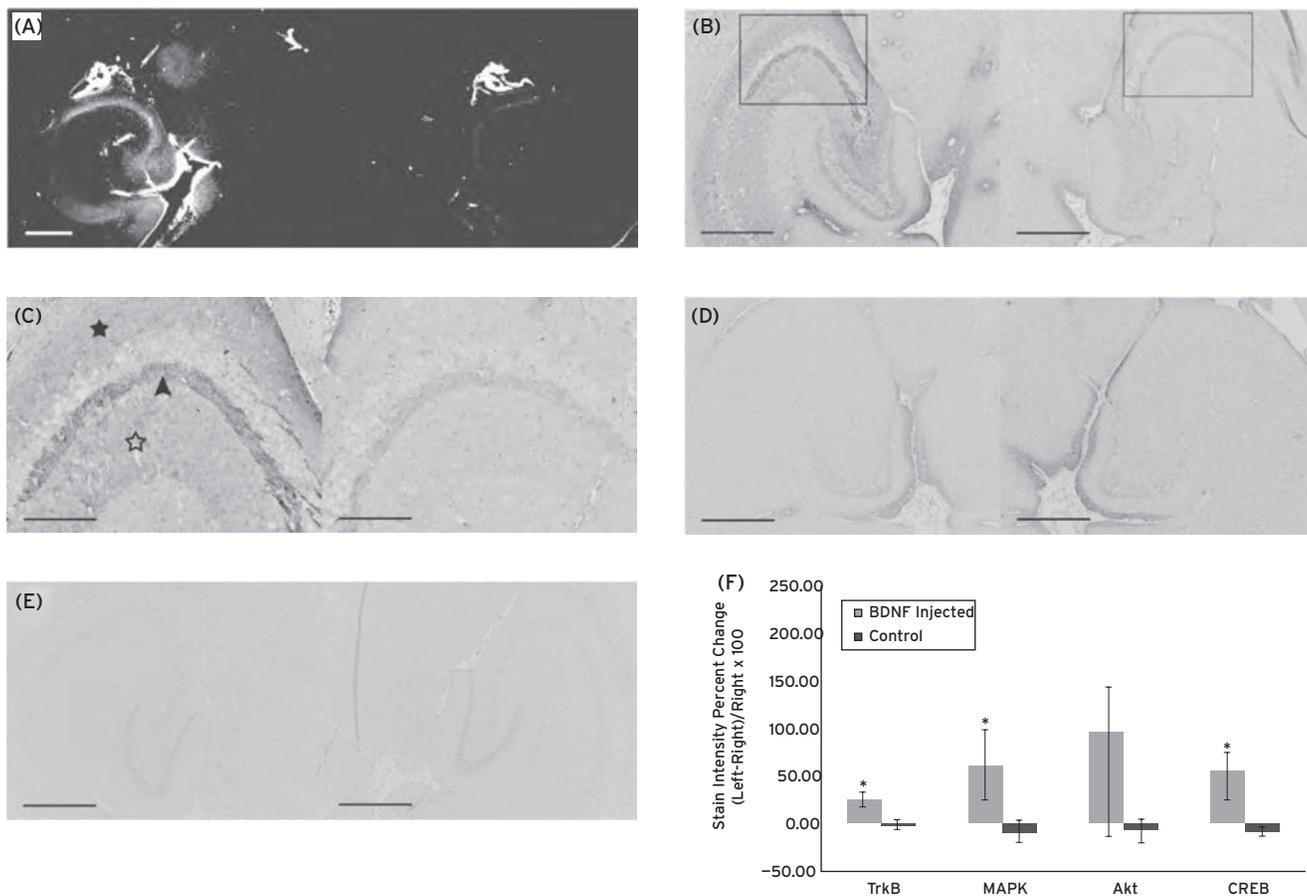

Figure 11.7 (A) Fluorescent image of a 100-micron frozen brain section from a mouse that was sacrificed 20 min after sonication. The sonicated hippocampus (left) shows much higher fluorescent intensity than the unsonicated hippocampus (right), depicting blood–brain barrier opening and the extravasation of fluorescent-tagged (Alexa Fluor 594) BDNF in the sonicated region; (B) a 5-micron frozen section from the same mouse was immunohistochemically stained using a primary antibody against phosphorylated MAPK (pMAPK). Consistent with the fluorescent image in (A), the intensity of DAB staining is much greater in the left sonicated hippocampus compared with the right control; the black box shows the enlarged area in (C), where immunoreactivity to pMAPK is shown in mossy fiber terminals (arrowhead), suprapyramidal CA3 dendrites (black star), and the axons of the Schaffer collateral system (hollow star). (D) Immunohistochemical staining of a 5-micron frozen section from a mouse that was sacrificed 3 min after sonication; the same primary antibody against pMAPK was used. No difference in DAB intensity is observed between the sonicated and the control hippocampus. (E) Negative control for the same mouse in (A); no primary antibody (against pMAPK) was added to this 5-micron frozen section during the staining procedure. All magnifications are 40 \times and scale bars are 500 μ m except for (C), which is 100 \times and 200 μ m, respectively. In (F), immunohistology stain intensity analysis shows percentage change between the left (FUS) and the right (no FUS) sides of the mice brains. A significant difference ($p < 0.05$, $N = 3$; depicted by asterisks) was found between the BDNF-administered animal group and the control (no BDNF) animal group for the TrkB, MAPK, and CREB antibodies. Bars represent mean \pm standard deviation.

by our group, not only was it shown that the brain-derived neurotrophic factor (BDNF) can cross the ultrasound-induced BBB opening but also that it can trigger signaling pathways in the pyramidal neurons of mice *in vivo* from the membrane to the nucleus (Fig. 11.7) (Baseri et al., 2012). This opens entirely new avenues in the brain drug delivery where focused ultrasound in conjunction with microbubbles can generate downstream effects at the cellular and molecular level and thus increase the drug's efficacy and potency in controlling or reversing the disease.

SUMMARY

The studies described this chapter demonstrate that FUS in conjunction with microbubbles was hereby shown to

effectively and reproducibly open the blood–brain barrier transcranially *in vivo* with its recovery occurring within the first 24 hours. The permeability of the FUS-opened BBB was shown to increase by at least two orders of magnitude, indicating facilitation of drug delivery through FUS. Molecules of a wide range of sizes were capable of traversing the opened BBB without any associated structural damage. A dependence of the BBB permeability on the pressure and the microbubble size indicated that multiple sites of BBB opening within the ultrasound beam occur simultaneously while each BBB opening site increases with the microbubble size. Finally, a new pulse sequence was designed that showed feasibility at very short pulse lengths, and transcranial BBB opening in larger animals, such as nonhuman primates and humans, was shown feasible in simulations and *ex vivo* experiments as well as *in vivo* primate monkeys (Fig. 11.6) (Marquet et al., 2011; Tung et al., 2011).

The preclinical studies described point to the considerable progress that has been made in understanding the characteristics of the BBB as well as the safety and efficacy of delivering small molecules into the brain parenchyma using focused ultrasound with microbubbles. Studies are ongoing in order to ensure successful clinical translation in the near future.

DISCLOSURE

Dr. Konofagou has no conflicts of interest to disclose. The research in the chapter was supported by NIH R01 EB009041, NIH R21 EY018505, NSF CAREER 064471, the Kinetics Foundation, and the Kavli Institute.

12 | GENETIC METHODOLOGIES AND APPLICATIONS

SHAUN M. PURCELL

The past decade has witnessed tremendous advances in the molecular technologies and data-analytic methods at our disposal for studying the genetic bases of complex diseases and traits. These advances have enabled the creation of comprehensive catalogs of different forms of human genetic variation, as well as large-scale studies focused on specific diseases or traits. In this chapter, we outline the general principles behind some of these advances and discuss their application to studying complex traits, with a focus on neuropsychiatric disease in particular.

MOTIVATIONS FOR MAPPING THE GENETIC BASIS OF DISEASE

Genetic epidemiology is fundamentally concerned with relating *genotype* (i.e., variation between individuals' genomes) to *phenotype* (i.e., the presence or absence of a disease, or measure of a trait such as height or cholesterol level) (Altshuler et al., 2008). There are a number of relatively distinct motivations for this work, which can be conceived of both in terms of proximal and distal goals of the research. Recently, there has been a great deal of focus on identifying specific *alleles* (variable forms of a *locus*, which is a gene or region) that “explain the heritability” as a primary benchmark and major goal of genetic studies, as discussed later. For many downstream applications, however, perhaps an equally important, but distinct, proximal goal of genetics is to point to the genes and/or gene networks that are causally associated with disease.

Following from these proximal goals (identifying the specific alleles that explain heritability and identifying the relevant genes and pathways) there are several distinct, more distal goals or applications, the success of which will depend on different aspects of the genetic discoveries made. In theory, understanding the genetics of a disease could be used for risk prediction, either at the population level or within families (following the model of genetic counseling for Mendelian disease); for prediction of disease course, severity, or drug response in affected individuals; to identify targets for drug discovery research; to inform on the relationships and comorbidities between different diseases; or even to provide a framework for causal inference around environmental effects (Smith and Ebrahim, 2003). More generally, advances in understanding disease genetics will ultimately, but undoubtedly, provide fundamental insights into human biology, development, and evolution. However, the ease with which genetics will achieve success in these various applications relates to different aspects

of the unknown, underlying *genetic architecture* of any particular disease or trait.

The question of the genetic architecture of common disease has been a central one: it relates to the types of approaches that will work best to map genes, as well as to what we can expect to learn from genetic studies in the near future. For a heritable disease, genetic architecture describes *how many* independent genetic effects contribute to risk, at the level of both the population and the specific individual; it also describes the typical *frequency* and *effect size* of these variants; *how they combine* to produce a phenotype (e.g., additively or interactively) and the extent to which multiple genetic risk factors for a disease coalesce into a smaller number of distinct *biological pathways or networks*. Other aspects of genetic architecture include the *mode of inheritance* (e.g., recessive effects), the presence of positive, negative, or balancing *selection* acting on risk variants, the extent to which genetic effects are shared (or contribute to different disease rates) *across populations*, the extent to which variants influence multiple outcomes through *pleiotropy* (one gene having multiple downstream effects), and the extent to which genetic effects are moderated by environmental exposures (*gene–environment interaction*).

The success of risk prediction, for example, in the general population will be crucially dependent on the proportion of variance explained by detected variants, which is a function of both the frequency and penetrance (a measure of effect size that equals the chance that a carrier develops disease) of risk alleles. By learning which specific alleles (the particular variants of genes) increase or decrease risk or type or course of disease, one can in theory predict an individual's risk or provide tailored medical treatment to patients based on their genotype. In practice, truly personalized genomic medicine is still only a long-term goal in most instances, rather than a current or imminent reality, although this is likely to be an area of great progress over the coming decade.

However, inasmuch as the distal goals relate to identifying *loci*, to point to potential drug targets, for example, the extent to which detected variants account for heritability might not be critically relevant: for instance, there are multiple examples of genetic studies that have pointed to weak genetic effects in genes that are already known targets of existing, successful therapies. Thus, genetic studies have a parallel set of aims that are almost orthogonal to the goal of explaining variability in a population, involving the identification of the *networks of genes* implicated in disease. Here the aim is to use this information to point to the biological mechanisms involved in disease pathogenesis.

CLASSICAL GENETIC EPIDEMIOLOGY: FROM FAMILY STUDIES, SEGREGATION, AND LINKAGE ANALYSIS, TO LINKAGE DISEQUILIBRIUM MAPPING

Classical genetic epidemiology posed a series of increasingly specific questions: For a particular disease or trait, are there genetic influences? Is the genetic basis simple or complex? Where are those genes located? Which specific forms of the gene cause disease? The tools to answer these questions were, respectively, family and twin studies, segregation analysis, linkage analysis, and association analysis. Twin and family studies are used primarily to estimate the heritability of a trait (the extent to which variation in outcome is due to variation in genes) by contrasting the phenotypic similarity of relatives of differing genetic similarity. More recently, twin and family study designs have also proved useful in molecular studies of genetic and epigenetic variation (van Dongen et al., 2012). One notable family study of schizophrenia and bipolar disorder involved tens of thousands of patients from Sweden and showed clear evidence for a shared genetic basis common to both disorders (Lichtenstein et al., 2009). Looking at a range of first-degree relative classes, such studies estimate the probandwise concordance rate (the probability an individual develops disease given they have an affected relative of a particular type) and the familial relative risk (λ), which for a given class of relative, is the concordance rate divided by the population prevalence of disease. Both approaches ask how much more likely an individual is to develop disease if he or she has an affected relative. Estimates of λ for MZ twins, full siblings, parent-offspring pairs, and half-siblings track strongly with the extent of genetic similarity in those pairs, indicative of a considerable genetic basis for these diseases. This and other studies put the heritability of schizophrenia to be very high, with estimates from 60% to 80%, for example.

Segregation analysis considers the broader pattern of disease within larger pedigrees. For Mendelian disease, segregation analysis can estimate whether there is likely to be a single disease allele in each family, and if so, its mode of inheritance. For complex diseases that are caused by multiple genes and environmental influences, segregation analysis is typically uninformative (beyond demonstrating above-chance levels of familial clustering). Linkage analysis also uses pedigrees to identify specific (but very broad) chromosomal loci that cosegregate with disease in a particular family. Linkage analysis primarily gained popularity after the introduction of molecular marker maps in the 1980s. For example, by genotyping 300–400 “microsatellite” markers (short tandem repeats of variable length between individuals), one can infer the pattern of gene flow in a family (specifically, of shared chromosomal regions coinherited from a single ancestor and so *identical-by-descent*, IBD) and then search for chromosomal positions at which the profile of IBD maximally correlates with the coinheritance pattern of the phenotype. Linkage analysis proved spectacularly useful in mapping Mendelian disease genes of major effect: rare mutations that almost always lead to correspondingly rare diseases. In contrast, for complex, common diseases, linkage analysis has yielded very few durable results (for neuropsychiatric disease, one notable exception is the *DISC1* locus).

This is, in large part, because linkage analysis has low power to detect variants of only modest effect. The general failure of linkage analysis (given that it has, in fact, been widely applied for many diseases, including schizophrenia) can be taken to indicate that the genetic architecture of most common diseases is unlikely to be well characterized as primarily consisting of a small number of “hotspot” regions: that is, genes or loci at which a sizeable proportion of cases carry a highly or even moderately penetrant risk variant.

Association analysis (or *linkage disequilibrium* mapping) has replaced linkage analysis as the workhorse of genetic epidemiology over the past decade. Association analysis is conceptually straightforward: typically in populations of unrelated individuals, association analysis simply looks for specific variants (alleles) that are significantly more frequent in people with the disease compared with those without. Compared with linkage analysis, this approach is more powerful to detect variants of smaller effect (Risch and Merikangas, 1996).

To more concretely contrast the effect sizes expected for a “major gene” disorder versus a complex, common disease, consider that for a rare disease, say, affecting 1 in 10,000 individuals, a major gene effect may increase risk more than 10,000-fold: for example, if baseline risk in noncarriers of the gene is 0.00003, then the *penetrance* (risk of disease given genotype) would be 30% or more. In this scenario, even though the gene is not completely Mendelian (deterministic in its effect), a very large proportion (more than one third) of carriers will develop the disease, and conversely, a very large proportion of all affected individuals will carry that particular disease allele (again, more than one third). In comparison, for a common disease with a population prevalence of 1 in 100 individuals, for common alleles researchers expect realistic effect sizes along the lines of, at most, a 1.2-fold, rather than 10,000-fold, increase in risk. If this risk allele has a population frequency of, say, 40%, it implies that carriers have ~1.2% risk of developing disease and we would expect to see the allele in ~44% of cases compared with ~40% of unaffected individuals. This relatively small difference means that the variant is harder to detect statistically. (It also means that this allele, by itself, will have very little predictive utility: i.e., knowing an individual’s genotype at this locus would only marginally improve one’s ability to predict, above chance, whether or not the individual will develop disease. Of course, for a heritable disease, we would expect many such loci to contribute to disease risk that could be informative if analyzed collectively.)

Historically, the principal limitation in applying association analysis broadly was that, unlike linkage analysis in which only a relatively modest number of molecular markers provide a genome-wide survey of gene flow within families (because very large chunks of chromosome are shared between closely related individuals), testing a specific marker for association only queries a tiny proportion of the total extent of variability that exists genome-wide. This arises from the properties of *linkage disequilibrium* in human populations, as described later. Thus, hundreds of thousands of markers would be needed to cover the whole genome, and the sufficiently high-throughput genotyping methods needed to achieve this have only come into existence more recently. In practice, for a long time this meant that association analysis was limited to testing a small

number of variants in a small number of *candidate genes*. Candidates were usually selected on the basis of prior knowledge, or assumptions, about the pathophysiology of disease. In neuropsychiatric genetics, despite a considerable body of work, studies of candidate genes largely failed to lead to broadly reproducible results. There are multiple reasons to explain this state of affairs (reviewed by Kim et al., 2011). Perhaps most obviously, many of the original hypotheses about the disease may have been incorrect, or at least fundamentally incomplete descriptions of a much more complex process. For a number of diseases such as Type II diabetes and Crohns' disease, the biology pointed to by recent, robust genetic findings from genome-wide association studies (see following) has often been at odds with the prior assumptions about what would be genetically important. This is, of course, a good thing from the perspective of genetic studies, in that we wish for genetics to be a source of novel insights and hypotheses—that is, to tell us something new. Typically the error rates of candidate genes studies would also have been high: false positives (Type I errors in hypothesis testing) are hard to control, given varying degrees of multiple testing, and false negatives (Type II errors) are likely as sample sizes used for most candidate gene studies were typically very small by today's standards. In schizophrenia, as of 2011, 732 autosomal genes had been tested by 1,374 hypothesis-driven candidate gene studies, although most genes were investigated in only one (61%) or two (16%) studies (Kim et al., 2011). Typically no replication was attempted, or it was underpowered, or the statistical evidence was, at best, hard to reconcile from the literature (e.g., when different markers in the same gene were tested across different studies, or when

replication was claimed but the direction of effect for the same marker differed between studies). Furthermore, genetic variation in the candidate genes tested was typically only very poorly captured, even for common variation, often with only one or two markers being genotyped per gene.

EXPANDING KNOWLEDGE OF THE HUMAN GENOME

Reference maps and databases have been critical in many areas of genomics: from the human genome reference sequence itself, to maps of coding and other functional elements in the sequence. Equally important for disease and population genetics has been the more recent construction of maps, or catalogs, of observed *variation* within and between different human populations. The two most notable efforts are the International HapMap project (International HapMap Consortium, 2007) and, more recently, the 1000 Genomes project (1000 Genomes Consortium, 2010). The HapMap project employed large-scale genotyping to type almost 4 million known single-nucleotide polymorphisms (SNPs) in 270 individuals of African, Asian, and European ancestry. As well as generating lists of technically validated polymorphic sites along with estimates of allele frequencies in multiple populations, a central aim was to characterize and describe the patterns of correlation between nearby variants, referred to as *linkage disequilibrium* (LD). As illustrated in Figure 12.1, two or more alleles at nearby sites are said to be in LD if they co-occur more than expected by chance, that is, than if they were inherited independently of

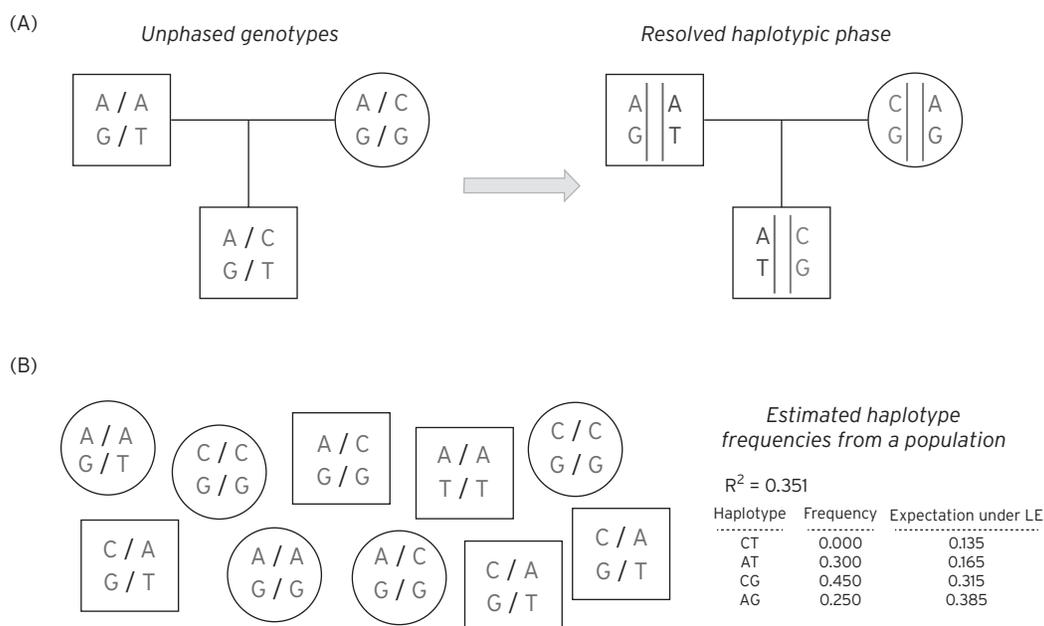

Figure 12.1 Linkage disequilibrium and haplotype phasing. (A) Using family information can often resolve phase unambiguously. Here a trio is genotyped for two biallelic SNPs: for the first site, A or C alleles (top genotype in all plots); for the second site, G or T alleles (bottom genotype in all plots) in this example. From inspection, the mother necessarily transmits the CG haplotype, implying that the offspring carries AT and CG haplotypes, rather than AG and CT haplotypes. (B) In the absence of family data, it is still possible to estimate haplotype frequencies from genotypes at SNPs in linkage equilibrium. In this toy, illustrative example, the EM algorithm would conclude that the CT haplotype does not exist in this population based on this very small sample of 10, meaning that the two SNPs are in LD (here R^2 is estimated at 0.351). Individuals would be assigned a combination of AT, CG, and AG haplotypes only, which will be consistent with their SNP genotypes.

each other. In reality, *haplotypes* (collections of alleles on the same physical stretch of chromosome) are the primary unit of inheritance, not individual alleles. Two alleles on the same haplotype will tend to be either both cotransmitted from parent to offspring, or will both be untransmitted, thereby inducing a correlation between the alleles at the population level. The further away two sites physically reside on the chromosome, the more likely that they will be separated by a meiotic *recombination event*. Thus, LD between any two sites tends to “break down,” or be attenuated, over distance. This property can be used to localize genes, in that it implies that two sites that are in LD are also likely to be physically colocated on the same stretch of chromosome. This is the principle behind linkage disequilibrium mapping.

Obtaining genotype data on an individual for two nearby heterozygous sites does not directly reveal the underlying haplotypes carried by that individual, although in families the haplotype can often be inferred straightforwardly. For example, if the individual carries an *A/C* (heterozygous) genotype for the first site and *G/T* for the second, there are two possible haplotypic configurations: that the *AG* haplotype was inherited from one parent, and therefore *CT* from the second, or that *AT* was inherited from the first and *CG* from the second. The process of resolving which configuration is more likely is called *phasing*. As in the Figure 12.1, phase is often unambiguous when one studies multiple members of the same family. Alternatively, statistical approaches (based on algorithms such as expectation maximization [EM] or Markov Chain Monte Carlo [MCMC] and population genetic models) can be used to resolve phase in samples of unrelated individuals, by considering the observed correlation between sites and treating the unknown phase information statistically in terms of a missing-data problem (Browning and Browning, 2012). In some situations it is also possible to use sequencing to type haplotypes directly, using molecular rather than statistical means, sequencing along the same physical stretch of chromosome.

The actual structure and extent of LD in humans reflects both demographic factors and the history of the population studied, as well as biological properties of the genome, influencing the rate of recombination at particular sites. The typical structure and extent of LD is of critical importance to the implementation of association analysis as applied to large genomic regions. Fundamentally, association mapping (or *linkage disequilibrium* mapping, as previously noted) relies on the fact that by testing a particular variant, one is implicitly testing a host of nearby variants, for which the genotyped markers act as proxies, or *tags*.

The HapMap project provides a comprehensive empirical description of the typical profiles of LD in the populations studied. To a first approximation, patterns of LD can be well characterized by “haplotype blocks,” meaning that there are regions of the genome (very variable in size, but often on the order of 10 to 100 kb) in which there is very high LD, meaning that only a small subset of all possible haplotypes (combinations of alleles in that region) are observed in the population. For example, considering 10 SNPs, each with two alleles, there are $2^{10} = 1024$ possible haplotypes, although under very strong LD we may observe only two or three of these at appreciable population

frequencies. These “blocks” are separated by “recombination hotspots”—places in the genome with a historically higher rate of recombination, which acts to reduce LD by separating alleles on the recombinant haplotype. The results from the HapMap helped inform the design of experiments that aimed to intelligently select the smallest possible set of markers necessary to capture, or tag, most of the known common variation in a region. In the 10-SNP example, it may only be necessary to genotype 1 or 2 SNPs for example, without significant loss of information compared with genotyping all 10.

A common measure of LD in association studies is R^2 , where a value of 0 indicates no LD (two sites are statistically independent) and 1 indicates that one marker is effectively a perfect proxy for the second. An intermediate value, say of 0.8, indicates that one marker captures 80% of the information one would obtain if using one marker as a proxy for the other, instead of directly genotyping the second marker. If the untyped marker is a causal risk factor for disease, then one may still expect to observe a statistical signal of association (e.g., based on a simple comparison of case and control allele frequencies) at the genotyped marker, albeit one that is attenuated due to incomplete LD. (In fact, to retain equivalent power to detect association at the marker, in this case one would require $1/R^2 = 1/0.8$ or 125% of the sample size compared with typing the causal marker directly). By estimating the average extent of LD, analyses of HapMap data showed that one could expect to capture the majority of common (typically defined as above 5% marker allele frequency) variation in European and Asian populations at a reasonable level of certainty (e.g., $R^2 > 0.8$) by genotyping on the order of 500,000 SNPs genome-wide. This paved the way for the first genome-wide association studies (GWASs), which began typing 100,000–300,000 markers using newly developed, standardized commercial microarrays, soon establishing 500,000–1,000,000 SNPs as routine (Carlson et al., 2004). As described later, association analysis of these datasets has driven many genetic discoveries in the past decade.

Superseding the tagging approach in many respects, the more general approach of *imputation* leverages the actual HapMap sample data itself to fill in data that are “missing” in a GWAS but present in the HapMap, relying on LD information implicit in the HapMap across all SNPs. Imputation allows researchers to probabilistically assign genotypes for all common HapMap SNPs (over 2 million in the European samples), even if only 500,000 have been directly genotyped in the study, by taking advantage of the redundancy due to LD. One of the major applications of imputation is to facilitate the comparison and aggregation of studies that use different GWAS arrays, by mapping everything to the common set of HapMap SNPs. This also obviates many of the practical difficulties that plagued candidate gene studies, in which different markers were typed in different studies.

The HapMap and GWAS in general are largely focused on assaying only common genetic variation: typically sites at which at least 5% of chromosomes carry an “alternate” allele compared with the reference sequence. The vast majority of variants that have population frequencies below 1% will not be present in the HapMap or on standard microarrays and so will be effectively invisible to GWAS approaches. A major

push in recent years has been to leverage advances in so-called *next-generation sequencing* (NGS) technologies to build catalogs of lower frequency variation. This technology employs massively parallel approaches to sequence many millions of small fragments of DNA, generating very large numbers of short reads (around 100 bases) that can be mapped back to the reference sequence and variant sites called in an individual. The 1000 Genomes Project (www.1000genomes.org/) has used this technology to sequence the entire genomes of over 1,000 individuals, in order to create maps of known low-frequency variants and reference panels for imputation. Combining publicly available 1000 Genomes data with standard GWAS data, one can reliably impute over 10,000,000 polymorphic sites, many of which are of low frequency (under 1%) and many of which represent potentially functional polymorphisms (e.g., nonsynonymous allelic substitutions in genes, or short insertions and deletions that could shift the reading frame of a gene). To measure very rare mutations that are specific to a family or a particular ancestral group that is not represented in the 1000 Genomes data, it will still be necessary to sequence samples directly. But given current cost constraints, the 1000 Genomes data afford a new lease of life for existing GWAS samples. In addition to utility in imputing a good deal of low-frequency variation, these data may be particularly helpful in ascribing a putative function to associated regions or haplotypes, as a consequence of the near-complete ascertainment of all commonly variable sites.

Another type of genomic map that has recently been completed, and that will likely play a critical part in both the analysis and interpretation of many genetic studies of disease, is the ENCODE project (Encyclopedia of DNA Elements; <http://www.genome.gov/10005107>). This project aimed to map all functional elements in the human genome sequence beyond protein-coding genes: for example, regions (that may often be cell- and tissue specific) related to factors such as chromatin structure, methylation, histone modification, sequence-specific transcription factors, and RNA-binding proteins. As many association signals from GWAS fall outside of known protein coding genes, a more comprehensive annotation and understanding of the full sequence will be important in translating statistical signal into biological knowledge (Degner et al., 2012).

GENOME-WIDE ASSOCIATION STUDIES

In many respects, the development of reliable, cost-effective, high-throughput genotyping technologies, using microarrays that can simultaneously assay hundreds of thousands of single-nucleotide polymorphisms, has addressed all the basic limitations inherent in the early application of association (or linkage disequilibrium) mapping. Because almost all of the common variation in the genome can be assayed, genetic studies have become fundamentally data-driven enterprises and do not need to rely on prior hypotheses being correct. Order-of-magnitude, cheaper, per-genotype costs have enabled a large amount of genetic data to be amassed; the use of standardized microarrays (combined with imputation analysis) has also facilitated pooling of data across studies to achieve larger samples through meta-analysis, and therefore greater power,

which is vitally important in complex trait genetics (Lohmueller et al., 2003). At the same time, the large multiple-testing burden inherent in genome-wide scans has forced investigators to address the issue of false positive rates early and head on in the context of GWAS. Based on empirical and theoretical considerations, most investigators now require a p -value of less than 5×10^{-8} for an association to be declared *genome-wide significant*. In a well-controlled study, findings that reach this stringent threshold have been shown to have a very high probability of replicating in subsequent studies. Finally, GWAS studies generally do a more comprehensive job at capturing common variation in a given gene compared with early candidate-based studies using older genotyping technologies, including capturing the vast amount of variation in intergenic regions).

APPLICATIONS OF GENOME-WIDE ASSOCIATION MAPPING AND ANALYTIC ISSUES

Genome-wide association studies have been very widely adopted for a large number of diseases. One of the pioneering studies was of seven diseases and a shared control sample, the Wellcome Trust Case Control Consortium (2007). The U.S. National Human Genome Research Institute (NHGRI) maintains a catalog (www.genome.gov/GWASudies) of published associations from GWAS for a diverse range of diseases and traits. To date, over 1,600 associations have been published, all meeting the strict threshold of genome-wide significance (Figure 12.2).

There is a great deal of evidence to suggest that for most common diseases these genome-wide findings represent the tip of the iceberg of true common variant associations. In many cases, including for neuropsychiatric disease, there are multiple lines of evidence that point to an abundance of true signals below the formal threshold for genome-wide significance. When looking at many replicated genome-wide significant results, the statistical power to detect a variant of that frequency and reported effect size is typically low, even acknowledging that they may be inflated by the so-called “winner’s curse” effect (that means that effect sizes for variants that are detected at very strict significance thresholds will tend to be larger than their true value, reflecting the fact that they may have needed “the luck of the draw” from sampling variation to push them over the bar). This implies either that the investigator was extremely lucky (managing to detect one particular true positive despite very low power to do so) or, perhaps more parsimoniously, that there must be a (much) larger reservoir of similar effects truly existing, from which this study sampled a particular subset, in proportion to the statistical power. More directly, one can take sets of independent subthreshold associations (e.g., SNPs with p -values between 1×10^{-4} and 5×10^{-8}) and ask whether more than expected are nominally significant in an independent sample (e.g., at $P < 0.01$ or $P < 0.05$), or show effects in a consistent direction (above 50% correspondence of risk versus protective effects expected by chance alone, often referred to as a “sign test”). For many diseases, such analyses strongly support the presence of many subthreshold true associations. Furthermore, approaches such

TABLE 12.1. Sample sizes required (case/control pairs for a 1% disease) under different genetic models

CAUSAL ALLELE		GENOTYPED MARKER		REQUIRED SAMPLE SIZE OF 80% POWER	
MAF	GRR	MAF	R^2	$\alpha = 0.05$	$\alpha = 5 \times 10^{-8}$
0.40	1.2	(Directly typed causal allele)		949	4,792
0.40	1.2	0.50	0.67	1,400	7,064
0.40	1.2	0.10	0.17	5,880	29,668
0.01	3.0	(Directly typed causal allele)		410	2,070
0.01	3.0	0.50	0.01	21,213	107,030
0.01	3.0	0.10	0.09	2,533	12,780

Contrasting power under two particular scenarios, involving a common and a low-frequency variant. Power calculated using the Genetic Power Calculator (<http://pngu.mgh.harvard.edu/purcell/gpc/>) and shows the number of case/control pairs required to achieve 80% power (i.e., an 80% chance of correctly rejecting the null hypothesis when the SNP truly has an effect) for two significant thresholds: a nominal 0.05, and genome-wide significant 5×10^{-8} . (These α values represent the chance of a false-positive test result.) The two causal scenarios are not intended to be directly comparable; rather, the numbers presented are meant to show the impact of requiring a strict significance threshold on required sample size, and the impact of incomplete LD (by genotyping a marker instead of directly genotyping the causal variant) under the two scenarios. Aside from the fact that, in general, large sample sizes are required for these types of effects, we see in particular that if the marker has a frequency very different from the causal variant, the R^2 , which is always set at the highest possible value given the two allele frequencies, it will be necessarily low, and therefore, power will be low, and the sample size required to achieve 80% will be high. The first scenario represents the type of SNP we may expect to find in a GWAS; the second scenario represents (perhaps an optimistically large) effect as one might hope to see in exome sequencing or an exome array study.

as *gene set-enrichment analysis* applied to lists of subthreshold associations can be used to indicate whether the genes implicated appear to be a random selection of all genes, as would be expected if the associated regions were, in fact, selected purely by chance, as opposed to preferentially belonging to certain known pathways, or clustering in networks, beyond chance expectation—that is consistent with a nontrivial proportion of the associations being true positives. For example, Lango Allen et al. (2010) reported hundreds of variants influencing human height clustered in functionally related pathways. Evidence for a substantial number of likely true subthreshold associations for a given disease can be taken to indicate that larger sample sizes will yield genome-wide significant associations, as more true positives are pushed over the threshold.

Other studies have taken more direct approaches to address the idea of *highly polygenic* disease architectures (i.e., involving hundreds or thousands of distinct genetic loci). In particular, analyses of common variants in GWAS data for various highly heritable phenotypes, including height (Yang et al., 2010) and schizophrenia (International Schizophrenia Consortium, 2009), have indicated that a sizeable proportion of the total heritability may be due to the combined action of extremely modest effects across many loci (many of which may never be expected to rise to the level of genome-wide significance even in very large samples). Under such models it is likely unrealistic to ever expect a complete genetic model of a disease, although it is important to note that very high polygenicity (in which the power to unambiguously detect any one of a large number of loci is very low) does not by itself preclude progress toward the broader goals of genetic studies, namely, the identification of critical biological pathways and networks, and even individual risk prediction and personalized therapies.

Table 12.1 gives concrete numbers for the sample sizes required under different genetic models, for both common

and rare variants of varying effect sizes. Given the large sample sizes indicated in Table 12.1 for the type of variant that characterizes most “GWAS hits,” *meta-analysis* (or combined, *mega-analysis*) has played an increasingly important role in genetic disease studies, in which consortia of consortia pool results or raw genotype data to collectively achieve greater power to detect variants of small effect.

Although it has become clear that Type II errors (false negatives) are the primary hurdle in GWAS (low power to detect small effects), there has been considerable attention to the issue of Type I errors (false positives). At the dawn of the GWAS era, many researchers were reasonably concerned that the massive multiple testing, as well as the scope for bias to arise from technical artifact or epidemiological confounding, would lead to hopelessly inflated false-positive signals. Given that most GWAS studies have been population based (utilizing samples of unrelated cases and controls) as opposed to family based, one concern was that *population stratification* might give rise to false positives, if cases and controls are not well matched for ancestry, given that different populations systematically vary in allele frequency at many sites across the genome, for reasons unrelated to the disease being studied. In contrast, association analyses that adopt a family-based approach (e.g., the *transmission disequilibrium test*, or TDT, which tests for over-transmission of a specific allele from heterozygous parents to affected offspring) implicitly guard against such confounding effects (e.g., by contrasting transmitted versus untransmitted alleles from within the same parent, in the case of the TDT). In practice, the presence of genome-wide genotypic data allows one to empirically assess the presence of heterogeneity in ancestry in a sample of individuals (Rosenberg et al., 2002), and to correct it statistically in tests of association (using approaches such as principal components analysis). Although most GWASs have been conducted in populations of European

Published Genome-Wide Associations through 09/2011
1,617 published GWA at $p \leq 5 \times 10^{-8}$ for 249 traits

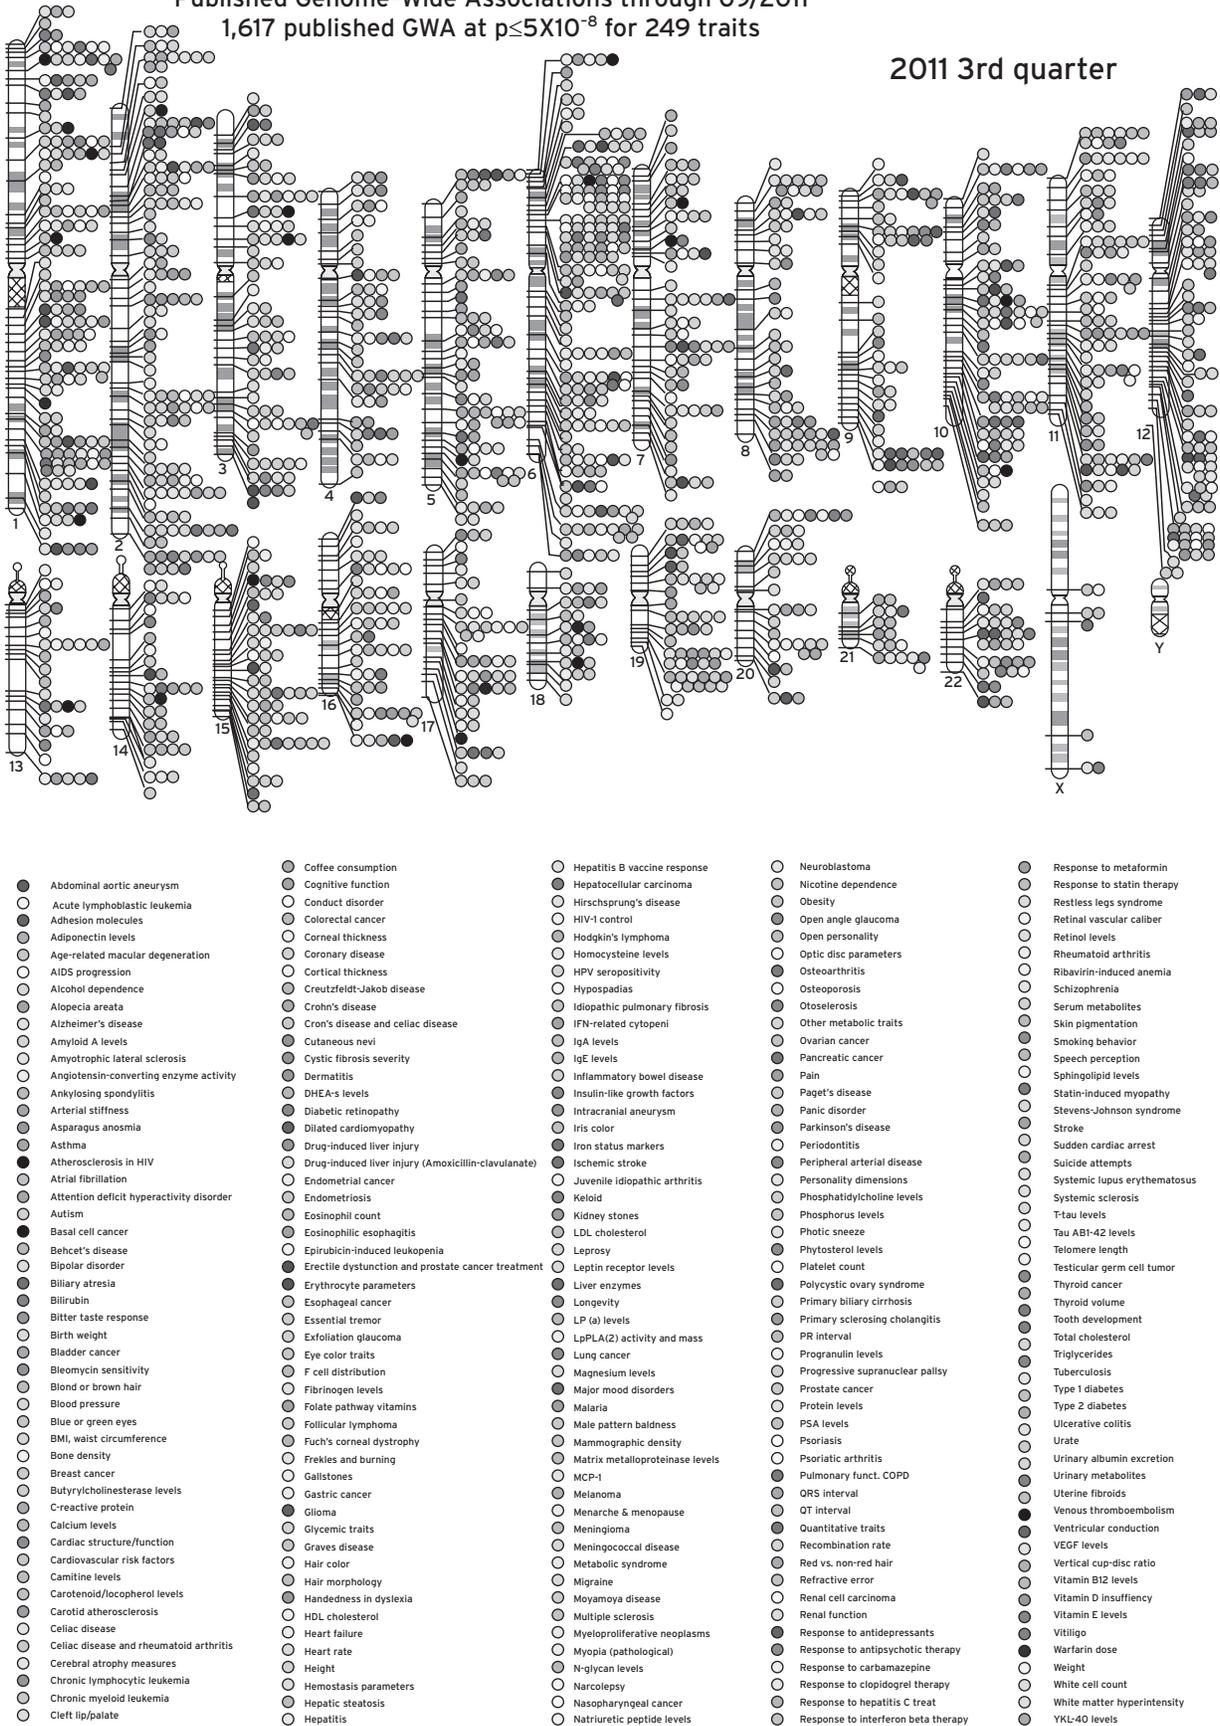

Figure 12.2 The National Human Genome Research Institute GWAS catalog. A list of published GWAS associations published up until 9/2011 (www.genome.gov/GWASStudies). Shaded circles indicate different classes of phenotype, enumerated in text that follows. The shaded-coded key does a rather poor job at indicating which associations are mapped genomically, but perhaps more importantly, the legend does convey the breadth of phenotypes for which successful GWAS have been performed. Many of these discovered loci were completely novel.

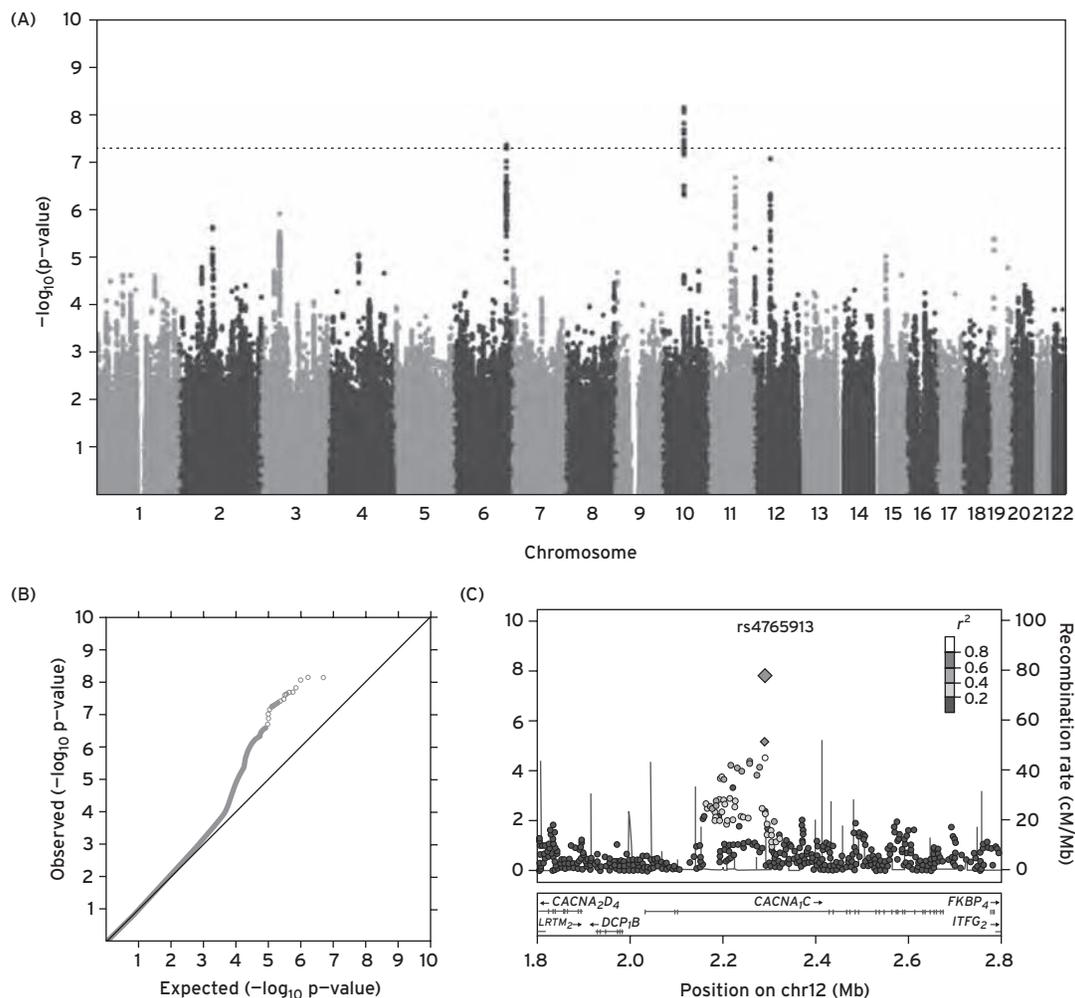

Figure 12.3 Reporting GWAS results: Q-Q, Manhattan, and “regional” plots. These figures are taken from the Psychiatric Genomics Consortium Bipolar Disorder Working Group’s *Nature Genetics* 2011 report of a mega-analysis of bipolar disorder GWAS data. (A) A so-called “Manhattan plot,” in which individual SNP association statistics are ordered along the x-axis; the p-value is plotted on a $-\log_{10}(P)$ scale, so values over 7.3 represent genome-wide significance. (B) The same data are shown in a Q-Q plot (quantile–quantile), which plots the observed statistic ($-\log_{10}(P)$) in rank order against the expected value under the global null hypothesis of no association. Points along the diagonal are therefore consistent with chance. The plots can show evidence of systematic bias (if the entire line grossly departs from the diagonal) or signal that is more likely to be true (if only the top portion of the data does, indicating there are more nominally significant hits than would be expected by chance). (C) A third commonly used plot when reporting GWAS results is a “regional” plot. This shows the association statistics in a particular region as well as gives information on the LD (R^2) between markers. (Psychiatric GWAS Consortium Bipolar Disorder Working Group, 2011).

decent, there is potentially a lot to be learned from application to a more diverse range of populations, and new analytic challenges, for example, in highly admixed populations (Rosenberg et al., 2010). Quality control procedures play an important role in GWAS—for example, testing for deviations from *Hardy-Weinberg equilibrium*, or detecting SNPs with particularly high rates of failed genotyping. GWAS can still be prone to false positives from technical bias or other types of analytic error, simply by virtue of the large number of tests performed: this concern is in large part addressed by placing a strong emphasis on the need to seek *replication* in independent samples of any putative strong signals.

Although one in theory can approach the analysis of genotype–phenotype relations using GWAS data in a number of ways, in practice most of the substantive findings (as represented in the NHGRI catalog) come from simple, sequential tests of one SNP (either imputed or directly genotyped) at a

time. Typically, a technique such as logistic or linear regression is employed, assuming a purely additive dosage model at each site. Simpler alternatives include Armitage trend test or Fisher’s exact test; more complex alternatives include nonparametric regression models, linear mixed models, and Bayesian approaches—in broad terms though, it is not obvious that the precise choice of statistical machinery employed would have impacted the substantive conclusions drawn to date.

Subsequent chapters summarize the results to date of GWAS and other types of genetic studies, for a range of neuropsychiatric diseases. There have been fewer, if any, cases of “low-hanging fruit” to emerge from common variant studies of diseases such as schizophrenia and bipolar disorder, compared with other common diseases such as Crohn’s disease or Type I diabetes. Nonetheless, numerous genome-wide significant hits have emerged for both disorders, and, as noted, consideration of subthreshold results would strongly suggest that more are

to be expected with larger sample sizes. Indeed, several large meta-analyses are currently underway: the analysis of common variation in neuropsychiatric disease is very much a work in progress, but one that appears to have found a steady footing from which to move forward.

THE FREQUENCY SPECTRUM OF DISEASE ALLELES: MODELS OF RARE AND COMMON VARIATION

Almost by definition, most genetic variation is attributable to common polymorphism in the human genome. For this reason, along with the fact that common SNPs in any one population constitute a relatively limited and easily assayable universe, common variation was an obvious first target for large-scale, genome-wide genetic studies, in the form of SNP-based GWASs. It has, of course, long been recognized that common SNPs are by no means the only class of variation a geneticist may wish to study. Particularly in the context of disease, one can reasonably argue (supported by observations in rare, Mendelian disease) that larger types of variant—those impacting more than just a single, usually intergenic, nucleotide—might also be more likely to have a strong impact on disease risk. *Structural variants* are one such class, involving the deletion, duplication, inversion, or translocation of potentially millions of nucleotides. Similarly, evolutionary arguments can be used to suggest that alleles of *high penetrance* are unlikely to be very common, assuming the disease has had a continued, negative impact on fitness over many generations, and so would have been selected against. The hypothesis that *rare variants* may primarily underlie common disease risk, in the same way they do for rare disease, expresses this logic (Cirulli and Goldstein, 2010).

For schizophrenia, examples of very rare structural variants that are strong risk alleles were identified over two decades ago, using the classical techniques of cytogenetics and linkage mapping in extended pedigrees. For example, a 1.5–3 Mb microdeletion at 22q11.2 leads to velo-cardio-facial syndrome (VCFS), a phenotypically heterogeneous syndrome, which displays an approximately 30% probability of leading to schizophrenia. Because the deletion occurs at 1 in ~4,000 live births, this variant is expected to contribute to risk in ~1% of all schizophrenia patients.

A second example of a highly penetrant, rare structural variant is the balanced translocation between 1q42 and 11q14, segregating with major psychiatric disease in a single extended Scottish pedigree and mapped using linkage analysis. One of the translocations breakpoints was later shown to disrupt a particular gene, now known as *DISC1*, “disrupted in schizophrenia 1” (St. Clair et al., 1990). The success of mapping *DISC1* prompted a wave of functional studies to investigate its roles in neurodevelopment, although the precise mechanism by which the translocation acts to increase risk for major psychiatric illness in this family still eludes researchers. Whether or not that mechanism is ever fully understood, many would argue that the finding still provides a useful window into the larger, more complex pathways involved in the disease.

In its extreme form, the *multiple rare variant* model is taken to mean that although many rare disease variants may exist *in a population*, most affected individuals will carry only one, which was sufficient to cause their disease; similarly, most unaffected individuals would not be expected to carry any risk alleles. This model is in contrast to the polygenic common variant model, in which both affected and unaffected individuals would be expected to carry many risk alleles: under this model, cases simply carry more of them on average, as a consequence of the increased genetic burden leading to increased risk of disease. The extreme form of the multiple rare variant model essentially recasts a common disease as a collection of multiple, clinically indistinguishable diseases—that could in theory also be etiological distinct in a fundamental manner, but that should often be amenable to the same family-based approaches that worked for Mendelian disease (i.e., if most affected families are, in fact, segregating a single, high-penetrance allele). In practice, extreme forms of the multiple-rare variant model are unlikely to be the general rule for any common disease (certainly if linkage analysis has been adequately performed in appropriately sized pedigree collections, this model can already be ruled out).

Perhaps a better default or working model for most common diseases should instead be that multiple variants of varying effect sizes are likely to exist anywhere across the frequency spectrum (Gibson, 2012; Owen et al., 2010). For diseases with childhood or early-adult onset at least, we would expect selection to constrain alleles of larger effect to lower population frequencies. Although the exact relationship between frequency and effect sizes arising from the action of selection will be hard to predict generally, it is safe to conclude that common variants of very large effect are unlikely to exist; otherwise, all combinations of variant will likely occur, in proportion to the frequency spectrum of neutral variation. What may make some diseases, including neuropsychiatric disease, particularly challenging from a genetic perspective, is likely to be the sheer number of loci in the genome that, if perturbed by either a rare or common variant, can increase risk for disease. This challenge will be equally pertinent for various study designs, from sequencing to GWAS.

STUDIES OF RARE STRUCTURAL VARIATION: COPY NUMBER VARIANTS AND NEUROPSYCHIATRIC DISEASE

Structural variants, such as the 22q11.2 deletion previously described, have a well-established role in a range of rare disease phenotypes as well as genomic alterations that occur in cancers (Mills et al., 2011; Wain et al., 2009). Technologies such as array-CGH (comparative genomic hybridization) are now routinely used in prenatal screening as well as research settings, replacing traditional karyotype techniques for detecting unbalanced chromosomal changes. Rare copy number variants (CNVs, deletions or duplications of genetic material) ranging from 100 kb or less to multiple megabases can also be called from analysis of the same SNP microarrays used in GWAS studies: this fortuitous fact has meant that relatively

large GWAS samples have been able to be assayed for changes in copy number variation. For autism and schizophrenia (International Schizophrenia Consortium, 2008; Sebat et al., 2007), such events clearly play an important role. Several studies have found, in particular, an increased rate of *de novo* CNVs in both autism and schizophrenia patients: such events will effectively be uncensored with respect to natural selection. The increased rate of *de novo* mutation in schizophrenia patients is also consistent with epidemiological observations of increased paternal age (as the probability of a germ line mutation in the father is known to increase with his age also).

Approximately a dozen specific loci have been mapped with high statistical confidence, being likely to harbor CNVs that increase risk for disease (Sullivan et al., 2012). Such events are typically large (often impacting dozens of genes), rare in the general population (with a frequency under 1/1000), and are estimated to increase risk for disease by up to 10-fold or more. Interestingly, the same CNVs have been shown to increase risk both for autism and schizophrenia as well as other neurodevelopmental and behavioral disorders. In addition, autism and schizophrenia patients show a modest but significant increased burden of rare CNVs across their genomes, again consistent with the high polygenicity of neuropsychiatric disease. For other neuropsychiatric diseases, the role of CNVs is either less pronounced or no relationship has yet been clearly established.

NEXT-GENERATION SEQUENCING TECHNOLOGIES AND MEDICAL SEQUENCING

The advent of next-generation sequencing, as well as driving large genomics projects such the 1000 Genomes, has been widely and largely very successfully applied to a host of rare, Mendelian diseases over the past few years. One of the most common applications of NGS to date has been *whole-exome sequencing* (Bamshad et al., 2011). Here targeted approaches allow investigators to first greatly enrich the pool of DNA fragments to be sequenced for particular regions of interest: in the case of whole-exome sequencing, this involves “capturing” the ~1% of the genome that is known to contain exons of protein-coding genes. This relatively small fraction of the genome can then be sequenced at high depth (i.e., with 20 or more reads spanning most targeted bases) to ensure high sensitivity to detect if not all then at least the vast majority of variant (nonreference) sites present in an individual’s exome. In comparison with sequencing the whole genome, exome sequencing is still considerably cheaper per unit, although *per base* sequenced, it is less cost effective. In practice, though, sequence data on the exome is typically more valuable in the sense that any one variant has a higher prior likelihood of being functional, and that one can more readily ascribe and interpret that function in terms of its impact on the resulting gene product, and what else is known about that gene (e.g., where it is expressed, what other disorders are associated with mutations in that gene, what other proteins interact with the protein coded by that gene). Perhaps the main drawback with

exome sequencing is the expanding definition of what is practically implied by “the exome”: other interesting regions such as regulatory regions near genes, rare transcripts, and noncoding RNAs are typically not captured comprehensively, and this fact alone may for many motivate the move to whole-genome sequencing. The amount of data generated by whole-genome sequencing is orders-of-magnitude larger than for the exome, and so computational challenges in analyzing and even storing the data become major concerns for large studies.

A typical exome-sequencing experiment on one individual currently targets around 200,000 genomic intervals, each usually corresponding to one exon of a protein-coding gene, around 150 bases in length, targeting around 20,000 RefSeq genes and spanning around 30 Mb of genomic sequence. In a high-depth sequencing study, each targeted base is often covered, on average, by as many as 50 to 100 “short reads.” These reads are typically 70–100 bases in length, often physically paired such that any two reads are expected to fall at nearby genomic locations. Variants are discovered by aligning these reads to the reference sequence and looking for differences: this is a technically involved and potentially error-prone procedure, although the informatics for this have improved markedly in the past few years, in no small part driven by large projects such as the 1000 Genomes. From a whole-genome sequencing study, one expects to find something on the order of 3 to 4 million variant sites; from whole-exome sequencing, this figure is typically in the range of 15,000–20,000 (depending on experimental details as well as the ancestry of the sampled individual).

When sequencing more than a few individuals, a very large proportion of all sites discovered will be “singletons”—variants observed in only one of the sequenced samples, and most of these will be novel, in the sense that they will not have been previously identified and deposited in databases such as dbSNP (<http://www.ncbi.nlm.nih.gov/projects/SNP/>), which currently contains around 50 million known variants. This fact alone clearly poses challenges for the analysis of sequence data to map risk alleles for disease. In practice, the rarity of individual variants means that researchers employ a range of methods to statistically aggregate multiple mutations across a particular gene and collectively test them for association with a disease, in so-called *gene-based* rare-variant analysis. Although large studies of thousands of patients and controls are underway, across a range of diseases, unambiguous discoveries are yet to emerge from these studies. For common, complex traits, exome sequencing will be much more challenging than for Mendelian disorders, and very large sample sizes may well be required, as is the case for studies of common variation (Kiezun et al., 2012).

Because genotyping technology is still cheaper and more accurate than sequencing, a number of groups have recently collaborated to create an *exome array* (http://genome.sph.umich.edu/wiki/Exome_Chip_Design): that is, a standard SNP microarray using the same technology deployed for GWAS, but that primarily contains approximately 200,000 low-frequency mutations that are *nonsynonymous* (alter the protein’s amino-acid sequence) and observed in at least two studies (and so represent variants that are segregating in populations at low frequencies, perhaps 0.1%, as opposed to truly “private”

mutations that may be specific to single families and may never be seen again). Because this array is far cheaper than exome sequencing on a per individual basis, it can be applied rapidly to very large samples. Comprehensive results from these studies are not yet available, although by the end of 2013, we should have a very clear sense of whether this particular slice of the frequency spectrum of nonsynonymous SNPs plays a major role for many diseases, or goes toward explaining the heritability not directly accounted for by the top results of GWASs.

Other applications of sequencing to map rare variants for common diseases are using families rather than standard case control, population-based designs. Families can have a number of advantages: ascertaining families with an unusually high “density” of affected individuals for a given disease increases the probability that a rare highly penetrant variant is present in that family. One can, in principle, use IBD information from linkage analysis to prioritize specific regions of the genome for sequencing or analysis. One can use family information to resolve haplotype phase and to impute sequence data across family members (as related individuals, by definition, represent different combinations of the same smaller set of “founder” chromosomes). One disadvantage is that for many adult-onset diseases it is far harder to collect intact family collections in large numbers.

Additionally, one can use families to detect new, or *de novo*, mutations. In neuropsychiatric disease, and particularly autism and schizophrenia, the hypothesis that *de novo* mutation may play a significant role in disease risk is attractive to many researchers and is supported by the epidemiological observation that affected individuals tend to have older fathers (which is, in turn, known to correlate within increased germ line mutation that will be transmitted to offspring). A number of exome-sequencing studies using *trios* (affected offspring and two parents) have been published for these two diseases. The results to date are interesting and do point to nonrandom networks of genes that are enriched for highly deleterious mutations in patients. At the same time, it does not appear to be the case that a sizeable proportion of affected individuals carry a *de novo* mutation that is likely to be the sole cause of their disease; furthermore, relatively few genes have emerged that are observed to be recurrently hit by *de novos* across these studies beyond the level expected by chance—again speaking to the very high polygenicity of these diseases. The genes and mutations in specific patients that do emerge from this approach may well be particularly interesting to study, however, in that

(because *de novo* mutations are effectively uncensored with respect to natural selection) they could in theory display a very high penetrance. Such “large-effect” alleles could in many cases be preferable mutations to follow up in functional studies, for example, using IPS cells or animal models.

Figure 12.4 illustrates some of the different genetic designs and technologies currently available for relating DNA variation to phenotype, in relation to the part of the allelic frequency spectrum they are designed to probe. Ultimately, it is likely that approaches that look for convergence of genetic signals across these different studies may be fruitful (Nejentsev et al., 2009).

INTEGRATIVE ANALYSES OF GENETIC NETWORKS AND PATHWAYS

Future progress in complex traits genetics is likely to rely on two factors, no matter what particular type of genetic study is adopted: (1) increasingly large sample collections and (2) integrative modeling approaches that not only consider genetic information from different studies as illustrated in Figure 12.4, but also consider multiple genetic signals in their broader context (Raychaudhuri, 2011). This includes intersection of multilocus genotype data with functional information, from gene expression studies, from protein–protein interaction networks, or from other curated gene sets and pathways. Jointly modeling the impact of risk variants on intermediate phenotypes or *endophenotypes* (Gottesman and Gould, 2003), for example, from brain imaging studies, and a fuller analysis of *pleiotropic* effects, where the same variant influences multiple (and potentially seemingly unconnected) disorders or traits (Cotsapas et al., 2011; Craddock et al., 2009), are both likely to be powerful approaches moving forward, particularly when seeded by solid knowledge of multiple associated loci from the primary genetics studies.

ALTERNATIVE GENETIC MODELS

The majority of genetic studies assume simple, additive models of effect, whether the variant is common or rare. On one hand this is typically a simplifying assumption of convenience made during analysis, although in practice it is often likely to be a reasonable one. Although there is little empirical evidence for *nonadditive* effects being a generally important component of

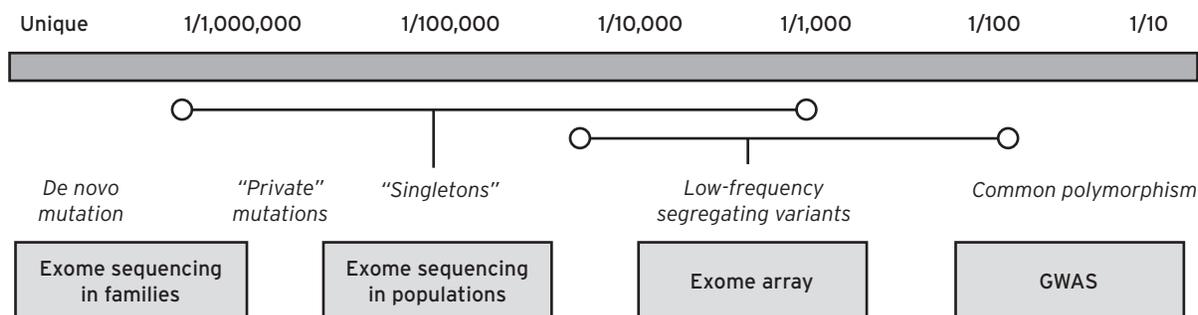

Figure 12.4 Summary of genetic study types targeting different intervals of the allelic frequency spectrum. The values along the horizontal bar indicate the minor allele frequency that is targeted by different genetic technologies, from common variation to sequencing for newly arising mutation.

the architecture of common disease, finding specific instances of such effects could be very informative. Examples of nonadditive effects include basic dominant/recessive (and compound heterozygote) models at a single locus and extended regions of homozygosity due to recent inbreeding unmasking rare recessive effects (Keller et al., 2012), interaction between genes (epistasis as reviewed by Cordell [2009]), and between genes and environments (Thomas, 2010), as well as sex-specific, imprinting, and parent-of-origin effects. Whether or not allowing for these more complex, potentially unbounded models will help to map disease genes is unclear, but in any case, intensive study of the growing number of genes already mapped by the additive models with respect to these alternate models (including pleiotropic effects on other phenotypes) has potential to be a great value.

SUMMARY

The tools available to the complex trait geneticist have evolved rapidly over the past decade. Consequently, psychiatric genetics has made considerable progress during the same time frame (Sullivan et al., 2012). Different genetic strategies, from studies of *de novo* variation in exome sequencing, large deletion and duplication copy number variants, and rare and low-frequency variants segregating in populations, to common polymorphisms are underway. It seems clear that all approaches will continue to bear fruit in the coming years, although the full promise of neuropsychiatric genetics is not yet achieved. In the (hopefully not too distant) future, the *interpretation* of multiple genetic associations in their biological context, rather than their initial discovery per se, will increasingly become the central challenge faced, but it will remain critically grounded on the initial gene discovery work going on today.

13 | THE BRAIN AND ITS EPIGENOME

AMANDA C. MITCHELL, YAN JIANG, CYRIL J. PETER,
KI A. GOOSENS, AND SCHAHRAM AKBARIAN

INTRODUCTION

Psychiatric disorders, including autism, mood and anxiety, or psychosis spectrum disorders, substance abuse, and addiction each lack a unifying molecular or cellular pathology, and most cases are believed to be of multifactorial etiology with numerous environmental and genetic components involved. This, taken together with the fact that laboratory animal models, including rats and mice, do not reflect the full complexities surrounding disorders of higher cognition and emotion (Nestler and Hyman, 2010), poses a formidable challenge to the quests of understanding the pathophysiology of disease and developing efficient therapies for the majority of patients. Consider that conventional psychopharmacology, including drugs targeting monoamine signaling, for example, dopaminergic, serotonergic, and noradrenergic pathways, elicits an insufficient therapeutic response in one half or less of patients diagnosed with schizophrenia and related illnesses (Lehman et al., 2004), or depression and anxiety (Krishnan and Nestler, 2010). Thus, it will be necessary to further explore the neurobiology and molecular pathology of mental disorders, in order to develop novel treatment strategies of higher efficacy.

One promising avenue of research that is moving center stage in basic and clinical neurosciences alike is *epi-* (Greek for “over,” “above”) genetics (Labrie et al., 2012). Not long ago *epigenetics* was mainly viewed through the prism of a single mark, DNA cytosine methylation, in the context of cell division related to, for example, embryonic development or cancer. This work might suggest that epigenetics bears little relevance for the postnatal and mature brain with its large proportion of postmitotic and differentiated cells. At least four independent lines of evidence fuel the current interest in neuroepigenetics, making it repeatedly a “hot topic” at recent annual conventions of neuroscientists and psychiatrists. First, based on human and animal brain studies, it is becoming increasingly clear that epigenetic markings, including DNA methylation and many types of histone modifications, remain “plastic” throughout all periods of development and aging, with ongoing dynamic regulation even in neurons and other differentiated cells. Changes in neuronal activity, learning, and memory, including the establishment of reward- and addiction-related behaviors, and numerous other paradigms all have been shown to be associated with DNA methylation and histone modification changes at specific genomic sequences in brain chromatin (Day and Sweatt, 2011; Robison and Nestler, 2011). These principal insights immediately

propelled epigenetics into the forefront of brain research, as it provides a molecular system operating at the genome–environment intersect, and obviously is a topic of interest deeply rooted in the concepts of modern psychology and the behavioral sciences. Second, recent work has revealed that each of the causative mutations in a subset of monogenetic neurological disorders (including but not limited to Rubinstein-Taybi, Kleeftstra, Rett, and other syndromes) disrupts the function of a protein involved in the regulation of chromatin structure and function (Haggarty and Tsai, 2011). These findings from clinical genetics indicated that the developing brain, indeed, is sensitive to dysregulation of the epigenetic machinery, and that some neurological conditions could arise from more widespread chromatin defects affecting the immature brain. Moreover, similar types of mutations were subsequently found in some cases with adult-onset psychosis or dementia, which implies that “chromatin disorders” encompass a much wider range of neuropsychiatric disease, contrasting the traditional view that they reflect “static” lesions confined to the developing nervous system (Jakocevski and Akbarian, 2012). Third, a subset of chromatin-modifying drugs—compounds with inhibitory activity directed against histone deacetylases are a well-known example—demonstrated a promising therapeutic potential in animal models for cognitive and emotional disease (Machado-Vieira et al., 2011), and even for neurodegenerative conditions (Fischer et al., 2010). Finally, even some of the most optimistic estimates on the role of protein-coding sequences as genetic risk factors for major psychiatric disease predict that only 25%–50% of sporadic cases of autism and schizophrenia carry disease-associated mutations altering protein sequence and function (O’Roak et al., 2011; Xu et al., 2011). Therefore, a subset of the remaining disease-associated variants are thought to involve regulatory and probably non-coding DNA, and by exploring the pattern and distribution of various epigenetic markings (which, in concert, define the functional architecture of chromatin, including open or silenced euchromatin, constitutive heterochromatin, etc.), one could expect to obtain important clues about the molecular pathology associated with the disease-related DNA variants (Houston et al., 2012). In the following, we will, after a concise introduction to the various markings and molecules that define a cell’s epigenome, touch upon each of four points raised in the preceding, and then finish this chapter with a brief discussion about how epigenetic technologies and discoveries could have a lasting impact on our understanding of the neurobiology and heritability of mental disorders.

THE EPIGENOME—GENERAL PRINCIPLES

The elementary unit of chromatin is the nucleosome, or 146 bp of genomic DNA wrapped around an octamer of core histones, connected by linker DNA and linker histones. The collective set of covalent DNA and histone modifications and variant histones provides the major building blocks for the “epigenome,” or the epigenetic landscapes that define the functional architecture of the genome, including its organization into many tens of thousands of transcriptional units, clusters of condensed chromatin, and other features that are differentially regulated in different cell types and developmental stages of the organism (Li and Reinberg, 2011; Rodriguez-Paredes and Esteller, 2011). An in-depth description of all epigenetic markings would be far beyond this review chapter, but multiple recent excellent reviews on this topic provide an excellent starting point for the reader interested to learn more about these topics (Ederveen et al., 2011; Kinney et al., 2011; Zhou et al., 2011). Here, we confine the discussion to a subset of the epigenetic markings repeatedly explored in the human and animal brain.

Common terminology used in chromatin studies includes (1) *nucleosomes*, comprised of a protein octamer of four small proteins, the *nucleosome core histones*, around which 146 bp of DNA is wrapped around. Transcription start sites are often defined by a nucleosome-free interval, probably for increased access of the transcriptional initiation complex and other regulators of gene expression. Arrays of nucleosomes,

connected by linker DNA and linker histones, comprise the 10-nm “beads-on-a-string” chromatin fiber; (2) *euchromatin* defines loose chromatin typically at sites of actively transcribed genes and units poised for transcription; (3) *heterochromatin* defines tightly packed nucleosomal arrays. Constitutive heterochromatin remains highly condensed in most interphase nuclei. Examples include pericentric and telomeric repeat DNA, the inactivated X chromosome (“Barr body”) of female somatic cells, and other chromosomal structures often found in close proximity to the nuclear envelope and also around the nucleolus (see Fig. 13.1). Facultative heterochromatin includes silenced genes that upon differentiation or other stimuli could switch to a state of active transcription.

DNA (HYDROXY)-METHYLATION

Two related but functionally very different types of DNA modifications, methylation (m) and hydroxymethylation (hm) of cytosines in CpG dinucleotides, provide the bulk of the epigenetic modifications in vertebrate DNA (Kriaucionis and Heintz, 2009). There are additional types of DNA modifications, which are mostly chemical intermediates in the context of mC5 and hmC5 (cytosines methylated at the carbon 5 position) synthesis and breakdown (He et al., 2011; Ito et al., 2011). While the majority of DNA (hydroxy)-methylation is found at sites of CpG dinucleotides and, more generally, in the CpG-enriched sequences of the genome, a recent study in rat cerebral cortex

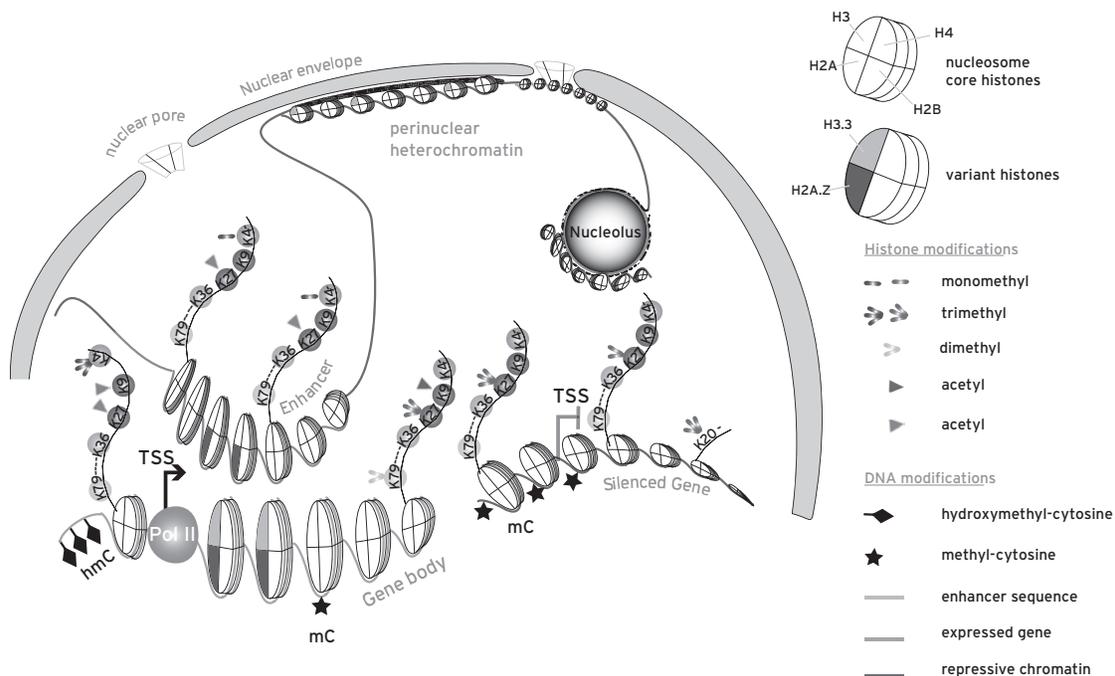

Figure 13.1 The epigenome, from nucleus to nucleosome. Schematic illustration of a gene poised for transcription by polymerase II (Pol II) initiation complex, with nucleosome-free interval at transcription start site (TSS). Distal enhancer sequence which in looplike structure moves in close proximity to active gene. Marks a small subset of heterochromatic portions of the genome, including silenced gene and heterochromatic structures bordering the nuclear envelope and pore complex, and also the nucleolar periphery. A small subset of representative histone variants and histone H3 site-specific lysine (K) residues at N-terminal tail (K4, K9, K27, K36, K79) and H4K20 residue are shown as indicated, together with panel of mono- and trimethyl, or acetyl modifications that differentiate between active promoters, transcribed gene bodies, and repressive chromatin, as indicated. DNA cytosines that are hydroxymethylated at the C5 position are mostly found at active promoters, while methylated cytosines are positioned within body of actively transcribed genes and around repressed promoters and in constitutive heterochromatin.

reported that the amount of mC5 found at nonCpG sites is far higher than previously assumed (Xie et al., 2012). The mC5 and hmC5 markings show a differential (but not mutually exclusive) pattern of genomic occupancy. The hmC5 mark is concentrated toward the 5' end of genes and the proximal-most portion of transcriptional units, and broadly correlates with local gene expression levels (Jin et al., 2011; Song et al., 2011). On the other hand, less than 3% of mC5 markings are positioned around the 5' end of genes (Maunakea et al., 2010). The classical concept on the transcriptional regulatory role of DNA methylation, which also has guided many brain-related studies, is that promoter-bound repressive chromatin remodeling complexes negatively regulate transcription (Sharma et al., 2005). There are many studies that report changes in promoter DNA methylation (mostly in conjunction with decreased gene expression) in preclinical models of psychosis, depression, and addiction, as well as in brain tissue in subjects diagnosed with one of these conditions. Interestingly, however, while the largest amount, or 97%, of mC5s are found in intra- and intergenic sequences and within DNA repeats (Maunakea et al., 2010), only few of these studies have explored brain DNA methylation changes at repeat DNA and other sequences outside of promoters.

The role of hmC5, however, in transcriptional regulation still remains controversial. Yi Zhang's group (Wu et al., 2011) performed genome-wide profile of 5hmC in both wild-type and Tet1-depleted mouse embryonic stem (ES) cells, and their data suggested that 5hmC is enriched at both gene bodies of actively transcribed genes and extended promoter regions of Polycomb-repressed developmental regulators. There is also evidence that besides TSSs, hmC5 is also enriched in enhancer region marked by H3K4me1 and H3K27ac in human embryonic stem cells (Stroud et al., 2011; Szulwach et al., 2011a). From a *Nature* paper published (Williams et al., 2011), it was reported that hmC5 was enriched by both TSSs and gene bodies, and its catalytic enzyme TET1 interacts with Sin3A corepressor complex and is involved in transcriptional repression of a significant portion of polycomb group target genes.

HISTONE MODIFICATIONS

The epigenetic regulation of chromatin by virtue of chemical histone modifications is even more complex than DNA methylation discussed previously, and it is now thought that there are far more than 100 amino acid residue-specific posttranslational modifications (PTMs) in a typical vertebrate cell (Tan et al., 2011), including mono (me1), di (me2)-, and tri (me3) methylation, acetylation, and crotonylation; polyADP-ribosylation and small protein (ubiquitin, SUMO) modification of specific lysine residues; and as arginine (R) methylation and "citrullination," serine (S) phosphorylation, tyrosine (T) hydroxylation, and several others (Kouzarides, 2007; Tan et al., 2011; Taverna et al., 2007). These site- and residue-specific PTMs are typically explored in the context of chromatin structure and function, with an epigenetic histone code (a combinatorial set of histone PTMs that differentiates between promoters, gene bodies, enhancer, and other regulatory sequences, condensed heterochromatin, and so on [Zhou et al., 2011]). For an

overview on the principle (but by far not an exhaustive illustration of all molecular markings defining the epigenome), see Figure 13.1. It is important to emphasize that histone PTMs rarely occur in isolation, and instead multiple histone PTMs appear to be coregulated and, as a group, define the aforementioned chromatin states (Berger, 2007). Many active promoters, for example, are defined by high levels of histone H3 lysine 4 methylation and various histone lysine acetylation markings (Zhou et al., 2011). Furthermore, there is also evidence for a coordinated and sequential regulation; phosphorylation of histone H3 at the serine (S)10 position often serves as a trigger for subsequent acetylation of neighboring lysine residues H3K9 and H3K14 in the context of transcriptional activation, while at the same time blocking repression-associated methylation of H3K9 (Nowak and Corces, 2004).

HISTONE VARIANTS

In addition to the core histones H2A/H2B/H3/H4, histone variants such as H3.3, H2A.Z, and H2A.X exist (Fig. 13.1). The role of these variant histones, which differ from the canonical histone only at very few amino acid positions, is often discussed in the context of replication-independent expression and assembly (Woodcock, 2006), and several histone variants robustly affect nucleosome stability and compaction (Jin and Felsenfeld, 2007). One popular model postulates that during the process of gene expression, RNA polymerase and the transcriptional activation and elongator complexes destabilize nucleosomes, which in turn promotes nucleosome remodeling and variant histone incorporation, which then further potentiate or stabilize gene expression (Bintu et al., 2011; Sutcliffe et al., 2009).

THE EPIGENOME IS PACKAGED INTO HIGHER ORDER CHROMATIN STRUCTURES

Epigenetic decoration of nucleosomes, including the DNA and histone modifications, and histone variants described previously, in itself, would fall short to adequately describe the epigenome, or even the localized chromatin architecture at any given (genomic) locus. This is because nucleosomal organization leads to only a 7-fold increase in packaging density of the genetic material, as compared with naked DNA; however, the actual level of compaction in the vertebrate nucleus in interphase (which defines the nucleus during the time period a cell is not dividing, including postmitotic cells such as neurons) is about three orders of magnitude higher (Belmont, 2006). The chromosomal arrangements in the interphase nucleus are not random, however. Specifically, loci at sites of active gene expression are more likely to be clustered together and positioned toward a central position within the nucleus, while heterochromatin and silenced loci move more toward the nuclear periphery (Cremer and Cremer, 2001; Duan et al., 2010). Chromatin loopings, in particular, are among the most highly regulated "supranucleosomal" structures and are associated with transcriptional regulation, by, for example, positioning distal regulatory enhancer or silencer elements that—in the linear genome—are positioned potentially many

hundred kilobases apart from a gene, to interact directly with that specific promoter (Gaszner and Felsenfeld, 2006; Wood et al., 2010). Despite the growing realization of the importance of these and other higher order chromatin structures for transcriptional regulation, this is an area where very little is known about regulation in the nervous system, let alone potential alterations in psychiatric disease. Until recently, there were only three studies in the literature that explored loop formations in brain tissue (Dhar et al., 2009; Horike et al., 2005; Jiang et al., 2010), with a few additional papers using the brain as negative control for their studies on the sensory epithelium of the nose (Lomvardas et al., 2006) or the hematopoietic system (Simonis et al., 2006). However, to date, nothing is known about chromatin loopings in human brain.

Three-dimensional chromatin architectures are commonly mapped using derivatives of chromosome conformation capture (3C). This technique was originally developed for simple eukaryote systems such as yeast (Dekker et al., 2002) but has been further advanced to include 4C, 5C, HiC, and ChIA-PET (Simonis et al., 2007), allowing the mapping of chromosomal architectures across many megabases, or in the case of HiC and ChIA-PET, even genome-wide. At its core, the technique explores physical interactions between DNA fragments separated by interspersed sequence (chromosome architecture *in cis*) or between sequences positioned in different chromosomes (interactions *in trans*). Cross-linked chromatin is digested with a specific restriction enzyme, religated and amplified using primer pairs for which forward and reverse primers match to different portions of the genomic locus of interest. It will be important to clarify in the nearby future whether the 3C technique and its derivatives are applicable to human postmortem brain tissue. If so, then the exploration of chromatin loopings in normal and diseased brain could potentially provide valuable insights about the chromosomal architectures surrounding any given locus, including potential aberrations in the context of disease-associated polymorphisms or DNA structural variants. Presently, the exploration of many regulatory sequences is simply not possible because they are, to put it simply, not “visible” in the linear genome sequence, because of their spatial separation from transcription start sites or annotated genes by many hundreds of kilobases, potentially. To highlight the potential use of chromosome conformation capture in the context of psychiatric disease, consider the example of the major histocompatibility complex (MHC) locus, which long has been implicated in psychiatric disease (Smeraldi et al., 1976), conferring significant genetic risk to schizophrenia and related disease as most recently shown in three large genome-wide association studies (GWASs) published jointly in 2009 (Purcell et al., 2009; Shi et al., 2009; Stefansson et al., 2009). These studies identified up to 45 disease-associated SNPs (single-nucleotide polymorphisms) in the 26–33 megabase region of the MHC loci on chromosome 6. Strikingly, 50% of these SNPs are not located near genes. In fact, the strongest SNP at rs13194053 ($p = 9.54 \times 10^{-9}$) is more than 29 kb away from its nearest gene, HIST1H2AH. A functional role for many intergenic regions would not be surprising since many intergenic regions alter expression of upstream and downstream genes (Kleinjan and van Heyningen, 2005), and the mechanistic workup of these

SNPs will certainly require application of chromosome conformation capture and related technologies.

CHROMATIN MARKINGS REMAIN PLASTIC THROUGHOUT THE LIFE SPAN OF THE HUMAN BRAIN, WITH IMPLICATIONS FOR THE NEUROBIOLOGY OF PSYCHIATRIC DISEASE

DEVELOPMENTAL PLASTICITY OF BRAIN EPIGENOMES

Most or perhaps all epigenetic markings studied to date, including DNA methylation, are now thought to be reversible and subject to bidirectional regulation in somatic tissues including brain, and there is no *a priori* reason for the unidirectional accumulation of a specific epigenetic mark while the brain is maturing and aging (Cheung et al., 2010; Guo et al., 2011; Klose and Zhang, 2007; Loenarz and Schofield, 2011; Miller and Sweatt, 2007; Ooi and Bestor, 2008). Nonetheless, multiple lines of evidence suggest that there is substantial reorganization of chromatin structures during the course of postnatal development and aging. Human cerebral cortex, for example, shows complex and gene-specific changes in the amount of methyl-cytosine (mC5; cytosines are methylated at the carbon 5 position). There is a fast rise in mC5 at many promoters during the transition from peri- to postnatal ages that continues at a slower pace into old age in conjunction with subtle changes (mostly a decline) in expression of transcripts originating from these promoters (Hernandez et al., 2011; Numata et al., 2012; Siegmund et al., 2007). Such age-related epigenetic drifts could impact vulnerability to neurodegenerative disease. A fascinating example has been recently reported for the cerebellum of the mouse, where levels of the mC5 derivative, hydroxymethyl-cytosine 5hmC, increase by 10-fold from postnatal Week 1 to adulthood (Szulwach et al., 2011b). Notably, among the genes that are affected by increasing 5hmC amounts at their promoters during cerebellar maturation, pathways for aging-related neurodegenerative diseases and angiogenesis were overrepresented and included at least 15 genes linked to hereditary forms of spinocerebellar ataxia, a neurological syndrome defined by severe motor dysfunction with the degeneration of cerebellar Purkinje neurons and other systems (Szulwach et al., 2011b). Also, of relevance, ten-eleven translocation (TET) proteins are responsible for converting mC5 to hmC5, and the active domains of these proteins belong to the same dioxygenase superfamily as hypoxia-inducible factor (HIF), an oxygen sensor that has been ascribed with a key role in angiogenesis and oxidative stress responses (Szulwach et al., 2011b). It will be extremely interesting to explore whether oxidation and other stress factors in the cellular environment, via TET-mediated regulation of DNA methylation levels, could leave a lasting imprint on chromatin structures in neurons or glia.

Like the aforementioned dynamic changes in DNA methylation during the course of development and aging, the epigenetic landscapes of histone modifications also undergo

substantial reorganization across the life span of the human brain. For example, histone methylation markings that differentiate between open and repressive chromatin surrounding NMDA receptor gene promoters show highly dynamic changes in cerebellar cortex during the transition from perinatal stages and infancy to adulthood (Stadler et al., 2005) that reflect, in part, development changes in levels of the corresponding gene transcripts (Akbarian et al., 1996). Furthermore, hundreds of loci undergo histone methylation changes in cortical neurons during the first few years of life (Cheung et al., 2010). The brains from mice that are prone to accelerated senescence (the SAMP8 line) and have learning and memory deficits show age-related drifts in histone PTMs: these epigenetic drifts are defined by a loss of the markings associated with active gene expression, such as histone H4 lysine 20 monomethyl (H4-K20me1) and H3-K36me3 (Fig. 13.1), in conjunction with a robust rise in the repressive mark, H3-K27me3 (Wang et al., 2010). The hippocampus of aged, 16-month-old wild-type mice shows deficits in acetylated histone H3-lysine 12 (H4K12) (Peleg et al., 2010), a histone PTM that is broadly correlated with the transcriptional elongation process (Hargreaves et al., 2009). In addition, drugs with histone deacetylase inhibitor (HDACi) activity induce upregulation of H4-K12ac dramatically and thereby could improve hippocampal-dependent learning and memory in aged mice (Peleg et al., 2010). It is possible that age-related drifts in brain epigenomes negatively affect neuronal (Fischer et al., 2010; Lu et al., 2004) and oligodendroglial (Copray et al., 2009) transcriptomes, thereby contributing to a decline in the signaling capacity of nerve cells, defects in axon myelination, and other molecular defects that have been linked to cognitive disorders of the adult brain, including those that like Alzheimer's disease are associated with neurodegeneration (Yankner et al., 2008) and others such as schizophrenia that are not accompanied by ongoing loss of nerve cells (Tang et al., 2009). Taken together, these findings leave little doubt that brain epigenomes are indeed subject to dynamic changes throughout all periods of maturation and aging, which may have important implications for the neurobiology of disease.

Posttraumatic stress disorder (PTSD) is probably a good example to illustrate how current concepts in epigenetics influence thoughts about pathophysiology of psychiatric disease. Obviously, from a heuristic perspective, it is very attractive to design working hypotheses that attribute a key role for epigenetic markings inside the nucleus of neurons and other brain cells subserving a memory function that, in response to an intense "environmental" influence (e.g., trauma), convey lasting alterations in a subject's emotional and physical health and resilience (Zovkic and Sweatt, 2012). Indeed, some recent studies in human subjects point to the promising potential of such types of working models. For example, a recent study on peripheral cells collected pre- and postdeployment from U.S. military service members identified global DNA methylation levels in repetitive DNA sequences, including LINE-1 and Alu repeat elements, as biomarkers that were significantly associated with resilience or, conversely, vulnerability to PTSD (Rusiecki et al., 2012). Similarly, studies in civilian/urban populations discovered that changes in blood DNA methylation signatures in PTSD subjects selectively affected cytokine and

steroid signaling, immune defense, and inflammation-related genes, consistent with various lines of evidence implicating some degree of peripheral immune dysregulation in this disorder (Smith et al., 2011; Uddin et al., 2010). Based on the aforementioned studies in blood, one would predict that brain chromatin, too, is involved in the neurobiology of PTSD, and human postmortem brain shows distinct DNA and histone methylation changes in amygdala and hippocampus, ventral striatum, and other anatomical structures with a critical role for emotion, affect, and memory (Zovkic and Sweatt, 2012). Indeed, there is excessive methylation of the glucocorticoid receptor gene promoter *NR3C1* and ribosomal DNA repeats in the hippocampus of adult suicide victims who also suffered childhood abuse (McGowan et al., 2008, 2009). Furthermore, the prefrontal cortex of suicide completers exhibits a shift from open to repressive chromatin-associated histone methylation for the *TRKB* neurotrophin high-affinity receptor, and for various genes regulating polyamine metabolism (Ernst et al., 2009; Fiori and Turecki, 2010). Furthermore, downregulated histone deacetylase 2 (HDAC2) expression in ventral striatum of subjects diagnosed with depression is thought to lead to an overall increase in histone H3 acetylation in this mesolimbic structure (Covington et al., 2009). In the aforementioned studies, many of these epigenetic changes are associated with decreased expression of the corresponding gene transcripts, which reaffirms the importance of epigenetic mechanisms and transcriptional regulation for the pathophysiology of psychiatric disease.

While postmortem brains of psychiatric disease cases are notoriously hampered by the fact that most subjects received psychoactive medication prior to death, some evidence from animal studies would suggest that at least a subset of the chromatin changes in diseased brain, as mentioned previously, are *not* mere epiphenomena due to medication or postmortem confounds such as tissue autolysis but, instead, closely associated with the disease process. To mention just two examples, the hippocampal glucocorticoid receptor gene *Nr3c1* shows excessive methylation not only in patients (McGowan et al., 2009), but also in adult rats brought up with suboptimal maternal care ("low licking" versus "high licking" mothers) (Weaver et al., 2004), and chronic social defeat stress in mice and rats elicits histone acetylation changes in ventral striatum and hippocampus very similar to those encountered in depressed human subjects (Covington et al., 2009; Hollis et al., 2010).

MONOGENETIC ETIOLOGIES OF NEUROPSYCHIATRIC DISEASE INCLUDES MUTATIONS IN PROTEINS INVOLVED IN READING, WRITING, OR ERASURE OF EPIGENETIC MARKINGS

There are many hundreds of genes that encode proteins that either write, erase, or read the molecular markings of the epigenome (Filippakopoulos et al., 2010; Janzen et al., 2010); however, we want to make the reader aware that some experts feel this type of terminology can be misleading, especially because the regulation of many epigenetic markings could turn out to

be only a “cog” in the chromatin-remodeling machinery but not a key driver (Henikoff and Shilatifard, 2011). The genome encodes three DNA methyltransferases, *DNMT1*, *DNMT3a*, and *DNMT3b*, that establish and maintain DNA methylation markings, and in addition, there are complex DNA demethylation pathways involving mC5 hydroxylation and oxidation via ten-eleven translocation dioxygenases, or activation-induced deaminase (AID)/APOBEC-mediated deamination of mC5 or hmC5, followed by base excision repair-mediated replacement with (unmethylated) cytosine (Bhutani et al., 2011; Guo et al., 2011). Furthermore, the collective set of histone methyltransferases (KMTs) and demethylases (KDMs) together could easily account for >100 genes in a mammalian genome, suggesting that the molecular framework to establish and erase histone methylation marks is likely to be extremely complex and probably differentially regulated across various cell types, or developmental stages, of the organism (Copeland et al., 2009; Rotili and Mai, 2011). Reader proteins, which bind to a specific epigenetic mark, are defined by their characteristic “reader module”; well-studied examples include the methyl-CpG binding domain (MBD) for mC5-DNA, the bromodomain for lysine acetylation, and “chromo,” “Tudor,” malignant brain tumor (“MBT”), “WD40repeat,” plant homeodomain (PHD) finger domains targeting methylated lysines or arginines in a residue-specific manner (Taverna et al., 2007). For the “open-chromatin” mark histone H3-trimethyl-lysine 4 (H3K4me3), these include many components of the RNA polymerase II-associated transcriptional initiation complex, while other marks such as H3K9me3 are primarily targeted by transcriptional repressors and regulators of chromatin condensation (Vermeulen et al., 2010).

The collective set of reader, writer, and eraser proteins includes at least 15 genes that are associated with monogenetic forms of neurodevelopmental or adult-onset neuropsychiatric disease (Jakocevski and Akbarian, 2012). While an exhaustive discussion of these various neurodevelopmental syndromes would be beyond the scope of this book chapter, it is important to point out that while chromatin defects in the brain were until very recently considered static lesions of early development that occurred in the context of rare genetic syndromes, it is now clear that mutations and maladaptations of the epigenetic machinery cover a much wider continuum, including adult-onset neurodegenerative disease. For example, while hypomorphic (partial loss-of-function) mutations in the DNA methyltransferase *DNMT3B* were already known to cause a multiorgan syndrome—Immunodeficiency, Centromere Instability, Facial anomalies (ICF 1)—that includes mental retardation and defective brain development (Hansen et al., 1999; Okano et al., 1999), it was only recently discovered that select mutations in DNA methyltransferase-coding regions, including *DNMT1*, are responsible for some cases of hereditary sensory and autonomic neuropathy, type 1 (HSAN1) (Klein et al., 2011), a rare neurodegenerative condition characterized by various neuropathies and early-onset dementia in the third or fourth decade of life. In other pedigrees, *DNMT1* mutations were linked to narcolepsy and late-onset deafness and cerebellar ataxia (Winkelmann et al., 2012). Likewise, structural variants in the X-linked gene *MECP2*, encoding the methyl-CpG-binding protein 2, not only

cause Rett syndrome (RTT), a disorder of early childhood with an incidence of 1 in 10,000 that is associated with cognitive deficits and a broad range of neurological symptoms (Amir et al., 1999; Chouery et al., 2011), but are also thought to be responsible for some cases of autism and schizophrenia with onset in childhood or adolescence (Piton et al., 2011). Furthermore, consider the DNA variants and mutations encompassing the *KMT1D* gene (9q34.3), encoding a histone H3-lysine 9 specific methyltransferase initially recognized as the causative gene responsible for a distinct neurodevelopmental and multiorgan syndrome, the Kleefstra mental retardation syndrome (Kleefstra et al., 2009). Meanwhile, however, *KMT1D* mutations are also responsible for some cases with schizophrenia (Kirov et al., 2012), and various nonspecific psychiatric phenotypes and even neurodegenerative disease in the postadolescence period (Verhoeven et al., 2011).

Taken together, these findings leave little doubt that mutations that fall within the coding sequence or otherwise affect levels of expression of a select set of regulatory proteins involved in DNA or histone methylation could cause neuropsychiatric disease even after brain development has largely been completed, including some cases diagnosed with psychosis or early-onset dementia. One could speculate that *DNMT1*, *MECP2*, *KMT1D*, and other monogenetic causes of neuropsychiatric disease (Jakocevski and Akbarian, 2012) could then also play a wider role in the pathophysiology of autism, schizophrenia, and other illnesses, outside of what has been discussed—and among the overall population of psychiatric patients very rarely occurring—cases with mutations and deletions of these chromatin regulatory proteins. For example, a recent post-mortem study on 16 cases on the autism spectrum, exploring genome-wide occupancies of histone H3-tri-methyl-lysine 4 (H3K4me3), a mark sharply upregulated at transcription start sites (see Fig. 13.1) in prefrontal neurons, reported an abnormally broad histone methylation profile (“spreading”) at the 5′ end of many hundreds or thousands of genes for four of their cases, while the remaining twelve cases showed much more limited alterations at a few loci only (Shulha et al., 2012). While purely speculative at this point, it remains possible that these subsets of autism cases with an apparently more generalized abnormality in prefrontal histone methylation profiles are affected by defects in the pathways governing the writing, reading, or erasure of H3K4me3 and related markings. These may include pathways that are critical for the orderly activity of *KDM5C/SMCX/JARID1C*, the X-linked H3K4-specific histone demethylase that is also responsible for some cases of mental retardation, autism, and other neurodevelopmental disease, or the H3K4 methyltransferase *MLL1* previously implicated in the neurobiology of schizophrenia (Adegbola et al., 2008; Akbarian and Huang, 2009; Huang et al., 2007; Iwase et al., 2007).

“EPIGENETIC DRUG” DEVELOPMENT IN PSYCHIATRY—READY FOR PRIME TIME?

While most major psychiatric disorders, including the broader range of autism, mood, or psychosis spectrum disorders, each lack a unifying neuropathology, the pathophysiology almost

certainly involves dysregulated gene expression in cerebral cortex and other brain regions. Starting with the initial reports on gene expression changes in prefrontal cortex and hippocampus of subjects diagnosed with schizophrenia, a large number of postmortem brain studies have been published, collectively suggesting that distinct sets of gene transcripts are frequently, albeit never consistently, expressed at altered levels in at least a subset of psychiatric disease cases, when compared with control brain cohorts. Well-known examples, as they pertain to schizophrenia or mood disorder, involve transcripts for GABAergic inhibitory signaling, or myelination and other oligodendrocyte-specific function, and in some studies more generalized transcriptome changes compromising metabolic activities, as well as many markers of pre- and postsynaptic neurotransmission (Akbarian and Huang, 2006; Aston et al., 2004; Benes, 2010; Charych et al., 2009; Dracheva et al., 2004; Duncan et al., 2010; Guidotti et al., 2005; Hakak et al., 2001; Hashimoto et al., 2008; Katsel et al., 2005; Martins-de-Souza et al., 2009; Regenold et al., 2007; Sibille et al., 2009; Tkachev et al., 2003; Woo et al., 2008).

Therefore, drugs that interfere with chromatin-bound proteins involved in transcriptional regulation could be of interest both to preclinical researchers interested in modeling the aforementioned gene expression deficits in the animal, as well as to groups in academia or industry that are interested in exploring novel psychopharmacologic treatments. In this context, it is worth mentioning that sodium valproate, one of the most frequently prescribed drugs in neurology and psychiatry largely due to its anticonvulsive and mood-stabilizing properties, is a weak but broadly acting inhibitor of histone deacetylase enzymes (HDAC) (Guidotti et al., 2011). Histone acetylation is viewed as a facilitative signal for transcription, while HDAC cleaves off the acetyl groups from the histone lysine residues and is commonly associated with repressive chromatin remodeling (Sharma et al., 2006). Thus, HDAC inhibitors (HDACi) are thought to upregulate gene expression at some loci, by shifting the balance toward acetylation (of promoter-bound histones). For example, it has been suggested that valproate-induced histone hyperacetylation may exert some of its therapeutic effects via transcriptional upregulation at “GABAergic” and other neuronal genes (Guidotti et al., 2011). In animal experiments, histone deacetylase inhibitors improve learning and memory function in a variety of paradigms, including at advanced age and also in mice with mutation in Creb-binding protein, CBP (which is mutated in subjects with Rubinstein-Taybi syndrome). Other preclinical work strongly suggests that HDACi may exert therapeutic effects in depression and related psychiatric illnesses (Covington et al., 2009; Morris et al., 2010; Schroeder et al., 2007). Whether HDACi’s would emerge in the future, indeed, as novel psychopharmacologic treatment options for the treatment of psychiatric disorders is not yet clear. However, it is the broad therapeutic potential of HDACi in the animal model, which goes far beyond the aforementioned psychiatric conditions and includes acute and chronic neurodegenerative disease including acute brain injury and stroke, as well as Parkinson’s, Alzheimer’s, and Lou Gehrig’s (motor neuron) disease, and various triplet repeat disorders including Huntington’s chorea and spinocerebellar

ataxia (Baltan et al., 2011; Chuang et al., 2009; Fischer et al., 2010; Tsou et al., 2009).

Similar to the HDACi previously mentioned, there is some evidence for the therapeutic potential of drugs affecting histone methylation, but it remains unclear whether these findings would in the future bear fruit and lead to novel psychiatric treatment options. Of interest are small molecules such as BIX-01294, which inhibit a select set of histone methyltransferases (HMTs), including histone H3K9-specific HMT G9a/Glp (Kubicek et al., 2007). The H3K9 methylation mark, particularly the di- and trimethylated forms, are associated with repression and negative regulation of transcription, and consequently, expression of some genes in brains is increased after exposure to BIX-01294 (Kubicek et al., 2007). Behavioral changes after BIX-01294 have been reported as well, including increased reward and addiction behavior in the context of cocaine and other stimulant exposure (Maze et al., 2010). The drug’s mechanism of action could, at least in part, involve the inhibition of G9a/Glp-mediated repressive chromatin remodeling at the promoters of *Bdnf*, *Cdk5*, *Arc*, and other genes, which then in turn could lead to increased spine density and synaptic connectivity (Maze et al., 2010). Like the histone-modifying drugs previously discussed, several structurally unrelated DNA methylation inhibitors, including cytidine analogues 5-azacytidine or compounds such as *N*-phthalyl-L-tryptophan/RG108, when administered directly into brain tissue of mice and rats, alter synaptic plasticity and hippocampal learning and memory and are thereby associated with powerful modulation of reward- and addiction-related behavior (Han et al., 2010; LaPlant et al., 2010; Levenson et al., 2006; Lubin et al., 2008; Miller et al., 2010; Miller and Sweatt, 2007). Whatever the underlying mechanism of action, we predict that, as in cancer treatment and other areas of medicine where presently worldwide hundreds of clinical trials involve epigenetic drug targets, in psychiatry, too, the therapeutic potential of chromatin-modifying drugs will soon be tested on a broader basis, given the plethora of promising findings that are currently emerging from preclinical and translational research.

EPIGENETICS AS A TOOL TO EXPLORE DISEASE-ASSOCIATED DNA STRUCTURAL VARIANTS AND POLYMORPHISMS OUTSIDE OF PROTEIN-CODING SEQUENCES

As already discussed, a significant portion of (psychiatric) disease-associated mutations and polymorphisms are thought to cause functional changes other than alterations in protein-coding sequence. This poses a potential challenge, as the functional role of the “normal” DNA sequence and the (disease-related) structural variants may be hard to discern by sequence analyses alone. To provide the reader with an illustrative example of the challenging tasks that lie ahead for psychiatric (epi)genetics, consider the example of the major histocompatibility complex locus, which long has been implicated in mental illness, conferring significant genetic

risk for schizophrenia and related diseases as most recently shown in three large genome-wide association studies published jointly in 2009 (Purcell et al., 2009; Shi et al., 2009; Stefansson et al., 2009). Intergenic disease-associated SNPs identified in the MHC region of chromosome 6 may interact via proteins with functional regions of the genome. Indeed, when open chromatin-associated histone methylation markings, including the H3K4 tri- and mono-methyl mark, and the genomic occupancy pattern of the transcription factor (and potential barrier protein preventing the uncontrolled spread of heterochromatin), CTCF (CCCTC-binding factor), was profiled in neuronal chromatin from human prefrontal cortex and in peripheral cell lines, it became apparent that several schizophrenia-associated SNPs are highly enriched with one or several of these markings (Fig. 13.2). Because the H3K4 tri- and mono-methyl markings are often associated with transcriptional regulation, including promoter- and enhancer-like functions, one could speculate that the risk alleles are probably interfering with local transcription. While this is purely speculative at this point in time, the preceding example illustrates how the study of epigenetic markings bears the potential to provide important clues on the role of otherwise poorly characterized DNA sequences outside of coding regions.

Obviously, the study of chromatin structures could also provide important information for DNA sequences for which a functional role is already known, such as an annotated promoter. One of the best-known examples involves the fragile X mental retardation (*FMRI*) gene in fragile X mental retardation syndrome, where the abnormal expansion of a CGG codon from (normally) 5–40 repeats from 50 to over 200 triggers excessive promoter DNA methylation, effectively shutting down gene expression by silencing the surrounding chromatin (Oberle et al., 1991). This is true even for genes with a much

more subtle contribution to disease risk, such as *GAD1* encoding glutamic acid decarboxylase (67kDa) GABA synthesis enzyme, for which some haplotypes and polymorphisms, positioned within a few Kb from the *GAD1* transcription start site, confer genetic risk for accelerated loss of frontal lobe gray matter (Addington et al., 2005; Straub et al., 2007) and, via epistatic interaction with catechol-o-methyltransferase (*COMT*) alleles, regulate synaptic dopamine and modulate overall GABA tissue levels in the prefrontal cortex (Marenco et al., 2010). The same genetic variants surrounding the *GAD1* promoter recently emerged as a major driver for the disease-related decline in *GAD67* transcript and the epigenetic decoration of the proximal *GAD1* promoter in subjects with schizophrenia, including the balance between “open” and “repressive” histone methylation markings histone H3 trimethyl-lysines, K4me3 and K27me3 (Huang et al., 2007). These findings, taken together, clearly illustrate the potential of epigenetic approaches to shed light on the functional impact of structural variants involving regulatory, noncoding DNA, both for rare mutations with high disease risk/penetrance (e.g., *FMRI* in fragile X) or for common variants that make only much smaller contribution to the overall disease risk (e.g., *GAD1* in schizophrenia).

SYNOPSIS AND OUTLOOK

“Neuroepigenetics” is a new discipline (Day and Sweatt, 2010) that presently takes center stage in the field of mental health research, mainly because: (1) Recent findings suggest that the epigenetic landscapes of the human brain remain “plastic” throughout all periods of brain development and aging, with ongoing dynamic regulation occurring even in neurons and other postmitotic constituents (Cheung et al., 2010; Hernandez et al., 2011; Numata et al., 2012; Siegmund et al., 2007). (2) The

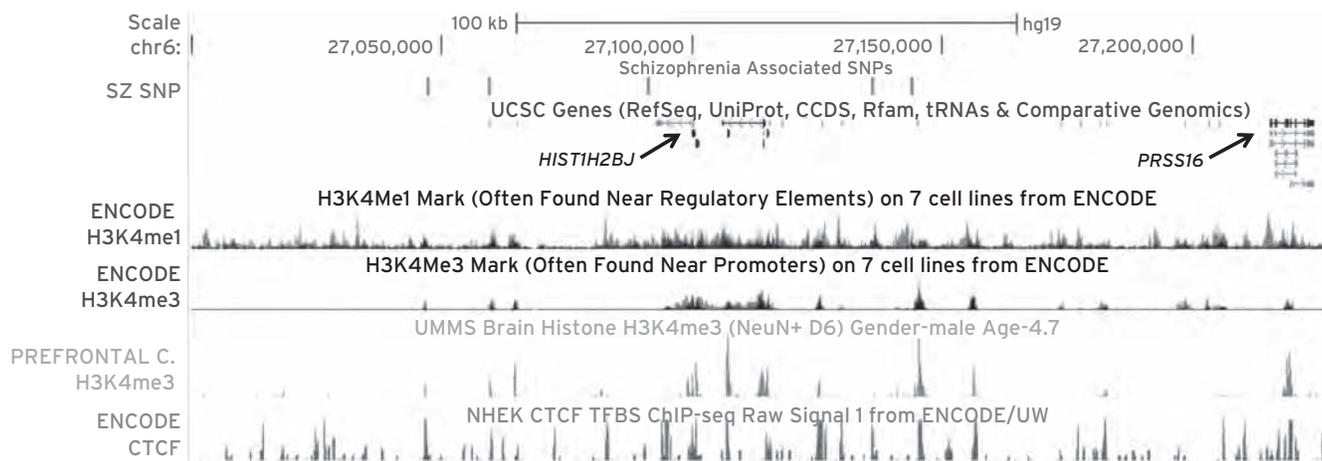

Figure 13.2 Epigenetic profiles encompassing the MHC region on chromosome 6, which harbors strong linkage disequilibrium ($r^2 = 0.52\text{--}0.77$) of five schizophrenia single-nucleotide polymorphisms (SNPs) in the major histocompatibility complex (MHC) region (27,000,000–27,300,000) (Purcell et al., 2009; Stefansson et al., 2009). The most significant SNP rs6913660 is located greater than 50 kb from the nearest gene (*HIST1H2BJ*). The chr 6:27,000,000–27,300,000 region on the UCSC genome browser is shown with six tracks represented: (i) five schizophrenia-associated SNPs in linkage disequilibrium in the following order: rs926300, rs6913660, rs13219181, and rs1319453; (ii) UCSC genes; (iii) histone 3 lysine 4 monomethylation (H3K4me1) marks on seven cells from ENCODE; (iv) histone 3 lysine 4 trimethylation (H3K4me3) marks on seven cell lines from ENCODE; (v) H3K4me3 marks from prefrontal cortex neuron in a 4.7-year-old boy; and (vi) CTCF ChIP-seq data from the NHEK cell line. Notice that several schizophrenia-associated SNPs are found within H3K4me1, H3K4me3, and CTCF peak sequences, indicating possible physical interactions between these various chromatin fragments.

range of neurological conditions due to a primary chromatin defect extends far beyond the early developmental period and may even include a subset of cases with adult-onset psychosis, or dementia and other neurodegenerative disease (Klein et al., 2011; Winkelmann et al., 2012). (3) Chromatin-modifying drugs could lead to novel treatments for neurological and psychiatric disease (Baltan et al., 2011; Chuang et al., 2009; Fischer et al., 2010; Peter and Akbarian, 2011; Tsou et al., 2009). (4) Exploration of chromatin structures could be expected to uncover, in a substantial portion of cases, the functional impact of disease-relevant mutations in regulatory and other sequences that are otherwise difficult to “capture” by DNA sequence analyses alone. Indeed, the important role of epigenetically regulated noncoding DNA was ascertained by recent bioinformatical studies showing that many noncoding DNA sequences are generally deficient of SNP and undergo a purifying selection (Tolstorukov et al., 2011).

Finally, it is worth mentioning that, based on next-generation sequencing of epigenetic markings in sperm, perhaps as much as 4% of the human genome could maintain nucleosomal organization and many types of epigenetic decoration when transmitted through the germline. This includes many loci considered of critical importance for early pre- and postimplantation development, imprinted gene clusters, microRNA clusters, homeobox (HOX) gene clusters, and the promoters of many stand-alone developmental transcription and signaling factors (Hammoud et al., 2010). These and related findings will most certainly further stimulate research aimed at uncovering evidence for epigenetic heritability of psychiatric disease, including depression, schizophrenia, and addiction, to name a few, which all have in common that for a majority of subjects no straightforward genetic risk architecture has been identified.

Without doubt, psychiatric epigenetics will remain a most productive area of research for many years to come.

14 | NETWORK METHODS FOR ELUCIDATING THE COMPLEXITY OF COMMON HUMAN DISEASES

ERIC E. SCHADT

INTRODUCTION

Our understanding of common human diseases and how best to treat them are hampered by the complexity of the human system in which they are manifested. Unlike simple Mendelian disorders in which highly expressive, highly penetrant mutations make it possible to identify the causal genes within families, segregating traits associated with the disorders (Mulvihill, 1999), common human diseases originate from a more complex interplay between constellations of changes in DNA (both rare and common variation) and a broad range of environmental factors like diet, age, sex, and exposure to environmental toxins.

With roughly 3 billion nucleotides making up the human genome, the number of nucleotide changes that can affect the activities of a moderate to large number of genes is effectively infinite with respect to our ability to experimentally determine the effects of combinations of such changes. Whereas the focus in years past regarding DNA variation and its association to disease had been focused on protein-coding sequences, given declarations of intergenic DNA being comprised mainly of “junk” (Smith et al., 1972), today we know that greater than 80% of the human genome is actively bound by proteins that regulate the expression of genes (Ecker et al., 2012), providing a vast array of knobs and switches to modulate not only the activity of genes, but also of whole gene networks. Therefore, leveraging naturally occurring DNA variation in human populations can be considered among the most attractive approaches to inferring the constellation of genes that affect disease risk. For most noncancer human diseases like Alzheimer’s disease, autism, and schizophrenia, changes in DNA that correlate with changes in disease can be inferred as tagging or directly representing causal components of disease. In this way, the DNA variation directly elucidates disease etiology and so is extremely useful. Genome-wide association studies (GWAS) are now well proven to uncover genetic loci that affect disease risk or disease progression (Stranger et al., 2011).

The complex array of interacting factors does not influence the activity of single genes in isolation but, instead, affects entire network states that, in turn, increase or decrease the risk of disease or affect disease severity. In the context of common human diseases, the disease states can be considered as emergent properties of molecular networks (Chen et al., 2008), as opposed to responses to changes in a small number of genes

driving core biological processes associated with the disease. Integrating large-scale, high-dimensional molecular and physiological data holds promise in not only defining the molecular networks that directly respond to genetic and environmental perturbations that associate with disease, but also in causally associating such networks with the physiological states associated with disease.

Of course, genetics is but one dimension in a big sea of data dimensions that we can now leverage to better understand human conditions such as psychiatric disorders. Models of disease that consider a greater diversity of data that inform on disease will necessarily deliver more accurate diagnoses. In fact, we are in the midst of a big data revolution that permeates nearly every aspect of our lives. Electronic devices that consume much of our attention on a daily basis enable rapid transactions among individuals on unprecedented scales, where all of the information involved in these daily transactions can be seamlessly stored in digital form, whether the transactions involve monitoring of activity levels using Fitbit-like devices, cell phone calls, text messages, credit card purchases, e-mail, or visits to the doctor’s office in which all tests carried out are digitized and entered into your electronic medical record (Fig. 14.1). The digital universe more generally now far exceeds one zettabyte (i.e., 21 zeros or one billion terabytes—think 63 billion 16 gigabyte iPhones). Thus, our ability to store and access unimaginable scales of data has been revolutionized by technological innovations that are often observed to operate at super Moore’s law rates.

The life and biomedical sciences have not stood on the sidelines of this revolution. There has been an incredible wave of new technologies in genomics—such as next-generation sequencing technologies (Eid et al., 2009), sophisticated imaging systems, and mass spectrometry-based flow cytometry (Bandura et al., 2009)—enabling data to be generated at very large scales. As a result we can monitor the expression of tens of thousands of protein- and noncoding genes simultaneously (Chen et al., 2008; Emilsson et al., 2008), score hundreds of thousands of SNPs (single-nucleotide polymorphisms) in individual samples (Sklar et al., 2011; Stranger et al., 2011), sequence entire human genomes now for less than \$5,000 (Drmanac et al., 2012), and relate all of these data patterns to a great diversity of other biologically relevant information (clinical data, biochemical data, social networking data, etc.). Given technologies on the horizon like the IBM DNA transistor with theoretical sequencing limits in the hundreds of millions of

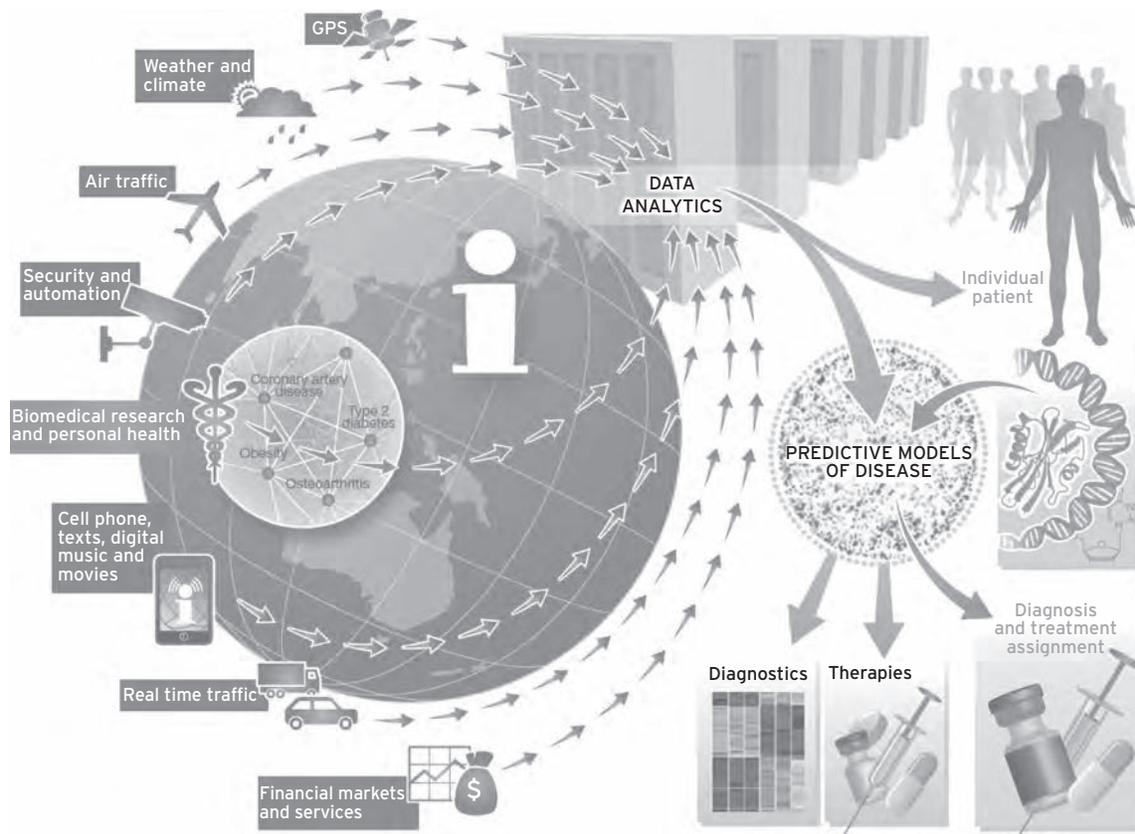

Figure 14.1 Big data is all around us, enabled by technological advances in micro- and nanoelectronics, nano materials, interconnectivity provided by sophisticated telecommunication infrastructure, massive network-attached storage capabilities, and commodity-based high-performance computing infrastructures. The ability to store all credit card transactions, all cell phone traffic, all e-mail traffic, video from extensive networks of surveillance devices, and satellite and ground sensing data informing on all aspects of the weather and overall climate, and to now generate and store massive data informing on our personal health including whole-genome sequencing data and extensive imaging data, is driving a revolution in high-end data analytics to make sense of the big data, and drive more accurate descriptive and predictive models that inform decision making on every level, whether identifying the next big security threat or making the best diagnosis and treatment choice for a given patient.

bases per second per transistor (imagine millions of these transistors packed together in a single handheld device) (Schadt et al., 2010), we would not be talking in the future about Google rolling through neighborhoods with Wi-Fi-sniffing equipment (Kravets, 2010), but rather, we'll be talking about DNA-sniffing equipment rolling through neighborhoods sequencing everything they encounter in real time and then pumping such data into big data clouds to link with all other available information in the digital universe.

If we want to achieve understanding from big data, organize it, compute on it, and build predictive models from it, then we must employ statistical reasoning beyond the more classic hypothesis testing of yesteryear. We have moved well beyond the idea that we can simply repeat experiments to validate findings generated in populations. In fact, while first instances of the central dogma of biology looked something like the simple graph depicted in Figure 14.2 (top), today, given that the complex interplay of multiple dimensions of data (DNA, RNA, protein, metabolite, cellular, physiologic, ecologic, and social structures more generally) demands a more holistic view be taken in which we embrace complexity in its entirety, the central dogma is evolving to look something more like the graph depicted in Figure 14.2 (bottom). Our emerging view

of complex biological systems is one of a dynamic, fluid system that is able to reconfigure itself as conditions demand (Barabasi and Oltvai, 2004; Han et al., 2004; Luscombe et al., 2004; Pinto et al., 2004; Zerhouni, 2003). Despite these transformative advances in technology and the need to embrace complexity, it remains difficult to assess where we are with respect to our understanding of living systems, relative to a complete comprehension of such systems. One of the primary difficulties in our making such an assessment is that the suite of research tools available to us seldom provides insights into aspects of the overall picture of the system that are not directly measured.

In this chapter I discuss a particular class of modeling approaches that integrate diverse types of data on broad scales, in ways that enable others to interpret their data in a more holistic, informative context, to derive predictions that inform decision making on multiple levels, whether deciding on the next set of genes to validate experimentally or the best treatment for a given individual, given detailed molecular and higher order data on their condition. Central to these models will be inferring causality among molecular traits and between molecular and higher order traits by leveraging DNA as a systematic source of perturbation. In contrast to the more

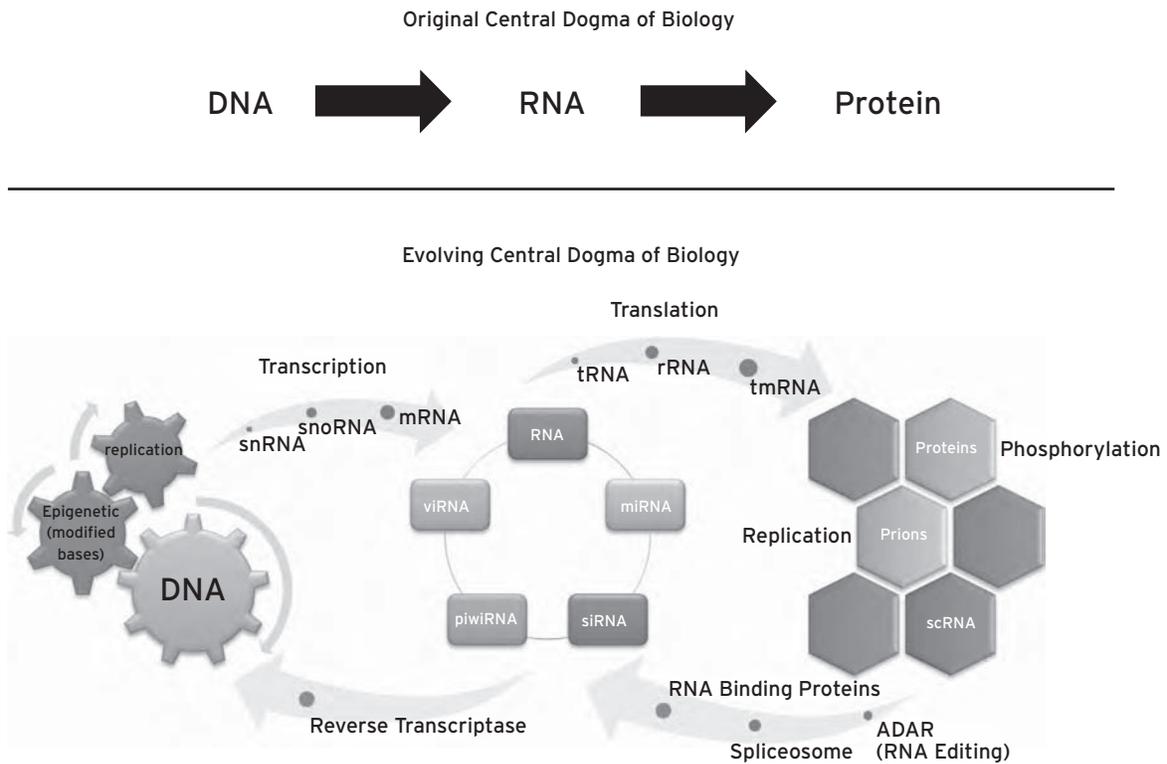

Figure 14.2 The evolving central dogma of biology. The upper panel represents the original central dogma of biology, a simple view driven by early observations with low-resolution tools that uncovered a central relationship between DNA, RNA, and proteins, namely, that RNA is transcribed from DNA, and RNA, in turn, is translated into proteins. New higher resolution technologies have enabled a far more complex view of the central dogma to emerge (bottom panel), with epigenetic changes to DNA that are transgenerational, leading to non-Mendelian patterns of inheritance, a complex array of RNA molecules such as microRNA, viRNA, piwiRNA, and siRNA that do not code for proteins but carry out complex regulatory functions, and sophisticated protein complexes involved in splicing, RNA editing, and RNA binding all feeding back on transcription, leading to a more network-oriented view of the central dogma.

qualitative approaches biological researchers have employed in the past, getting the most from these new types of high-dimensional, large-scale data requires constructing more complex, predictive models from them, refining the ability of such models to assess disease risk, progression, and best treatment strategies, and ultimately translating these complex models into a clinical setting where doctors can employ them as tools to understand most optimally your current condition and how best to improve it. Such solutions require a robust engineering approach, where integrating the new breed of large-scale datasets streaming out of the biological sciences and constructing predictive models from them will require approaches more akin to those employed by physicists, climatologists, and other strongly quantitative disciplines that have mastered the collection and predictive modeling of high-dimensional data.

THE MANY MOVING PIECES OF BIOLOGICAL SYSTEMS: A MOVIE ANALOGY

Tools to interrogate biological systems in the past were crude and did not permit the more holistic querying of such systems at multiple scales. In fact, if we were to view the full suite of interacting parts in living systems, from the molecular on up to

the ecological levels, we would achieve a more complete understanding of the cellular-, organ-, and organism-level processes that underlie complex phenotypes such as disease, much in the same way we achieve understanding by watching a movie. The continuous flow of information in a movie enables our minds to exercise an array of priors that provide the appropriate context and that constrain the possible relationships (structures) not only within a given frame or scene, but also over the entire course of the movie. As our senses take in all of the streaming audio and visual information, our internal network reconstruction engine (centered at the brain) pieces the information together to represent highly complex and nonlinear relationships depicted in the movie, so that in the end we are able to achieve an understanding of what the movie intends to convey at a hierarchy of levels.

What if we were to view a movie as we have viewed biological systems in the past? What if instead of viewing a movie as a continuous stream of frames of coherent pixels and sound, we viewed single dimensions of these data, and we viewed them independently from one another? Understanding in this case would likely be difficult, if not impossible, to achieve. As an example, consider a 2-hour feature length film comprised of 216,000 frames (30 frames per second), where each frame is comprised of $1,280 \times 720$ pixels (roughly one million pixels). First, it is worth noting that the number of pixels of information, roughly 199 billion, represented in this film is quite large

(if each pixel were represented by 32 bits, the film would comprise more than 6 terabytes of information). Suppose we decided to use the tools of reductionist biology to view the film, where instead of viewing the film as a rapid succession of frames of one million pixels each, we viewed a single frame in which the intensity value for each pixel across all 216,000 frames in the movie was averaged. This gross, aggregate average would provide very little, if any, information regarding the movie, not unlike our attempts to understand complex living systems by examining single snapshots of a subset of molecular traits in a single cell type and in a single context at a single point in time. Even if we viewed our movie as independent, one-dimensional slices through its frames, where each slice was viewed as pixel intensities across that one dimension changing over time (like a dynamic mass spectrometry trace), this view would provide significantly more information, but it would still be very difficult to understand the meaning of the movie by looking at all of the one-dimensional traces independently, unless more sophisticated mathematical algorithms were employed to link the information together.

Despite the complexity of biological systems, even at the cellular level, research in the context of large-scale, high-dimensional omics data has tended to focus on single data dimensions, whether constructing coexpression networks based on gene expression data, carrying out genome-wide association analyses based on DNA variation information, or constructing protein interaction networks based on protein-protein interaction data. While we achieve some understanding in this way, progress is limited because none of the dimensions on their own provide a complete enough context within which to interpret results fully. This type of limitation has become apparent in genome-wide association studies or whole-exome or genome-sequencing studies, where thousands of highly replicated loci have been identified and highly replicated as associated with disease, but our understanding of disease is still limited because the genetic loci do not necessarily inform on the gene affected, on how gene function is altered, or more generally, how the biological processes involving a given gene are altered at particular points of time or in particular contexts (Altshuler et al., 2008; Chen et al., 2008; Emilsson et al., 2008; Witte, 2010). It is apparent that if different biological data dimensions could be formally considered simultaneously, we would achieve a more complete understanding of biological systems (Chen et al., 2008; Emilsson et al., 2008; Hsu et al., 2010; Schadt et al., 2008; Zhong et al., 2010). (See the documentary film *The New Biology* at <http://www.youtube.com/watch?v=sjTQD6E3IH4>.)

To form a more complete understanding of complex human diseases like psychiatric disorders, we must not only evolve technologies to sample systems at ever higher rates and with ever greater breadth, but we must also innovate methods that consider many different dimensions of information to produce more descriptive models (movies) of the system. There are, of course, many different types of modeling approaches that have been and continue to be explored. Descriptive models quantify relationships among variables in data that can, in turn, enable classification of systems under study into different meaningful

groups; whether stratifying disease populations into disease subtypes to assign patients to the most appropriate treatment, or categorizing customers by product preference, descriptive models are useful for classifying but cannot necessarily be used to predict how any given variable will respond to another at the individual level. For example, while patterns of gene expression such as those identified for breast cancer and now in play at companies like Genomic Health can very well distinguish good from poor prognoses (van 't Veer et al., 2002; van de Vijver et al., 2002), such models are not generally as useful for understanding how genes in patterns associated with disease are causally related or distinguishing key driver genes from passenger genes.

Predictive models, on the other hand, incorporate historic and current data to predict how one variable may respond to another in a particular context or predict response or future states of components of a system at the individual level. In the biological context, predictive models aim to accurately predict (*in silico*—using the model to run simulations on a computer) molecule expression-level changes, cell state dynamics, and phenotype transitions in response to specific perturbation events. For example, understanding how the constellation of genes identified for diseases like schizophrenia or autism (Neale et al., 2012; Ripke et al., 2011) are actually related to one another in probabilistic causal ways can lead to an understanding of how perturbing a given gene (say, for treatment) will impact the corresponding molecular networks and ultimately the pathophysiology of the diseases they impact. Key to constructing predictive models is elucidating causal relationships between traits of interest. Resolving causal relationships requires a systematic source of perturbation, and here I discuss the use of DNA variation as a systematic perturbation source to infer causal relationships among molecular traits and between molecular traits and higher order traits like disease (Chen et al., 2008; Emilsson et al., 2008; Mehrabian et al., 2005; Millstein et al., 2009; Schadt et al., 2005; Yang et al., 2009; Zhu et al., 2004; Zhu et al., 2012; Zhu et al., 2008).

CAUSALITY AS A STATISTICAL INFERENCE

In the life sciences, most researchers are accustomed to thinking about causality from the standpoint of physical interactions. In the molecular biology or biochemistry setting, when two molecular traits are indicated as causally related, we typically mean that one of the molecular entities (e.g., a small molecule compound) has been determined experimentally to physically interact with or to induce processes that directly affect the other molecular entity (e.g., the target protein of the small molecule) and consequently leads to a phenotypic change of interest (e.g., lower LDL cholesterol levels). In this case we have an understanding of the causal factors relevant to the activity of interest, so that careful experimental manipulation of these factors allows for the identification of genuine causal relationships. However, in the context of many thousands of variables related in unknown ways, the aim is to examine the behavior of those variables across populations in

ways that facilitate statistically inferring causal relationships. For example, statistical associations between changes in DNA, changes in molecular phenotypes, and changes in higher order phenotypes like functional MRI readouts or disease can be examined for patterns of conditional dependency among the variables that allow directionality to be inferred among them. In this case we can employ indirect measures of processes that mediate changes in one trait conditional on another to make a statistically inferred causal link. This is not unlike the types of statistical inferences that are leveraged in other disciplines to make new discoveries. For example, less than 5% of known extrasolar planets have been directly observed, so that most are observed indirectly. One method for detecting planets that cannot be directly observed considers that when a planet is orbiting a star, the gravitational pull of the planet on the star will place the star into a subtle orbit, which from our vantage point will appear as the star moving closer to and further away from the Earth in a cyclical fashion. Such movement can be measured as displacements in the star's spectral lines due to the Doppler effect (Erskine et al., 2005), and so the presence of the planet acting on the star can be statistically inferred.

Similarly, consider genetic variants associated with, say, schizophrenia or autism (many such loci have now been identified; Elia et al., 2012; Glessner et al., 2009; Neale et al., 2012; Pinto et al., 2010; Ripke et al., 2011; Wang et al., 2009). Further, suppose the expression of some number of genes assayed in relevant regions of the brain relating to these disorders were also associated with these same genetic variants. By examining the changes in the levels of expression of these genes in response to changes in genotype at any of the genetic loci of interest, one can directly assess the extent to which these expression changes induced by the genetic loci well explain the degree of association between the locus genotypes and disease trait. In this way, just as the characteristic wobble of a star induced by an orbiting planet predicts the presence of the planet, the characteristic “wobble” of the expression levels of a gene and its association to the disease state predicts a causal path between the gene and disease state, as described in more detail later.

Critical to identifying causal relationships is distinguishing between correlation and causation. The old adage, “correlation does not imply causation,” is familiar to most. This is among the first fallacies one learns about in beginning logic courses: *post hoc ergo propter hoc* (Latin for “after this, therefore because of this”). Measurements taken over time on independent variables can be correlated because trends reflected by such variables are coincidentally similar or changes in each variable are independently caused by a common source, in addition to being correlated as a result of a cause–effect relationship. It is also interesting to note that while correlation and causation are related, our intuitive notation that causation implies correlation is not always correct either. For example, suppose U and V are random variables with the same distribution and suppose $X = U + V$ and $Y = U - V$. In this case the covariance between X and Y [defined as $E(XY) - E(X)E(Y)$, where E represents the expectation function] is 0 and so the correlation is 0, even though there is a direct functional dependence between the

variables (Feller, 1967). Only when two variables are linearly dependent (which is often the case in research) is our intuitive notion of functional dependence implying perfect correlation correct.

Structure learning approaches that seek to infer causal relationships among correlated variables often employ conditional dependency arguments or mutual information measures to resolve causality by introducing a third correlated variable. By conditioning each of the variables on the third and examining the residual correlation between them in each case, a decision can be made as to the direction of the flow of information between the variables. However, this type of reasoning has generally failed to result in predictive causal inference because in the absence of systematic perturbations, the number of graphs that can be represented between just three traits is large (125 graphs representing directed and undirected relationships between three correlated variables are possible), and many of these possible relationships between the traits are not statistically distinguishable (Sieberts and Schadt, 2007). For example, if variables X , Y , and Z are observed in a population to be correlated (e.g., suppose X , Y , and Z represent the expression levels of three genes assayed in a given region of the brain in a population of individuals with schizophrenia) and the true relationship between the variables is $X \rightarrow Z \leftarrow Y$, this relationship cannot be statistically distinguished from $X \rightarrow Y \leftarrow Z$ and $Z \rightarrow X \leftarrow Y$, even though these relationships give rise to contradictory causal relationships.

To break this type of statistical symmetry, a source of perturbation is required. Classically in biology we have introduced artificial perturbations by knocking a gene out, overexpressing a gene, or chemically perturbing a given protein to assess the consequences on a given trait of interest. More recently, in the neurosciences, optogenetics methods have provided novel ways to perturb genes on the short time scales needed to elucidate the complexity of networks at play in neurons in living mammals (Boyden et al., 2005). If experimentally controlled artificial perturbations on a given gene cause a change in a trait of interest, then we infer a causal relationship between that gene and trait. However, DNA variation in the germline provides an excellent systematic perturbation source that can also be used to resolve causal relationships in biological systems. Because variations in DNA cause variations in RNA, proteins, metabolites, and subsequently, higher order phenotypes, this source of variation can be leveraged to infer causality. Unlike artificial perturbations such as gene knockouts, transgenics, or chemical or optogenetic perturbations that may induce artificial correlations that are not observed in more natural settings, naturally occurring genetic variation defines those perturbations that give rise to the broad array of phenotypic variations (such as disease and drug response) that we are precisely interested in elucidating. The past seven years has demonstrated that causal links between DNA variations and molecular and higher order phenotypes can provide information on causal relationships between those traits (Chen et al., 2007; Chen et al., 2008; Davey Smith and Ebrahim, 2003; Didelez and Sheehan, 2007; Emilsson et al., 2008; Kulp and Jagalur, 2006; Millstein et al., 2009; Schadt et al., 2005; Schadt et al., 2003; Yang et al., 2009; Zhu et al., 2004; Zhu et al., 2008). Causality in this instance can

be inferred because there is random segregation of the chromosomes during gametogenesis, thus providing the appropriate randomization mechanism to protect against confounding, similar to what is achieved in randomized clinical trials by randomly assigning patients to treatments to test the causal effects of a drug of interest (Lawlor et al., 2008; Nitsch et al., 2006). However, quantifying the uncertainty in making such causal calls has been challenging. For example, causal effect estimates often considered in Mendelian randomization approaches can be confounded by pleiotropic effects and reverse causation, limiting the utility of such approaches for problems that involve the reconstruction of regulatory networks, in which pleiotropy is common and there may be little a priori information regarding the structure of the causal relationships between the traits of interest (Millstein et al., 2009).

Recently, though, formal statistical tests for inferring causal relationships between quantitative traits mediated by a common genetic locus have been developed (Millstein et al., 2009). To understand how such a test works, consider marker genotypes at a given DNA locus L that are correlated with a given molecular phenotype, G, and a higher order phenotype T (Fig. 14.3). The causal relationship $G \rightarrow T$ is implied if three conditions are satisfied under the assumption that L is sufficiently randomized: (1) L and G are associated, (2) L and T are associated, and (3) L is independent of T given G (i.e., L and T|G are not associated) (Chen et al., 2007). If a given locus L is independent of G given T (G|T), this is consistent with T being causal for G ($T \rightarrow G$), and if L is associated with G|T, then this is consistent with G being causal for T ($G \rightarrow T$). We can boil all of these observations down to four conditions from which a statistical test can be formed to test for causality: (1) L and T are associated, (2) L is associated with G|T, (3) G is associated with T|L, and (4) L is independent of T|G. Each of these conditions can be assessed with a corresponding statistical test. For example, if we assume the marker corresponding to locus L is biallelic, where L_1 and L_2 represent indicator variables for the

two alleles in a codominant coding scheme, then the four conditions can be tested in the parameters of the following three regression models:

$$T_i = \alpha_1 + \beta_1 L_{1i} + \beta_2 L_{2i} + \epsilon_{1i} \quad (14.1)$$

$$G_i = \alpha_2 + \beta_3 T_i + \beta_4 L_{1i} + \beta_5 L_{2i} + \epsilon_{2i} \quad (14.2)$$

$$T_i = \alpha_3 + \beta_6 G_i + \beta_7 L_{1i} + \beta_8 L_{2i} + \epsilon_{3i}, \quad (14.3)$$

where G_i and T_i represent the gene and trait levels, respectively, for individual i in a population of interest, and the ϵ_j represents independently distributed random noise variables with variance σ_j^2 (Chen et al., 2007). Given these models the four component tests of interest are:

$$H_0 : \{\beta_1, \beta_2 = 0\}, \quad H_1 : \{\beta_1, \beta_2\} \neq 0 \quad (14.4)$$

$$H_0 : \{\beta_4, \beta_5 = 0\}, \quad H_1 : \{\beta_4, \beta_5\} \neq 0 \quad (14.5)$$

$$H_0 : \beta_6 = 0, \quad H_1 : \beta_6 \neq 0 \quad (14.6)$$

$$H_0 : \{\beta_7, \beta_8 \neq 0\}, \quad H_1 : \{\beta_7, \beta_8\} = 0. \quad (14.7)$$

The four conditions of interest can be tested using standard F -tests for linear model coefficients (conditions 1–3) and a slightly more involved test for the last condition, given it is an equivalence testing problem (Millstein et al., 2009). Given these individual statistical tests on the different regression parameters, a causal inference test can then be carried out by testing the strength of the chain of mathematical conditions that collectively are consistent with causal mediation (i.e., the strength of the chain is only as strong as its weakest link, so that the intersection of the rejection regions of the component tests provides for the causality test we seek). For a series of statistical tests of size α_ν and rejection region R_ν , the “intersection union” test with rejection region equal to the intersection over all R_ν , is a level $\sup(\alpha_\nu)$ test, so that the p -value for the causal inference test corresponds to the p -value for an intersection union test, or, simply, the supremum of the four p -values for the component tests (Chen et al., 2007). This test has been implemented as the CIT package in the R statistical programming language and is freely available.

Applications of this type of test can be applied to resolve the types of causal relationships depicted in Fig. 14.3. Application of these ideas in segregating mouse populations have led to the identification and validation of many genes causal for a number of metabolic traits, including obesity, diabetes, and heart disease. In one such population constructed between the B6 and DBA inbred strains of mouse, 111 F2 intercross animals were placed on a high-fat, atherogenic diet for 4 months at 12 months of age. All animals were genotyped using a genome-wide panel of markers, clinically characterized with respect to a number of metabolic traits, and the livers were expression profiled using a comprehensive gene expression microarray. Given the pattern of genetic association between the metabolic and gene expression traits, causal inference testing was carried

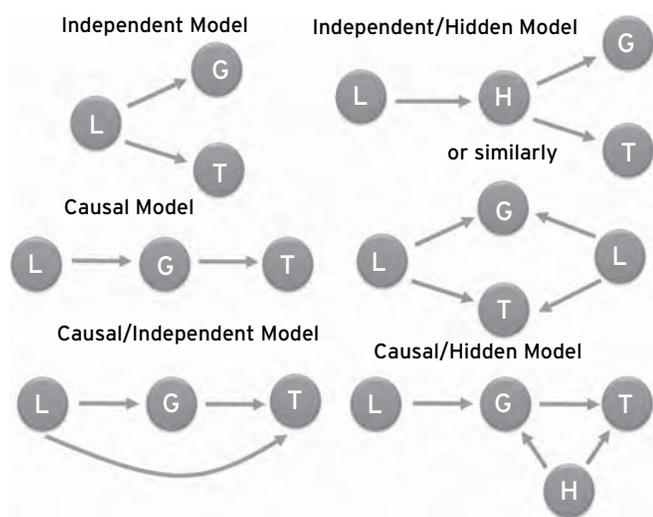

Figure 14.3 Given two traits G and T are correlated in a given population with changes in DNA at locus L, there are five basic causal models to consider in testing the hypothesis that variations in trait G cause variations in trait T. Here H denotes an unmeasured molecular or higher order trait.

out to identify the genes in this population best supported as causal of obesity-related traits (Schadt et al., 2003; Schadt et al., 2005). Of the top nine genes identified in this study supported as causal for obesity-related traits, eight of the genes were ultimately experimentally validated (Yang et al., 2009). The only gene that failed to validate was an X-linked gene that was lethal if completely knocked out and so represented a more complicated example for which the appropriate tools could not be constructed to validate.

Of course, this exact same type of reasoning can be used to causally relate imaging traits, DNA variation, and expression data to clinical phenotype data in the context of psychiatric disorders (Fig. 14.4). Consider associations identified between SNP genotypes and gene expression traits assayed in dorsal-lateral prefrontal cortex (DLPFC). Given the association of SNPs with expression in DLPFC, such SNPs are of interest for testing association to functional MRI (fMRI) traits. Given a set of SNPs in which there is an association between gene expression in DLPFC, fMRI, and schizophrenia status, we can statistically model whether the relationship between the traits is causal, reactive, or independent as described in the preceding (Fig. 14.4). This provides a causal statistical inference procedure applied to functional MRI

and disease trait data, using DNA variation as the systematic perturbation source that can address the pressing question of whether changes in neuroimaging traits are the result of schizophrenia or whether these changes lead to the schizophrenia phenotype.

FROM ASSESSING CAUSAL RELATIONSHIPS AMONG TRAIT PAIRS TO PREDICTIVE GENE NETWORKS

Leveraging DNA variation as a systematic perturbation source to resolve the causal relationships among traits is necessary but not sufficient for understanding the complexity of living systems. Cells are comprised of many tens of thousands of proteins, metabolites, RNA, and DNA, all interacting in complex ways. Complex biological systems are comprised of many different types of cells operating within and between many different types of tissues that make up different organ systems, all of which interact in complex ways to give rise to a vast array of phenotypes that manifest themselves in living systems. Modeling the extent of such relationships between molecular entities, between cells, and between organ systems is a daunting

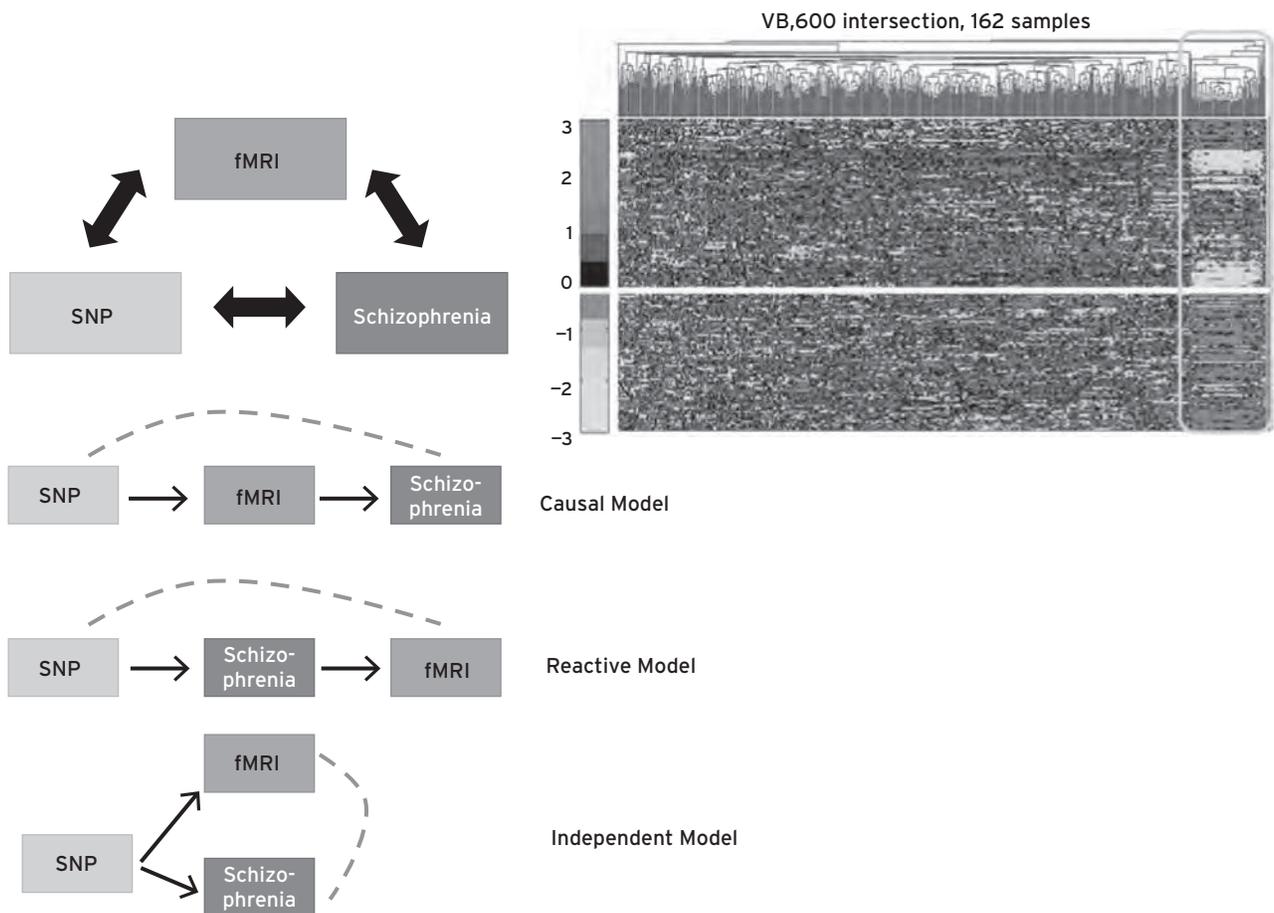

Figure 14.4 Inferring causal relationships between functional MRI traits and schizophrenia traits using SNPs that associate with the expression of genes in the dorsal-lateral prefrontal cortex as a perturbation source. The heat map represents a two-dimensional hierarchical clustering of functional MRI traits in which the highlighted cluster distinguishes schizophrenia cases from controls. Associations between functional MRI traits, gene expression, disease status, and SNP genotypes can be integrated to infer causal relationships between functional MRI traits and disease status.

task. Networks are a convenient framework for representing the relationships among these different variables. In the context of biological systems, a network can be viewed as a graphical model that represents relationships among DNA, RNA, protein, metabolite, and higher order phenotypes like disease state. In this way, networks provide a way to represent extremely large-scale and complex relationships among molecular and higher order phenotypes like disease in any given context.

BUILDING FROM THE BOTTOM UP OR TOP DOWN?

Two fundamental approaches to the reconstruction of molecular networks dominate computational biology today. The first is what is referred to as the bottom-up approach in which fundamental relationships between small sets of genes that may comprise a given pathway are established, thus providing the fundamental building blocks of higher order processes that are then constructed from the bottom up. This approach typically assumes that we have more complete knowledge regarding the fundamental topology (connectivity structure) of pathways, and given this knowledge, models are constructed that precisely detail how changes to any component of the pathway affect other components as well as the known functions carried out by the pathway (i.e., bottom-up approaches are hypothesis driven). The second approach is referred to as a top-down approach in which we take into account all data and our existing understanding of systems and construct a model that reflects whole system behavior and from there tease apart the fundamental components from the top down. This approach typically assumes that our understanding of how the network is actually wired is sufficiently incomplete, that our knowledge is sufficiently incomplete, and that we must objectively infer the relationships by considering large-scale, high-dimensional data that informs on all relationships of interest (i.e., top-down approaches are data driven).

Given our incomplete understanding of more general networks and pathways in living systems, in this chapter I focus on a top-down approach to reconstructing predictive networks, given that this type of structure learning from data is critical to derive hypotheses that cannot otherwise be efficiently proposed in the context of what is known (from the literature, pathway databases, or other such sources). However, top-down and bottom-up approaches are complementary to one another, although these approaches have largely been pursued as separate disciplines, with, interestingly, little crosstalk occurring between them. One of the future directions I discuss in the conclusion is the need to mathematically unify these two classes of predictive modeling to produce probabilistic causal networks that more maximally leverage all available data and knowledge.

In the context of integrating genetic, molecular profiling and higher order phenotypic data, biological networks are comprised of nodes that represent molecular entities that are observed to vary in a given population under study (e.g., DNA variations, RNA levels, protein states, or metabolite levels). Edges between the nodes represent relationships between the molecular entities, and these edges can either be directed,

indicating a cause–effect relationship, or undirected, indicating an association or interaction. For example, a DNA node in the network representing a given locus that varies in a population of interest may be connected to a transcript abundance trait, indicating that changes at the particular DNA locus induce changes in the levels of the transcript. The potentially millions of such relationships represented in a network define the overall connectivity structure of the network, or what is otherwise known as the topology of the network. Any realistic network topology will be necessarily complicated and nonlinear from the standpoint of the more classic biochemical pathway diagrams represented in textbooks and pathway databases like KEGG (Kanehisa, 2002). The more classic pathway view represents molecular processes on an individual level, while networks represent global (population-level) metrics that describe variation between individuals in a population of interest, which, in turn, define coherent biological processes in the tissue or cells associated with the network. One way to manage the complexity of network structures that can obtain is to impose constraints on network structures to make them more computational tractable. For example, it is common when learning network structures to disallow loops or cycles in the network structure (otherwise known as the network topology, the connectivity structure of the network), in which cases we refer to the network as acyclic.

The neurosciences have a rich history of employing network-based approaches to understand the complexity of the human brain and the causes of psychiatric illnesses. Resources like the Allen Brain Atlas (<http://www.alleninstitute.org>) provide an anatomically comprehensive map of gene expression of the human brain that can facilitate network-based analyses (Hawrylycz et al., 2012). Others have employed techniques developed for constructing gene coexpression networks to construct interaction networks on fMRI data (Mumford et al., 2010), and others still have generated protein interaction networks to reflect features of the network architecture in brains of those with illnesses such as Huntington's disease (Shirasaki et al., 2012). Larger scale efforts have also been undertaken to integrate larger scale transcriptomic data in the context of diseases like autism to understand how changes in these networks may give rise to autism or reflect the types of pathways or biological processes involved in such a disease (Voineagu et al., 2011). These efforts are important not only for better understanding psychiatric diseases, but also for elucidating novel drug targets or biomarkers that better assess disease risk or severity. However, most of these current efforts do not lead to predictive models of disease but, rather, provide a descriptive framework within which to uncover associations between a myriad of molecular, cellular, imaging, and clinical traits and disease.

AN INTEGRATIVE GENOMICS APPROACH TO CONSTRUCTIVE PREDICTIVE NETWORK MODELS

Systematically integrating different types of data into probabilistic networks using Bayesian networks has been proposed and applied for the purpose of predicting protein–protein interactions (Jansen et al., 2003) and protein function (Lee et al., 2004). However, these Bayesian networks are still based

on associations between nodes in the network as opposed to causal relationships. As previously discussed for the simple case of two traits, from these types of networks we cannot infer whether a specific perturbation will affect a complex disease trait. To make such predictions, we need networks capable of representing causal relationships. Probabilistic causal networks are one way to model from the top down such relationships, where causality again in this context reflects a probabilistic belief that one node in the network affects the behavior of another. Bayesian networks (Pearl, 1988) are one type of probabilistic causal network that provides a natural framework for integrating highly dissimilar types of data.

Bayesian networks are directed acyclic graphs in which the edges of the graph are defined by conditional probabilities that characterize the distribution of states of each node given the state of its parents (Pearl, 1988). The network topology defines a partitioned joint probability distribution over all nodes in a network, such that the probability distribution of states of a node depends only on the states of its parent nodes: formally, a joint probability distribution $p(X)$ on a set of nodes X can be decomposed as $p(X) = \prod p(X^i | \text{Pa}(X^i))$, where $\text{Pa}(X^i)$ represents the parent set of X^i . The biological networks of interest we wish to construct are comprised of nodes that represent a quantitative trait such as the transcript abundance of a given gene or levels of a given metabolite. The conditional probabilities reflect not only relationships between genes, but also the stochastic nature of these relationships, as well as noise in the data used to reconstruct the network.

The aim in any network reconstruction such as this is to find the best model, the model that best reflects the relationships between all of the variables under consideration, given a set of data that informs on the variables of interest. In a probabilistic sense, we want to search the space of all possible networks (or models) for that network that gives the highest likelihood of occurring given the data. Bayes' formula allows us to determine the likelihood of a network model M given observed data D as a function of our prior belief that the model is correct and the probability of the observed data given the model is: $P(M|D) \sim P(D|M)P(M)$. The number of possible network structures grows superexponentially with the number of nodes, so an exhaustive search of all possible structures to find the one best supported by the data is not feasible, even for a relatively small number of nodes. A number of algorithms exist to find the optimal network without searching exhaustively, like Monte Carlo Markov Chain (MCMC) (Madigan and York, 1995) simulation. With the MCMC algorithm, optimal networks are constructed from a set of starting conditions. This algorithm is run thousands of times to identify different plausible networks, each time beginning with different starting conditions. These most plausible networks can then be combined to obtain a consensus network. For each of the reconstructions using the MCMC algorithm, the starting point is a null network. Small random changes are made to the network by flipping, adding, or deleting individual edges, ultimately accepting those changes that lead to an overall improvement in the fit of the network to the data. To assess whether a change improves the network model or not, information measures like the Bayesian Information Criterion (BIC) (Schwarz, 1978) are

employed, which reduces overfitting by imposing a cost on the addition of new parameters. This is equivalent to imposing a lower prior probability $P(M)$ on models with larger numbers of parameters.

Even though edges in Bayesian networks are directed, we cannot in general infer causal relationships from the structure directly, just as I discussed in relation to the causal inference test. For a network with three nodes, X_1 , X_2 , and X_3 , there are multiple groups of structures that are mathematically equivalent. For example, the three models, $M1: X_1 \rightarrow X_2, X_2 \rightarrow X_3$; $M2: X_2 \rightarrow X_1, X_2 \rightarrow X_3$; and $M3: X_2 \rightarrow X_1, X_3 \rightarrow X_2$, are all Markov equivalent, meaning that they all encode for the same conditional independence relationship: $X_1 \perp X_3 | X_2$, X_1 and X_3 are independent conditional on X_2 . In addition, these models are mathematically equivalent:

$$\begin{aligned} p(X) &= p(M1|D) = p(X_2|X_1)p(X_1)p(X_3|X_2) \\ &= p(M2|D) = p(X_1|X_2)p(X_2)p(X_3|X_2) \\ &= p(M3|D) = p(X_2|X_3)p(X_3)p(X_1|X_2). \end{aligned}$$

Thus, from correlation data alone we cannot infer whether X_1 is causal for X_2 or vice versa from these types of structures. It is worth noting, however, that there is a class of structures, V-shape structures (e.g., $Mv: X_1 \rightarrow X_2, X_3 \rightarrow X_2$), that have no Markov-equivalent structure. In such cases it is not possible based on correlation data alone to infer causal relationships. Because there are more parameters to estimate in the Mv model than in the $M1$, $M2$, or $M3$ models, there is a large penalty in the Bayesian information criterion (BIC) score for the Mv model. Therefore, in practice, a large sample size is needed to differentiate the Mv model from the $M1$, $M2$, or $M3$ models.

INTEGRATING GENETIC DATA AS A STRUCTURE PRIOR TO ENHANCE CAUSAL INFERENCE IN THE BAYESIAN NETWORK RECONSTRUCTION PROCESS

In general, Bayesian networks can only be solved to Markov-equivalent structures, so it is often not possible to determine the causal direction of a link between two nodes even though Bayesian networks are directed graphs. However, the Bayesian network reconstruction algorithm can take advantage of genetic data to break the symmetry among nodes in the network that lead to Markov-equivalent structures, thereby providing a way to infer causal directions in the network in an unambiguous fashion (Zhu et al., 2004). The reconstruction algorithm can be modified to incorporate genetic data as prior evidence that two quantitative traits may be causally related based on a previously described causality test (Zhu et al., 2004). The genetic priors can be constructed from three basic sources. First, gene expression traits associated with DNA variants that are coincident with the gene's physical location (referred to as *cis-acting expression quantitative trait loci* or *cis eQTLs*) (Doss et al., 2005) are allowed to be parent nodes of genes with coincident trans eQTLs (the gene in this case does not physically reside at the genetic locus of

interest), $p(cis \rightarrow trans) = 1$, but genes with trans eQTLs are not allowed to be parents of genes with cis eQTLs, $p(trans \rightarrow cis) = 0$. Second, after identifying all associations between different genetic loci and expression traits at some reasonable significance threshold, genes from this analysis with cis- or trans-eQTL can be tested individually for pleiotropic effects at each of their eQTLs to determine whether any other genes in the set are driven by common eQTLs (Jiang and Zeng, 1995; Lum et al., 2006). If such pleiotropic effects are detected, the corresponding gene pair and locus giving rise to the pleiotropic effect can then be used to infer a causal/reactive or independent relationship based on the causality test previously described. If an independent relationship is inferred, then the prior probability that gene A is a parent of gene B can be scaled as

$$p(A \rightarrow B) = 1 - \frac{\sum_i p(A \perp B | A, B, l_i)}{\sum_i 1},$$

where the sums are taken over all loci used to infer the relationship. If a causal or reactive relationship is inferred, then the prior probability is scaled as

$$p(A \rightarrow B) = \frac{2 \sum_i p(A \rightarrow B | A, B, l_i)}{\sum_i p(A \rightarrow B | A, B, l_i) + p(B \rightarrow A | A, B, l_i)} P.$$

Finally, if the causal/reactive relationship between genes A and B cannot be determined from the first two sources, the complexity of the eQTL signature for each gene can be taken into consideration. Genes with a simpler, albeit stronger, eQTL signature (i.e., a small number of eQTL that explain the genetic variance component for the gene, with a significant proportion of the overall variance explained by the genetic effects) can be considered as more likely to be causal compared with genes with more complex and possibly weaker eQTL signatures (i.e., a larger number of eQTLs explaining the genetic variance component for the gene, with less of the overall variance explained by the genetic effects). The structure prior that gene A is a parent of gene B can then be taken to be

$$p(A \rightarrow B) = 2 \frac{1 + n(B)}{2 + n(A) + n(B)},$$

where $n(A)$ and $n(B)$ are the number of eQTLs at some predetermined significance level for genes A and B, respectively.

INCORPORATING OTHER OMICS DATA AS NETWORK PRIORS IN THE BAYESIAN NETWORK RECONSTRUCTION PROCESS

Just as genetic data can be incorporated as a network prior in the Bayesian network reconstruction algorithm, so can other types of data like transcription factor binding site (TFBS) data, protein-protein interaction (PPI) data, and protein-small molecule interaction data. PPI data can be used to infer protein complexes to enhance the set of manually curated protein complexes (Guldener et al., 2006). PPI-inferred

protein complexes can be combined with manually curated sets, and each protein complex can then be examined for common transcription factor binding sites at the corresponding genes. If some proportion of the genes in a protein complex (e.g., half) carry a given TFBS, then all genes in the complex can be included in the TFBS gene set as being under the control of the corresponding transcription factor.

Given that the scale-free property is a general property of biological networks (i.e., most nodes in the network are linked to a small number of nodes whereas a smaller number of nodes are linked to many nodes) (Albert et al., 2000), inferred and experimentally determined TFBS data can be incorporated into the network reconstruction process by constructing scale-free priors, in a manner similar to the scale-free priors others have constructed to integrate expression and genetic data (Lee et al., 2006). Given a transcription factor T , and a set of genes, G , that contain the binding site of T , the TF prior, p_{TF} , can be defined so that it is proportional to the number of expression traits correlated with the TF expression levels, for genes carrying the corresponding TFBS:

$$\log(p_{TF}(T \rightarrow g)) \propto \log\left(\sum_{g \in G} p_{qtl}(T \rightarrow g_i) \delta\right)$$

where $p_{qtl}(T \rightarrow g)$ is the prior for the QTL and $\delta = \begin{cases} 1, & \text{if } \text{corr}(T, g_i) \geq r_{cutoff} \\ 0, & \text{if } \text{corr}(T, g_i) < r_{cutoff} \end{cases}$. The correlation cutoff r_{cutoff} can be

determined by permuting the data and then selecting the maximum correlation values in the permuted datasets (corresponding to some predetermined, reasonable false discovery rate). This form of the structure prior favors transcription factors that have a large number of correlated responding genes. From the set of priors computed from the inferred and experimentally determined TFBS set, only nonnegative priors should be used to reconstruct the Bayesian network. For those protein complexes that could not be integrated into the network reconstruction process using scale-free priors, uniform priors were used for pairs of genes in these complexes (i.e., $p_{pc}(g_i \rightarrow g_j) = p_{pc}(g_j \rightarrow g_i) = c$).

Small molecule-protein interactions can also be incorporated into the Bayesian network reconstruction process. Chemical reactions reflected in biochemical pathways and the associated catalyzing enzymes can be identified as metabolite-enzyme pairs from existing pathway databases like KEGG. These relationships can then be stored in an adjacency matrix in which a 1 in a cell represents a direct connection between the metabolite and the enzyme. The shortest distance $d_{m,e}$ from an enzyme e to a metabolite m can then be calculated using the repeated matrix multiplication algorithm. The structure prior for the gene expression of an enzyme e affecting the metabolite concentration is related to their shortest distance $d_{m,e}$ as $p(m \rightarrow e) \propto e^{-\lambda d_{m,e}}$. The shorter the distance, the stronger the prior.

ILLUSTRATING THE CONSTRUCTION OF PREDICTIVE BAYESIAN NETWORKS WITH AN EXAMPLE

To illustrate how different types of data can be integrated to construct predictive gene networks, we can consider a simple model system, yeast, that makes the point on how different pieces of molecular information can be brought together to infer causal networks. A yeast example in this instance is preferable to one involving psychiatric disorders given the latter would be complicated and the validations less straightforward than we can demonstrate in a simple model system. However, the procedures applied and steps indicated in the following would be essentially the same for any disease or system of interest, given that the Bayesian network reconstruction algorithm described is generally applicable to data collected in any population and for any phenotype of interest.

In our simple yeast system, consider the following two classes of data: (1) DNA variation, gene expression, and metabolite data measured in a previously described cross between laboratory (BY) and wild (RM) yeast strains (referred to here

as the BXR cross) for which DNA variation, RNA expression, and metabolite levels have been assessed (Brem and Kruglyak, 2005; Brem et al., 2002; Zhu et al., 2012), and (2) protein–DNA binding, protein–protein interaction, and metabolite–protein interaction data available from public data sources and generated independently of the BXR cross (referred to here as non-BXR data). The BXR yeast data are reflected as nodes in the network to be constructed, where edges in the network reflect statistically inferred causal relationships among the expression and metabolite traits. The non-BXR interaction data from public sources are used to derive the types of structure priors previously discussed on the network to both constrain the size of the search space in finding the best network and enhance the ability to infer causal relationships between the network nodes (Zhu et al., 2008).

To illustrate the steps in the type of Bayesian network reconstruction procedure previously described and detailed more formally (Zhu, Chen et al.) and to examine contributions from the different data types used to construct the network, I focus on genes and metabolites involved in the *de novo* biosynthesis of pyrimidine ribonucleotides (Fig. 14.5). For

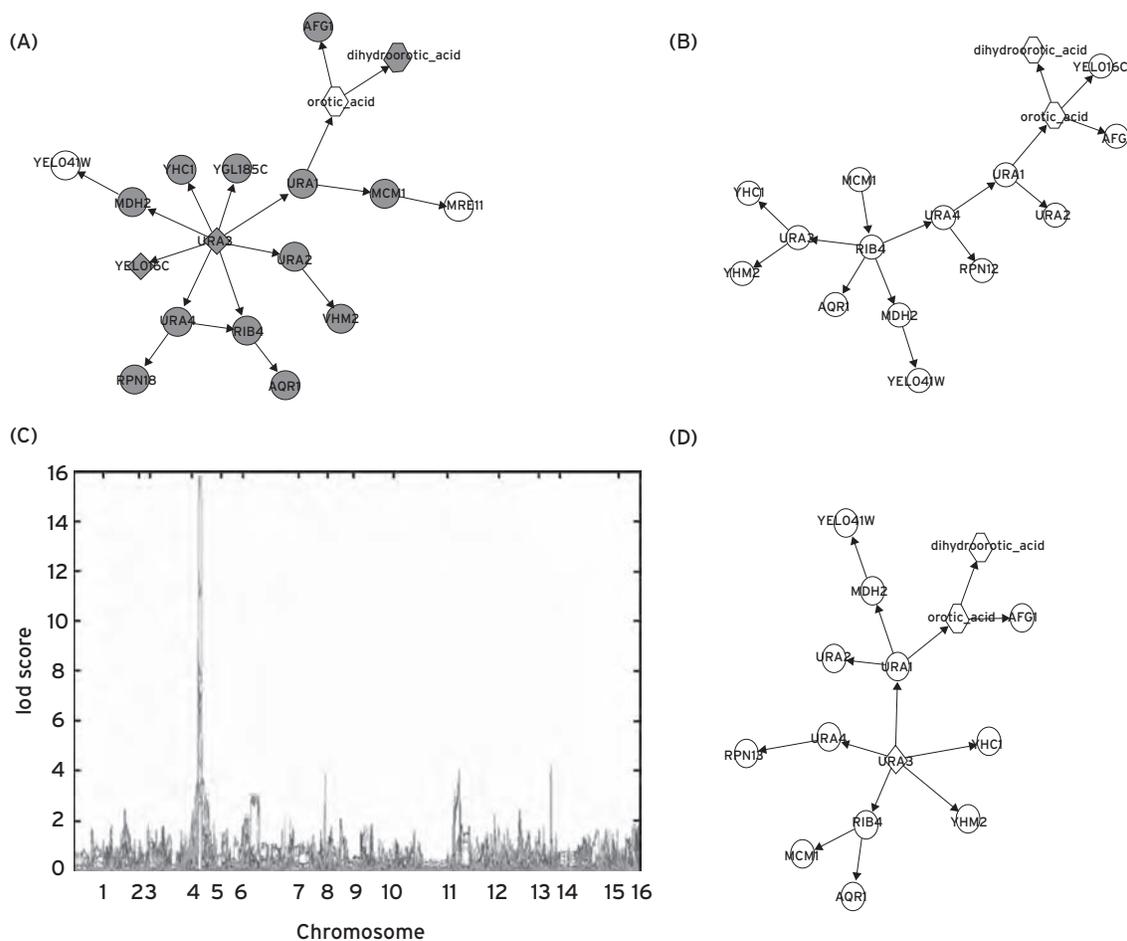

Figure 14.5 Example yeast network. (A) Subnetwork identified in a previously constructed whole-genome yeast network in which URA3 was predicted as the causal regulator for genes and metabolites linked to a genetic locus on chromosome 5 coincident with the physical location of URA3. Gray nodes are genes or metabolites whose variations are linked to the chromosome 5 locus. Hexagon-shaped nodes represent metabolites, circular nodes represent genes, and diamond-shaped nodes represent genes with *cis* eQTLs. (B) Trait values of nodes compared with genotype data for the URA3 subnetwork. eQTLs and metQTLs are prominently featured as residing in the chromosome 5 URA3 locus. (C) Bayesian network reconstructed using only trait data. (D) Bayesian network reconstructed using trait data and priors derived from other types of data.

simplicity I focus on the reconstruction of this smaller subset of genes, although the steps are similar if building a network from a more comprehensive set of genes. The subnetwork depicted in Figure 14.5a was identified from the full Bayesian network constructed from the BXR data (Zhu, Chen et al.). *URA3* in this network was predicted as a causal regulator of gene expression traits linked to the *URA3* locus. That is, using the full Bayesian network, in silico perturbations were carried out by simulating changes in each of the nodes and identifying those nodes that resulted in the most significant changes in other nodes in the network. As a result of this simulation, *URA3* was identified as the regulator modulating the most significant number of nodes in the subnetwork in a causal fashion (Fig. 14.5a). A deletion of *URA3* was engineered in the parental strain RM11-1a as a selectable marker, and segregation of this locus among the BXR progeny is the most likely cause for expression variation of uracil biosynthesis genes linked to this locus (Brem et al., 2002). Variations of two metabolites are also linked to this locus: dihydroorotic acid, which is converted to orotic acid by the enzyme Ura1p, and orotic acid itself, reflecting the functional consequence of transcriptional variation in genes involved in de novo pyrimidine base biosynthetic processes on metabolite levels. The causal relationships between *URA1*, orotic acid, and dihydroorotic acid as well as the subnetwork for genes linked to the *URA3* locus recapitulate the known pyrimidine base biosynthesis pathway (Zhu, Chen et al.). This subnetwork not only captures the coregulation of gene expression and metabolite abundance but also elucidates the mechanism of how genetic variation in *URA3* affects orotic acid and dihydroorotic acid levels.

Step 1: Identification of the URA3-centered de novo biosynthesis of pyrimidine ribonucleotides subnetwork.

There are 18 nodes in the subnetwork shown in Figure 14.5a. These nodes are highly correlated with one another, with 68% of all pairwise relationships significant at the 0.01 significance level. The continuous gene expression data for these 18 genes can then be discretized into three states representing downregulated, no-change, and upregulated states, and then the mutual information of all pairs of nodes are calculated. In this case, 54% of all pairs are significant at $p < 0.01$ (the mutual information of the permuted data is calculated and fit into a normal distribution, which is then used to assess significance of the mutual information of the observed data). All 18 of the trait values corresponding to these nodes are significantly associated with the genotypes at the *URA3* locus (Fig. 14.5c).

Step 2: Reconstructing networks using only expression and metabolite traits (excluding DNA variation data). The process of reconstructing networks using only trait data is straightforward. The trait data are input into a standard Bayesian network reconstruction program in which 1,000 network structures are generated from a Monte Carlo Markov Chain process using different random seed numbers (1,000 random seed numbers are generated by a

master process, then each slave process starts an MCMC process using one of the generated seed numbers). Once the 1,000 network structures have been generated, common features are extracted to derive a consensus network. With this construction, the consensus network may contain loops, which are prohibited in Bayesian networks. Therefore, to ensure the consensus network structure is a directed acyclic graph, the edges in the original consensus network are removed if and only if (1) the edge was involved in a loop, and (2) the edge was the most weakly supported of all edges making up the loop. The network resulting from this process is depicted in Figure 14.5b.

Step 3: Constructing priors using eQTL data. The network in Step 2 is constructed without considering any of the genetic data. Because eQTL data represent a systematic source of perturbation on the expression data, integrating these data has the potential to better resolve causal relationships. Toward this end, expression and genotype data in the BXR cross are compared to detect eQTLs. The gray nodes in Figure 14.5a indicate that nearly all of the nodes have QTLs linked to a single locus on chromosome 5. Expression traits that associate with a common eQTL are then subjected to a statistical test to infer causal relationships between the traits, as described. Among the nodes tested, *URA3* and *YEL016C* have cis-acting eQTLs linked to the chromosome 5 locus. Nodes with cis-acting eQTLs are allowed to be causal parent nodes to nodes with trans-acting QTLs. However, nodes with trans-QTLs are not allowed to be causal parent nodes to nodes with cis-acting eQTLs.

Step 4: Constructing priors using KEGG data. The network constructed in Step 2 also does not consider known relationships among genes and metabolites as defined by canonical pathways. The relationships between enzymes and metabolites are well established in many cases. To incorporate this knowledge into the network reconstruction process, we construct priors using canonical pathway data in the following way. There are two metabolites in the *URA3* subnetwork. Their distances to each other and related enzymes are defined in the KEGG database. The structure prior for the gene expression of an enzyme e affecting a metabolite concentration is constructed using their shortest distance $d_{m,e}$ as $p(m \rightarrow e) \propto e^{-\lambda d_{m,e}}$.

Step 5: Constructing networks using expression data, metabolite data, and the genetic and canonical pathway priors defined in Steps 3 and 4. The process of reconstructing networks using trait data and priors from other data types is similar to the reconstruction process applied to trait data only described in Step 2. In addition to trait data, priors derived from other data types are also input into the standard Bayesian network reconstruction process. The trait data of the 18 nodes and related priors are input into the network reconstruction process, and the resulting network is shown in Figure 14.5d. The root node of the Bayesian network is *URA3*, which is the gene

with the cis-acting eQTL associated with other traits in the network.

Step 6: Comparing the networks constructed in Steps 2 and 5. The main difference between the networks depicted in Fig. 14.5b and 14.5d are the head nodes. In general, directed links in a Bayesian network do not necessarily represent causal relationships (Zhu et al., 2004). The network constructed from the trait data only reflects relationships not supported by the genetic perturbation data. The genetic relationships are well captured by the more integrated network described in Step 5. For example, the link RIB4 → URA3 depicted in Fig. 14.5b is opposite that identified in Fig. 14.5d. Because the genetic perturbation at the URA3 locus affects the expression activity of that gene in cis and the expression activity of the gene RIB4 in trans, the experimentally supported relationship is URA3 → RIB4. I note that the enzyme/metabolite and metabolite/metabolite relationships are similar with or without the priors derived from the KEGG pathways.

All data and software used to construct the Bayesian networks for this example are available at <http://www.mssm.edu/research/institutes/genomics-institute/rimbanet>.

ELUCIDATING THE COMPLEXITY OF HUMAN DISEASE: FROM THE METABOLIC TO THE PSYCHIATRIC

We have carried out studies using the modeling described in detail for the yeast cross, but in human and mouse population segregating a number of different diseases such as obesity, diabetes, and heart disease. For example, in a segregating mouse population in which an extensive suite of disease traits associated with metabolic syndrome were manifested, including obesity, diabetes, and atherosclerosis (Chen et al., 2008), we carried out the type of network analysis previously discussed using genetic data typed in all animals and gene expression data generated from the liver and adipose tissues of all animals in the population. With this approach we found that of the many functional units (subnetworks) identified in the networks that reflected core biological processes specific to the liver and adipose tissues, only a handful were strongly causally associated with the metabolic syndrome traits. One module (referred to here as the inflammatome module) in particular stood out not only because it was conserved across the liver and adipose tissues, between the sexes, and between species (Emilsson et al., 2008), but also because it was supported as strongly causal for nearly all of the metabolic traits scored in the cross (fat mass, weight, plasma glucose, insulin, and lipid levels, and aortic lesions) (Chen et al., 2008). Again, the causal relationship between the inflammatome module and the disease traits was established by leveraging the changes in DNA in this population that were simultaneously associated with disease and expression traits. The entire subnetwork was shown to be under the control of genomic loci associated with the metabolic traits, while the predictive network modeling

strongly indicated that the module was causal for the disease traits and was not simply reacting to or acting independently of these traits.

Of the more than 100 genes supported in the inflammatome module as causal for metabolic disease traits like obesity and diabetes, many genes like *Zfp90*, *Alox5*, *C3ar1*, and *Tgfbr2* had been previously identified and validated as causal for metabolic traits (Mehrabian et al., 2005; Schadt et al., 2005). In addition, three other genes were selected for validation because they were independently supported as causal for metabolic traits in other studies (*Lpl* and *Lactb*) or because they were supported as causal for such a wide variety of metabolic traits (*Ppm1l*) (Chen et al., 2008). Interestingly, the degree of connectivity in this causal metabolic subnetwork was extreme. Perturbations to genes in this module that were previously validated as causal for the metabolic traits caused expression changes in many other genes validated as causal for metabolic traits. For example, overexpression of *Zfp90* in mouse not only generated an expression response that was significantly overlapping with the causal metabolic module but also caused changes in other genes like *Pparg* known to have an impact on metabolic traits (Chen et al., 2008).

These same approaches can be applied to brain-related disorders, such as Alzheimer's disease. In fact, we recently more fully characterized the inflammatome module described earlier, linking it to 11 different diseases: atherosclerosis, obesity, diabetes, inflammatory pain, COPD (chronic obstructive pulmonary disease), asthma, fibrosis, stroke, neuropathic pain, sarcopenia, and inflammation (Wang et al., 2012). This same module can also be seen to be significantly enriched not only for genes that are differentially expressed in the brain between Alzheimer's and control subjects, but also for genes that are differentially expressed in different brain regions in both Alzheimer's and schizophrenia patients versus controls. That is, the intersection between the set of genes identified as differentially expressed in both Alzheimer's and schizophrenia patients (Horesh et al., 2011) is very significantly enriched for genes that are in the inflammatome module. Therefore, the extensive research carried out on the inflammatome module, the causal networks that have been constructed for this network, may hold clues regarding inflammation-related processes that are at play in brain-associated disorders such as Alzheimer's and schizophrenia.

CONCLUSION AND FUTURE DIRECTIONS

The generation of ever higher dimensional data (DNA sequencing, RNA sequencing, epigenomic profiling, proteomic profiling, metabolomic profiling, and so on) at ever higher scales demands sophisticated mathematical approaches to integrate these data in more holistic ways to uncover not only patterns of molecular, cellular, and higher order activities that underlie the biological processes that define physiological states of interest, but also causal relationships among molecular and cellular phenotypes and between these phenotypes and clinical traits like disease or drug response. Among the more successful frameworks for representing large-scale, high-dimensional

data are networks. Here I have detailed one particular approach to reconstructing predictive network models of living systems that leverages DNA variation as a systematic variation source and Bayesian network reconstruction algorithms to take a top-down approach to modeling complex systems. Because state-of-the-art therapies in the future will be based on targeting combinations of genes (Schadt, 2009; Schadt, Friend et al., 2009), and for such applications not only is it important to infer the direction of each interaction (i.e., do you antagonize or activate a given target?), but also one must be able to predict the degree to which each gene should be knocked down or activated (in a quantitative sense), only by generating accurate predictive models of complex phenotypes can we most efficiently search for such combinations to pursue for experimental proof of concept.

The success of modeling complex systems in the future will depend on constructing networks that are predictive of complex behavior, not merely descriptive. In order to achieve these more predictive models in complex systems like humans, we must expand existing networks so that they reflect relationships between cell types and tissues, not just within a single cell type or tissue; capture a greater range of molecular phenotypes to enhance understanding of relevant functional units that define biological processes of interest; and improve modeling capabilities, ideally drawing on the expertise of other fields that have pioneered causality-type reasoning. The complex phenotype-associated molecular networks we can construct today are necessarily based on grossly incomplete sets of data. Even given the ability to assay DNA and RNA variation in whole populations in a comprehensive manner, the information is not complete, given rare variation, DNA variation other than SNP/co number, variation in noncoding RNA levels, and variation in the different isoforms of genes are far from being completely characterized in any sample, let alone in entire populations. Beyond DNA and RNA, measuring all protein-associated traits, interactions between proteins and DNA/RNA, metabolite levels, epigenetic changes, and other molecular entities important to the functioning of living systems are not yet possible with existing technologies. Further, the types of high-dimensional data we are able to routinely generate today in populations represent only a snapshot at a single time point, which may enable the identification of the functional units of the system under study and how these units relate to one another, but it does not enable a complete understanding of how the functional units are put together, the mechanistic underpinnings of the complex set of functions carried out by individual cells and by entire organs and whole systems comprised of multiple organs.

One of the future developments expected to be most impactful in this context is the unification of bottom-up and top-down modeling approaches that maximally leverage the strengths of each approach while minimizing the weaknesses. Integrating models derived from bottom-up approaches into top-down approaches is currently hampered by the fact that the existing approaches do not typically fully parameterize the network structure in ways that match the intrinsic quantitative nature of top-down approaches. In bottom up-approaches, the structural information detailing how different molecular

entities are connected is typically derived from the literature or pathway databases, but such structural information is only qualitative, failing to define quantitatively how one node responds to another. On the other hand, in existing top-down approaches, unless a tremendous amount of training data are available to cover all of the categories represented in the conditional probability distribution (CPD) defining how nodes are connected in the network (such as with Bayesian network reconstruction approaches), it is not generally possible to accurately estimate the full set of parameters associated with the reconstructed network structure. Worse, carrying out parameter estimation on a network structure that is not correct can be misleading, given false-positive and false-negative predictions. In cases where heuristic searches are used to orient the edges in a given network structure, the end result is that model parameters have not been fitted accurately, given the network itself is not correct. Without proper parameterization of network structures from these conventional systems biology approaches, the networks serve only as descriptive models that are not generally capable of generating *in silico* predictions.

The limitations of bottom-up and top-down approaches can be addressed by devising bottom-up modeling approaches that deliver structures that can serve as prior information for top-down approaches, thereby providing a direct path for parameterizing bottom-up models in the context of a richer set of omics data and network architectures, while simultaneously reducing the size of the search space for top-down approaches. Such bottom-up approaches are beginning to emerge (Chang et al., 2011). By automatically parameterizing large networks given a particular network structure and corresponding interaction functions (e.g., activation or repression of gene activity) associated with all node pairs by either leveraging prior information or performing a heuristic search, bottom-up approaches will be capable of generating direct quantitative predictions that are compatible with top-down approaches. Central to the success of this approach is the observation that the complexity of the structure of biological networks leads to robust parameter estimates in a constrained parameter space (Blanchini and Franco, 2011; Wilhelm et al., 2004; Wu et al., 2009) and the fact that a statistical model's parameters are, in fact, constrained to a cubic space (e.g., the conditional probabilities that represent parameters in our modeling approach are constrained to fall between 0 and 1). This stands in contrast to current bottom-up modeling approaches like continuous ordinary differential equation (ODE) modeling in which the parameter space is generally unconstrained (infinitely large).

Current systems biology approaches relating to network learning and modeling have exclusively utilized a top-down (reverse-engineering) approach to learn network structure based on association scores (Carro et al., 2010; Fiedler et al., 2009; Margolin et al., 2006; Stuart et al., 2003; Zhu et al., 2008). Association scores are designed to uncover the best correlations between variables. Bayesian networks are among the most popular models for this purpose. In theory, it is known that learning the optimal (global maximum) Bayesian network structure from the data is a problem that cannot be solved in polynomial time (what is referred to as an NP-hard problem);

further, because many substructures that must be considered during the reconstruction process are from classes of structures that are equivalent (the Markov equivalence issue previously noted), the statistical scores for all of the structures in a given equivalence class are equal, so that completely contradictory causal relationships are indistinguishable from one another. The integration of bottom-up and top-down approaches in a more holistic mathematical framework has the potential to further address these issues, potentially enhancing the power to uncover true causal relationships.

15 | BRAIN IMAGING METHODOLOGIES

HANZHANG LU, YIHONG YANG, AND PEIYING LIU

Neuroimaging is versatile in that it contains many sub-modalities that can reflect different aspects of brain anatomy, physiology, and function. Collectively, they provide a powerful toolbox for researchers and clinicians to better understand the neurobiology of the disease and improve diagnosis. The greatest advantage of neuroimaging is that most modalities can be performed noninvasively; thereby it represents the most direct means to “look” inside the brain in living humans. This chapter focuses on several emerging methodologies that are capable of making a major impact in mental illness in the coming years.

MEASUREMENT OF CEREBRAL PERFUSION USING MRI

Estimation of cerebral perfusion parameters provides a useful means to evaluate tissue integrity and viability (Alsop et al., 2000; de Crespiigny et al., 1998; Harris et al., 1996; Loeber et al., 1999). It should be emphasized that the utility of cerebral perfusion measurement is not limited to diseases of vascular origin (e.g., stroke or vascular dementia), but many psychiatric and neurologic diseases may also benefit from perfusion measurement. The reason is that perfusion measures can provide an indirect index of neural activity in the brain parenchyma due to neurovascular coupling (Roy and Sherrington, 1890). That is, if the brain region has greater neural activity, the local perfusion tends to be greater, too (Kuschinsky, 1996). Over the past few years, several MRI techniques have been extensively tested for the purpose of perfusion measurement, and they can now be used to quantitatively study perfusion parameters, including cerebral blood flow (CBF), cerebral blood volume (CBV), and mean transit time (MTT).

Dynamic susceptibility contrast (DSC) MRI uses a Food and Drug Administration (FDA)-approved MR contrast reagent (namely, the *gadolinium complex of diethylenetriamine pentaacetic acid*, *Gd-DTPA*) administered intravenously and employs rapid image acquisitions (e.g., 1 image/second) to monitor the first passage of the reagent in the brain (Ostergaard et al., 1996b; Rosen et al., 1990). Unlike perfusion tracers used in positron emission tomography (PET), the *Gd-DTPA* reagent is a nondiffusible tracer and does not penetrate the blood-brain barrier (BBB). However, using a model that accounts for the input-output functions of the vasculature, it is still possible to estimate the perfusion parameters, including CBV, CBF, and MTT (Ostergaard et al., 1996a, 1996b). One important requirement to accurately determine perfusion using DSC MRI is the

estimation of arterial input function (AIF), which describes the time course of the reagent concentration in the incoming arterial blood (Calamante et al., 2004; Rausch et al., 2000; van Osch et al., 2003). This is typically done by selecting pixels containing large arteries and using the averaged time course as the AIF (Cha et al., 2005; Law et al., 2004). If absolute quantification is not necessary, one can calculate the relative perfusion parameters by normalizing the values against the value in a region-of-interest (ROI), often the white matter.

A steady-state (SS) contrast MRI approach can also be used to evaluate cerebral perfusion, in this case only the CBV. This method acquires two MRI images before and after the contrast reagent injection and utilizes the fact that *Gd-DTPA* is an intravascular reagent and only occupies the vascular space (Kuppusamy et al., 1996; Lu et al., 2005; Moseley et al., 1992; Schwarzbauer et al., 1993). As a result, the difference signal is proportional to the CBV. Several variants of the technique are available, and their main differences reside in the use of different methods to normalize the signal, thereby converting the dimensionless MRI signal to physiologic values. Figure 15.1 shows a CBV map using the vascular-space-occupancy (VASO) approach, in which the normalization factor was obtained from a cerebrospinal fluid (CSF) region (Lu et al., 2005). In comparison with DSC MRI, the SS contrast MRI has the advantages that the model is relatively simple and does not require the knowledge of the AIF. In addition, the SS approach does not require rapid acquisitions; therefore, higher spatial resolution can be achieved and the image distortion is minimal. A pitfall is that this technique only estimates CBV (Lu et al., 2005), but not other parameters such as CBF, which is believed to be more useful in predicting tissue viability.

Cerebral blood flow can also be evaluated noninvasively using a technique called *arterial spin labeling* (ASL) MRI (Aslan et al., 2010; Dai et al., 2008; Detre et al., 1992; Detre and Alsop, 1999; Edelman et al., 1994; Golay et al., 1999; Kim, 1995; Kwong et al., 1995; Wong, 2007; Wu et al., 2007). The ASL pulse sequence starts with a radiofrequency (RF) pulse to magnetically label the incoming blood in the arterial vessels. Then, after a certain waiting period (1–2 seconds) to allow the blood to flow into the perfused tissue, an image is taken that contains signal from labeled blood and static tissue. In a second scan, the blood is not labeled, and similar waiting and acquisition schemes are undertaken. By subtracting one image from the other, the static tissue signal is canceled out, and the remaining difference image reflects the amount of labeled blood water that has flowed into the tissue, which can be used to calculate CBF. This technique can now measure a whole-brain CBF map

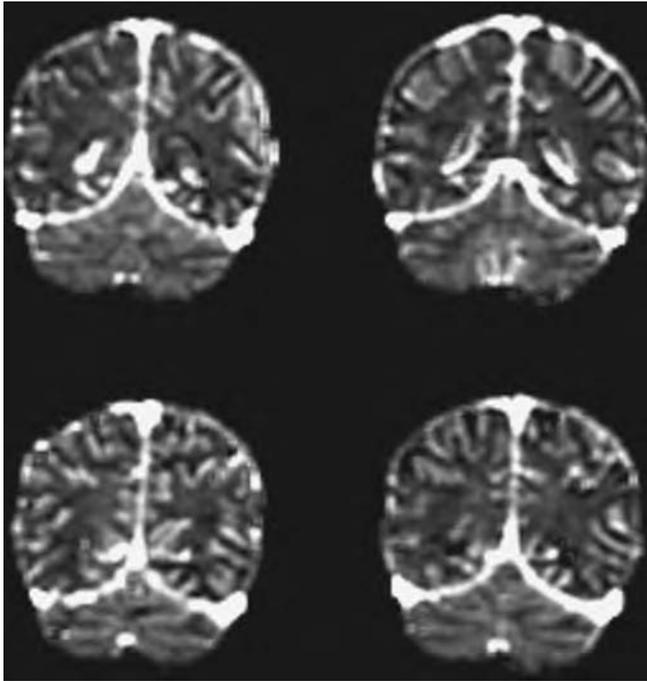

Figure 15.1 Absolute cerebral blood volume maps using VASO MRI. Imaging parameters: coronal slices, resolution $1.5 \times 1.5 \text{ mm}^2$; acquisition time was 5 minutes.

within 5 minutes on a standard clinical MRI scanner; thus, it can be easily included in an imaging session with relatively little added cost. Figure 15.2 shows a CBF map measured with a pseudocontinuous ASL method. The main advantage of the ASL technique is that the experimental procedure is noninvasive and straightforward. A pitfall is that the quantification is not trivial, and it involves several confounding factors,

including arterial transit time and vessel signal contributions (Buxton et al., 1998; Calamante et al., 1996; Hendrikse et al., 2003; Liu et al., 2011; Yang et al., 2000).

ASSESSING BRAIN FUNCTIONS USING MRI

Neuronal activity in the brain is accompanied by an increased consumption of glucose and oxygen. In addition, there are pronounced changes in blood supply to the activated regions, characterized by increased CBF and CBV (Roy and Sherrington, 1890). The precise mechanism of this neurovascular coupling is not clear. But it is thought to be mediated by one or more factors related to metabolism and/or neurotransmitters (Iadecola, 2004). Regardless of the mechanism, it is important to note that the increase in blood supply overcompensates for the increase in oxygen metabolism. As a result, the blood oxygenation in the draining veins and the capillaries is actually more oxygenated during the stimulation period compared with the resting state. This forms the basis of blood oxygenation level-dependent (BOLD) functional magnetic resonance imaging (fMRI) signal (Kwong et al., 1992; Ogawa et al., 1992). The hemoglobin in erythrocytes has different MR properties during the oxygenated and deoxygenated states. Deoxygenated blood is paramagnetic, which reduces the transverse relaxation times (T_2 and T_2^*) of the water signal (inside the blood compartment and outside the blood compartment), whereas oxygenated blood is not paramagnetic. As a result, the MR signal is directly correlated with the amount of deoxyhemoglobin in the voxel (Ogawa et al., 1993). The BOLD effect on T_2^* is more pronounced than that on T_2 . As a result, the T_2^* weighted gradient-echo echo-planar-imaging (EPI) sequence is the most widely used pulse sequence.

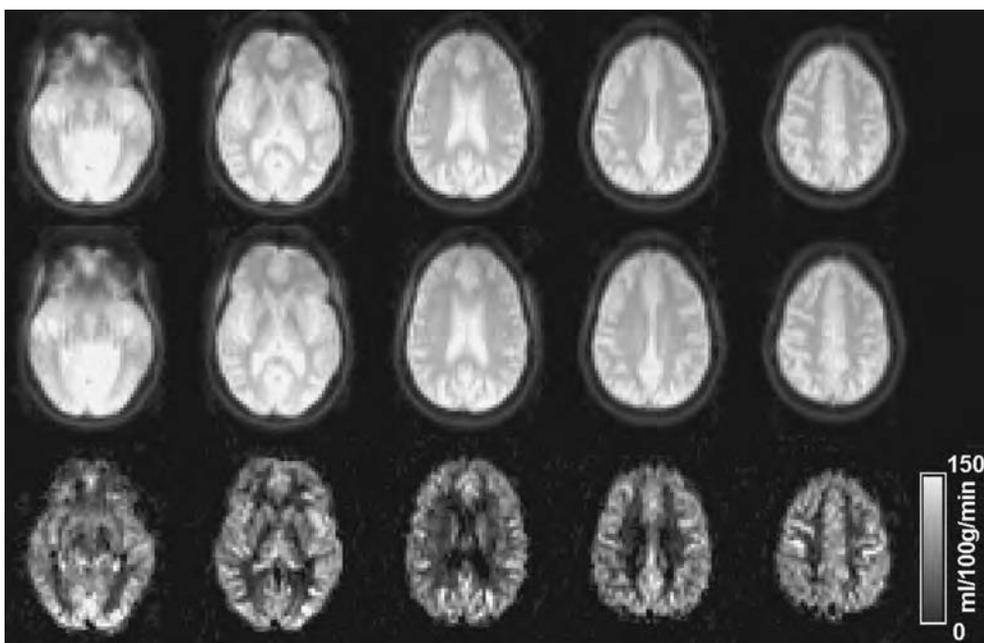

Figure 15.2 Absolute cerebral blood flow (CBF) maps using pseudocontinuous ASL MRI. The duration of the image acquisition was approximately 5 minutes and no contrast agent was used.

While evoked fMRI based on specific external stimuli has been used for more than two decades, there has been a recent surge in the use of BOLD MRI to study resting-state brain activity. We therefore focus our discussion on the resting state fMRI. Since the current analysis of the resting state data has primarily focused on the connection between two or more brain regions rather than individual regions, this technique is also known to as functional connectivity MRI (fcMRI).

Intrinsic brain activity can be investigated using spontaneous fluctuations in resting-state fMRI signals (Biswal et al., 1995). As illustrated in Figure 15.3, fMRI signals from the left and right primary sensorimotor cortices show highly synchronized fluctuations at rest, and “functional connectivity” maps based on the synchrony can be obtained by cross-correlation analysis using signal from a selected brain area as a “seed point” or reference. Brain connectivity maps in the absence of task performance have been reported to follow specific brain circuits, including sensorimotor, visual, auditory, and language-processing networks (Beckmann et al., 2005; Biswal et al., 1995; Cordes et al., 2000; Fox et al., 2005; Greicius et al., 2003; Lowe et al., 1998; Xiong et al., 1999). Among these observations, the existence of a brain network including posterior cingulate cortex (PCC) and medial prefrontal cortex (MPF) has been reported (Fox et al., 2005; Greicius et al., 2003). This finding supports previous suggestions that there is a functionally significant “default brain mode” in the resting state (Gusnard et al., 2001; Raichle et al., 2001). Because the brain expends a considerable amount of energy for neuronal-signaling

processes in the absence of a particular task (Shulman et al., 2004; Sibson et al., 1998), it is further argued that, in pursuit of better understanding of brain functions, observation of intrinsic brain activity may be at least as important as that of evoked activity (Gusnard et al., 2001; Raichle et al., 2001).

Various applications of resting-state fMRI to brain diseases have been demonstrated, including studies of Alzheimer’s disease (Greicius et al., 2003; Li et al., 2002), schizophrenia (Liang et al., 2006), epilepsy (Waites et al., 2006), cocaine dependence (Li et al., 2000), and antidepressant effects (Anand et al., 2005). Using a cross-correlation-based analysis method, Li et al. (2002) quantified functional synchrony in the hippocampus of patients with Alzheimer’s disease and demonstrated lower correlation of signals in patients with Alzheimer’s disease compared with age-matched mild cognitive impairment (MCI) participants and healthy controls. Their study suggested that resting-state synchrony may be used as a quantitative marker for diagnosis and stage of Alzheimer’s disease. Greicius et al. (2003) investigated the default brain mode activity in patients with Alzheimer’s disease using independent component analysis (ICA). They found that patients with Alzheimer’s disease showed decreased resting-state activity in the posterior cingulate and hippocampus, suggesting disrupted connectivity between these two brain regions, consistent with the posterior cingulate hypometabolism commonly found in previous PET studies of early Alzheimer’s disease. These studies demonstrated the utility of resting-state functional connectivity in the study of neurological and neuropsychiatric disorders.

Advanced approaches for analyzing resting-state fMRI data, beyond the traditional seed-based and ICA methods, have been developed in recent years. Quantitative analysis of complex networks, based on graph theory, has been successfully exploited to study brain organizations (Bullmore and Sporns, 2009; Sporns et al., 2005). Graph theory analyzes “graphs” consisting of nodes (e.g., anatomical regions of the brain) and edges (e.g., functional connectivity strength) connecting the nodes. It has been shown that brain systems exhibit topological features of complex networks, including “small-world” characteristics (Watts and Strogatz, 1998), modular structures (Meunier et al., 2010), and highly connected hubs (Buckner et al., 2009). For example, a small-world network possesses both high clustering and short path lengths, resulting in efficient information transfer on both local and global scales. The human brain, like many other networks such as social network and electrical power grids, has small-world properties representing an optimal balance between integration and segregation between subunits. Network analysis methods have been demonstrated to be useful in identifying dynamic changes of brain networks associated with development (Fan et al., 2011), aging (Wu et al., 2012), and neuropsychiatric diseases (Yao et al., 2010).

Despite extensive applications of resting-state functional connectivity in basic and clinical studies, the underlying neural mechanisms of these synchronized fluctuations in resting-state fMRI signal remain obscure. Effort has been made in recent years to investigate whether these coherent fluctuations have a neural basis. Using an animal model, the mechanisms were first examined by combined electrophysiological recordings and fMRI scans in the resting rat brain

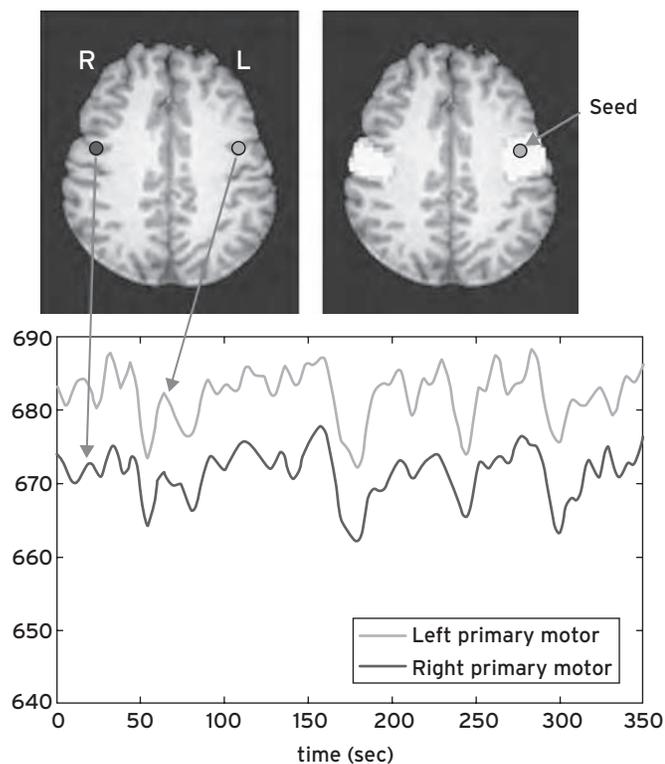

Figure 15.3 Functional MRI signals at rest (bottom) from the left and right primary sensorimotor cortices (upper left), and functional connectivity map (upper right), obtained from cross-correlation analysis using the left sensorimotor cortex as a reference.

(Lu et al., 2007). It was demonstrated that the interhemispheric γ -band power correlation and functional connectivity between the left and right somatosensory cortices were significantly greater than those between the somatosensory cortex and the visual cortex, and the electrophysiological and hemodynamic metrics were significantly and similarly modulated by anesthetic dose, suggesting a region-specific and anesthetic-induced state-dependent effect (Lu et al., 2007). The tight relationship between electrophysiological and resting fMRI signals was also demonstrated in human brains in patients with intractable epilepsy undergoing evaluation with surgically implanted grids of subdural electrodes (He et al., 2008). These studies provided an important bridge between the brain networks readily revealed by spontaneous BOLD signals and their underlying neurophysiology.

DIFFUSION-BASED MRI TECHNIQUES

Diffusion occurs as a result of random thermal motion of small particles such as water molecules in a given medium. The effects of molecular diffusion on MR signals have been studied since 1950s (Carr and Purcell, 1954; Hahn, 1950). A significant improvement of diffusion measurement using MR techniques was made in 1960s (Stejskal and Tanner, 1965) by utilizing magnetic gradient pulses to encode the phase dispersion caused by diffusion. Diffusion-weighted imaging (DWI) was developed in 1980s (Le Bihan et al., 1986) as an integration of MRI and diffusion-sensitive magnetic gradients. In ideal free diffusion, the diffusivity is uniform along all directions, or *isotropic*. However, a diffusion process in biological tissue, such as brain white matter, could be *anisotropic* because the diffusive molecules may experience direction-dependent restrictions due to specific arrangements of tissue structures. Diffusion tensor imaging (DTI) was developed in 1990s (Basser et al., 1994) as a tool to quantify the anisotropy of diffusion in biological tissue. An important advantage of DTI is that it provides rotation-invariant measurements, which means that the measurements are independent from participant positions, thus making longitudinal and group comparisons possible (Basser and Pierpaoli, 1996). In recent years, “beyond-tensor” imaging techniques (Tuch et al., 2003) have been proposed to overcome challenges encompassed in DTI, such as the handling of complex white matter structures. Tractography, a promising technique to delineate neuronal

pathways based on DTI or beyond-tensor techniques, has also been developed (Xue et al., 1999).

PRINCIPLES OF DIFFUSION MRI

For unrestricted diffusion in a three-dimensional space, the displacements of an ensemble of molecules can be described by the Einstein equation (Einstein, 1926)

$$\langle r^2 \rangle = 6D\tau_d$$

where $\langle r^2 \rangle$ is the mean-squared displacement, τ_d is the diffusion time, and D is the diffusion coefficient. Fundamental principles of diffusion MRI can be illustrated by the traditional pulsed gradient experiment (Stejskal and Tanner, 1965) designed to measure the spin echo signal attenuation caused by phase dispersion of diffusive nuclear spins in the presence of diffusion-sensitive gradients. As illustrated in Figure 15.4, in a spin echo pulse sequence, a pair of identical gradients is placed on both sides of the 180-degree refocus RF pulse. For a static spin, the two gradients would result in phase shifts with the same magnitude but opposite signs, respectively, leading to cancellation of the phase change at the echo time. However, for a diffusive spin the gradients would produce a net phase shift, and phase dispersion in an ensemble of spins would cause signal attenuation at the echo time. The spin echo signal in the presence of diffusion gradients, $S(b)$, with respect to that in the absence of the gradients, $S(0)$, can be expressed as

$$S(b) = S(0)\exp(-bD)$$

where b is called “b-factor,” a measure of the strength of the diffusion-weighting gradients, and is determined by the duration of the gradients δ , separation of the gradients Δ , and the amplitude of the gradient G . For the setting in Figure 15.4, $b = \gamma^2 G^2 \Delta^2 (\Delta - \delta/3)$, where γ is the gyromagnetic ratio. Diffusion MRI can be implemented by a combination of an imaging sequence with the diffusion-sensitive gradients to map diffusion coefficient in an object. Diffusion coefficient measured in biological tissue is often influenced by restricted diffusion due to complex microscopic structures as well as macroscopic motion such as blood perfusion, and therefore, diffusion strength measured in biological systems is generally termed *apparent diffusion coefficient* or ADC.

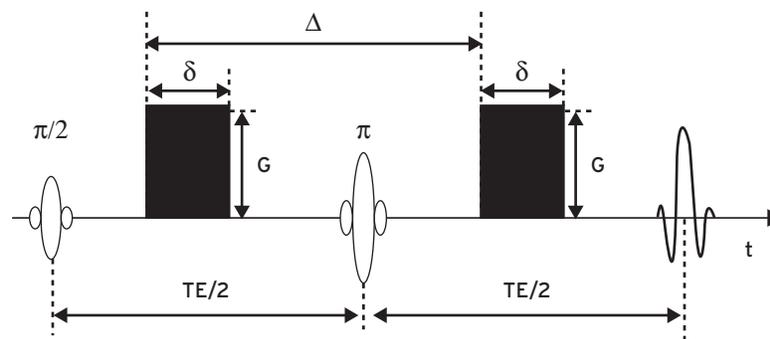

Figure 15.4 Schematic diagram of the Stejskal-Tanner pulsed gradient diffusion experiment.

DIFFUSION TENSOR IMAGING

Diffusion tensor imaging is a diffusion-imaging technique to characterize diffusion anisotropy (Basser et al., 1994). Molecular diffusion in biological tissue is often anisotropic due to varied restriction along different directions. For instance, water molecules in a white matter fiber fascicle typically diffuse faster along the fibers compared with those that cross the fibers. Diffusion in such an anisotropic medium needs to be described by multiple diffusion coefficients accounting for the direction dependence. In the formulation of DTI (Basser et al., 1994), the diffusion coefficient is no longer characterized by a scalar parameter D , but rather, by a 3×3 tensor D :

$$D = \begin{pmatrix} D_{XX} & D_{XY} & D_{XZ} \\ D_{YX} & D_{YY} & D_{YZ} \\ D_{ZX} & D_{ZY} & D_{ZZ} \end{pmatrix}$$

where $D_{ij}(i, j = x, y, z)$ denotes the cross-correlation of the diffusion coefficient between the i and j axis, and thus, D is always symmetric, that is, $D_{ij} = D_{ji}$. Similarly, a 3×3 matrix b is employed in DTI with elements b_{ij} representing the b-factor corresponding to the element D_{ij} in D . Thus, the diffusion-weighted signal attenuation can be expressed in the DTI formulation,

$$S(b) = S(0) \exp\left(-\sum_{i=X,Y,Z} \sum_{j=X,Y,Z} b_{ij} D_{ij}\right)$$

To determine the six independent elements in D , one needs to perform at least six diffusion-weighted measurements with the b matrices independent from each other. An additional experiment is also needed to provide a nondiffusion-weighted reference image. Therefore, a minimum of seven measurements is required to determine the diffusion tensor D . Recent studies have indicated that using more directions for diffusion encoding generally helps to improve the accuracy and/or the efficiency of the DTI technique, if these directions are appropriately optimized (Le Bihan et al., 2001).

Diffusion tensor can be analyzed based on the eigenanalysis theorem (Golub and Van Loan, 1996). Several

rotation-invariant indices have been widely used to visualize and quantify diffusion tensor maps in biological applications. These include (Basser et al., 1994) the mean diffusivity (MD), the average diffusion strength in all directions

$$MD = \langle D \rangle = \frac{\lambda_1 + \lambda_2 + \lambda_3}{3}$$

and the fractional anisotropy (FA), a *normalized* ($0 \leq FA < 1$) degree of the diffusion anisotropy

$$FA = \sqrt{\frac{3((\lambda_1 - \langle D \rangle)^2 + (\lambda_2 - \langle D \rangle)^2 + (\lambda_3 - \langle D \rangle)^2)}{2(\lambda_1^2 + \lambda_2^2 + \lambda_3^2)}}$$

where λ_1 , λ_2 , and λ_3 are eigenvalues of the diffusion tensor. Figure 15.5 illustrates maps of MD and FA calculated from the diffusion tensor map acquired from a human brain. In general, the MD map shows high intensities in ventricles and gray matter, where the diffusion is relatively isotropic with higher strength. The FA map highlights the white matter tracts in the brain, where the diffusion is highly anisotropic. The primary eigenvector of the diffusion tensor is useful to indicate the orientation of the well-organized tissue, such as fiber bundles in white matter, and can be used to track neural pathways.

“BEYOND-TENSOR” DIFFUSION TECHNIQUES

Despite the success of DTI in a variety of applications, challenges exist in handling complex brain structures, in which diffusion patterns are far more complicated than a tensor model can deal with. For instance, DTI often fails to correctly describe diffusion patterns in brain areas with fiber crossings. In the case of multiple fiber components sharing a single voxel, the major eigenvector of the diffusion tensor could be substantially biased from the actual fiber orientation, resulting in misleading fiber tracing. This is fundamentally limited by the tensor model because the diffusion tensor is only a second-order approximation (in terms of mean square fitting) to the real three-dimensional diffusion process (Basser et al., 2000). “Beyond-tensor” diffusion techniques based on

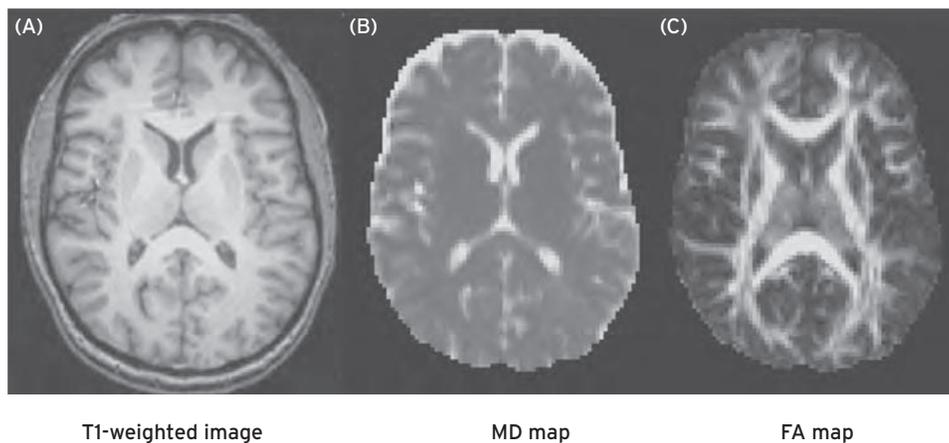

Figure 15.5 T1-weighted image (A) and corresponding mean diffusivity (B) and fractional anisotropic (C) images of a brain section.

higher order mathematical models, such as high angular resolution diffusion (HARD) and q-space imaging (QSI) have been proposed recently to overcome these difficulties (Frank, 2001; Jensen et al., 2005; Tuch et al., 2003; Zhan et al., 2004).

MAGNETIC RESONANCE SPECTROSCOPY

Magnetic resonance spectroscopy (MRS) is a noninvasive technique that can be used to investigate biochemistry of living systems. The first *in vivo* ^{31}P MRS experiment was conducted on a mouse head using a conventional spectrometer with a RF coil surrounding the entire head (Chance et al., 1978). Spectra of brain without contamination from other tissues were first obtained using a localization technique with a surface coil (Ackerman et al., 1980). In the past decades, MRS has evolved into a powerful tool for biological research and clinical diagnosis. Unlike MRI, which measures the signal from protons in water molecules, MRS usually detects the signal from compounds in much lower concentrations. Besides the most sensitive nuclear ^1H , MRS can also detect a range of nuclei including ^{31}P , ^{13}C , ^{19}F , ^{15}N , ^{23}Na , and ^7Li .

SPATIAL LOCALIZATION

The simplest way to obtain a localized spectrum is to use a surface coil, which produces a limited excitation volume close to the coil (Ackerman et al., 1980). The sensitivity distribution of the volume depends on the shape and orientation of the coil. For a single-loop coil, the selective volume is roughly a cylindrical

region with a radius and length about the same as the coil radius. A disadvantage of using surface coils for localization is that the sensitivity is extremely inhomogeneous in the volume, which makes quantification of spectroscopic data difficult.

Single-volume spectroscopy techniques use shaped RF pulses along with field gradients to selectively excite the spins in a defined volume. The most commonly used approaches in this category are point resolved spectroscopy (PRESS) (Bottomley, 1984) and stimulated echo acquisition mode (STEAM) (Frahm et al., 1987). Similar to slice selection in imaging, these techniques select a volume using three slab-selective RF pulses in the presence of field gradients in three orthogonal directions. A spin echo or stimulated echo is formed by the signal from the intersection of the three selected slabs.

Spectroscopic imaging (SI) or chemical shift imaging (CSI) uses phase encoding and/or frequency encoding to obtain spatial and spectroscopic information (Brown et al., 1982; Lauterbur et al., 1975). Like imaging, this technique acquires spectroscopic data in a matrix of spatially resolved voxels, allowing for observation of spectra in multiple regions simultaneously.

^1H MRS

Proton MRS can reliably detect *N*-acetyl-aspartate (NAA), creatine (Cr)/phosphocreatine (PCr), choline (Cho)-containing compounds including phosphocholine (PC) and glycerophosphocholine (GPC), and *myo*-inositol (Ins) in the brain. At high field strengths (>7 T), glutamate (Glu), glutamine (Gln), and other metabolites can be resolved. A spectrum acquired from the cingulate of a rat brain at 9.4 T is illustrated in Figure 15.6.

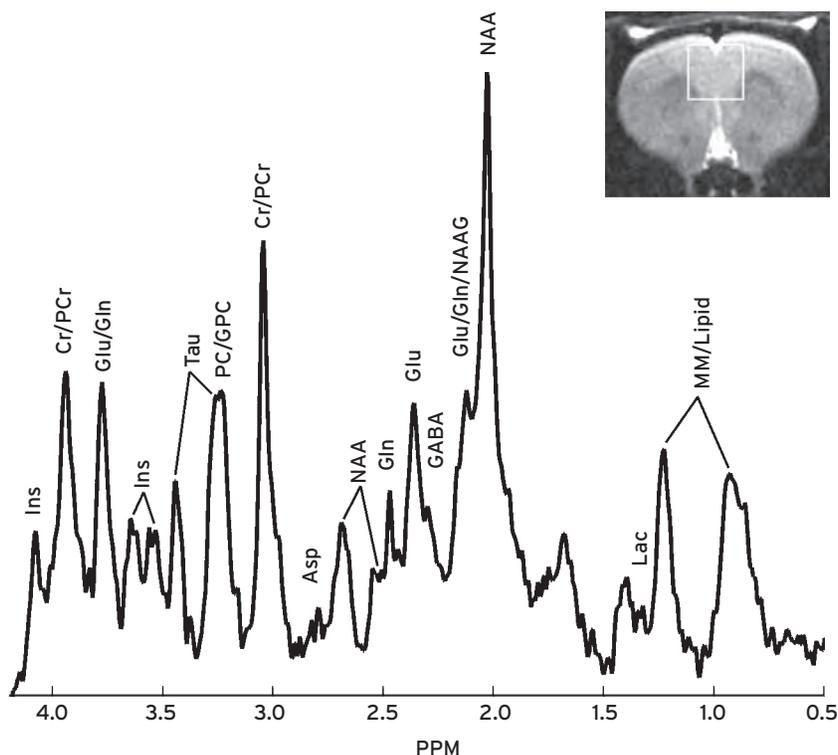

Figure 15.6 A STEAM spectrum from the rat cingulate, volume size = $3 \times 3 \times 3 \text{ mm}^3$, TR/TE/TM = 3000/9.1/10 ms, NEX = 300. Asp = aspartate, Cr = creatine, GABA = γ -aminobutyric acid, Gln = glutamine, GPC = glycerophosphocholine, Glu = glutamate, Lac = lactate, Ins = *myo*-inositol, NAA = *N*-acetyl-aspartate, NAAG = *N*-acetyl-aspartyl-glutamate, PC = phosphocholine, PCr = phosphocreatine, Tau = taurine, MM = macromolecules.

Brain metabolites measured by ^1H MRS are involved in cellular metabolism, neurotransmission, and cell membrane synthesis, or serve as a marker specific to neurons or glia (de Graaf, 1998; Govindaraju et al., 2000). NAA is commonly believed to be a marker of mature neurons, and a reduction of NAA level in the brain is indicative of neuronal loss and/or dysfunction. The protons of an *N*-acetyl CH_3 group provide the most prominent singlet resonance at 2.02 ppm, which can be measured robustly. Cr and PCr are observed as a strong singlet resonance at 3.03 ppm. The Cr/PCr level is relatively stable across the brain and is, therefore, often used as an internal concentration reference. This measure should be used with caution because reduced levels of Cr are observed in some pathological conditions, such as tumors and stroke. Cho is an important precursor of cell membrane synthesis, and increases of Cho indicate membrane damage to myelin or neuron. Cho, PC, and GPC give rise to a prominent singlet resonance at 3.20 ppm. Ins is believed to be a glial marker and an increase of Ins reflects gliosis. This compound has a prominent doublet of doublet centered at 3.52 ppm and a triplet at 3.61 ppm.

Glu is the major excitatory neurotransmitter in the central nervous system (CNS). Closely coupled to Glu, Gln is mostly located in glial cells as the end product of Glu catabolism and is a reservoir for Glu production in the neuron. γ -aminobutyric acid (GABA) is the major inhibitory neurotransmitter in CNS. These neurotransmitters play important roles in many neurological and psychiatric disorders, such as epilepsy, depression, and drug addiction. However, reliable detection and accurate quantification of Glu, Gln, or GABA *in vivo* remains challenging using proton ^1H MRS at low and middle magnetic field strengths (1.5–4.7 T), primarily due to spectral overlap of these compounds. Recently, new techniques such as echo time (TE)-averaged PRESS (Hurd et al., 2004) and STEAM with optimized timing parameters (Hu et al., 2007) have been developed to deal with this problem. An example of resolved Glu and Gln STEAM spectrum on the human brain with optimized TE and mixing time (TM) at 3 T is illustrated in Figure 15.7. Glu and Gln peaks at 2.35–2.45 ppm are well resolved and can be accurately quantified.

The three resonances of GABA at 1.89, 2.28, and 3.01 ppm are overlapped with the much stronger signals of NAA, Glu, and Cr, respectively. However, the resonance frequencies of GABA are affected by “J-coupling” while the overlapping singlet peaks of NAA and Cr are not. As such, editing spectroscopic techniques can separate the desired J-coupled compounds from the overlapping ones by manipulating their magnetizations (Mescher et al., 1998; Rothman et al., 1993). In the difference editing sequence, a selective 180° pulse is used to refocus the magnetization evolution due to J-coupling of the GABA-H4 spin (3.01 ppm). When editing pulses are turned ON/OFF in a two-step acquisition, the J-evolution of GABA-H4 is refocused/intact respectively, while the strong singlet resonance Cr at 3.03 ppm remains unchanged between the two scans. Difference of the two scans will eliminate the Cr resonance while preserving the GABA-H4 resonance at almost the same frequency. This spectral editing technique has been successfully implemented on 3T MR scanners recently and

has shown promise in assessing patients with neuropsychiatric disorders (Hasler et al., 2007).

SPECTRAL QUANTIFICATION

The goal of spectral quantification is to estimate metabolite concentrations from spectroscopic data. Although the area underneath a spectrum is directly proportional to the number of nuclei within the sensitive volume of the coil, it is not straightforward to achieve this goal. A number of factors have to be taken into account in quantifying spectroscopic data (Kauppinen and Williams, 1994).

Spectroscopic signal intensity is related to relaxation times and equilibrium magnetization. Magnetization recovers during a repetition time (TR) with longitudinal relaxation time (T_1) and decays during a TE with transverse relaxation time (T_2). Effects of T_1 and T_2 can be minimized using long TR and short TE. In many circumstances, however, knowledge of the relaxation times is needed to correct for these effects.

Spectral peak intensities can be affected by data acquisition and processing strategies as well as the existence of macromolecules in the sensitive volume. For instance, in chemical shift imaging using phase encoding for spatial localization (Brown et al., 1982), the early data points in the free induction decay (FID) are not collected, resulting in baseline and line shape distortions in the spectrum. Appropriate processing techniques are needed to estimate the missing data points and thus to correct for spectral distortions. Macromolecules contribute to a broad baseline in a spectrum, which has to be removed in data acquisition or processing. Techniques to extract signal intensities, such as LCModel (Provencher, 1993) and jMRUI (Naressi et al., 2001), have been developed and widely used for spectral quantification.

Metabolite concentrations can be presented as ratios, for example, relative to Cr, which is thought to be relatively stable in normal brains. Recent studies demonstrated that absolute quantification of metabolites has added value for unambiguous data interpretation (Jansen et al., 2006). However, extra calibration steps are required to achieve absolute quantification. Several strategies have been developed for this purpose, including internal endogenous marker, external reference, replace-and-match method, water signal reference, and principle of reciprocity (Jansen et al., 2006). Although absolute quantification requires more time and expertise, it can improve the diagnosis utility of MR spectroscopy.

MEASUREMENT OF CEREBRAL METABOLIC RATE OF OXYGEN

Cerebral metabolic rate of oxygen (CMRO_2) is a measure of energy consumption in the brain. Because aerobic metabolism is the primary form of energy production in the brain (Magistretti and Pellerin, 1999), CMRO_2 is an important index of tissue viability and brain function. Disrupted oxygen metabolism is associated with a number of pathophysiologic conditions such as Alzheimer’s disease (Buckner et al., 2005; Ogawa et al., 1996), brain aging (Lu et al., 2011), multiple sclerosis

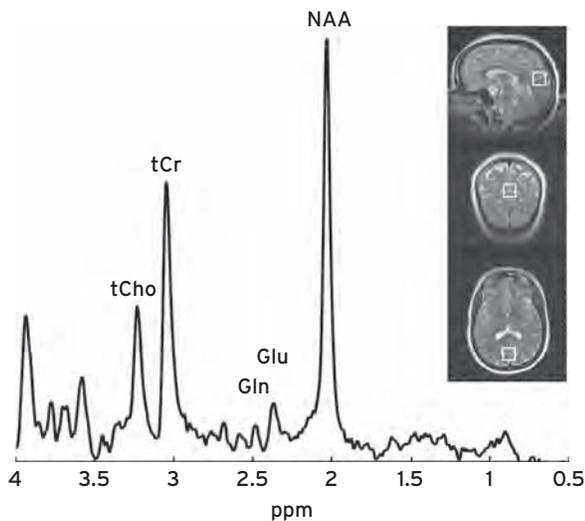

Figure 15.7 A STEAM spectrum with optimized TE/TM (72/6 ms) in the medial occipitoparietal junction of the human brain (voxel size = $20 \times 20 \times 20$ mm³). Glu and Gln peaks are well resolved at 2.35–2.45 ppm.

(Ge et al., 2012; Sun et al., 1998), Parkinson's disease (Borghammer et al., 2008), diabetes (Sieber et al., 1993; Uchino et al., 2010), traumatic brain injury (Glenn et al., 2003), and normal pressure hydrocephalus (Walter et al., 2005). Traditionally, brain oxygen metabolism can only be measured with positron emission tomography (PET). Unfortunately, the measurement is only available in a limited number of institutions where an on-site cyclotron is available and, furthermore, technical limitations such as long scan duration, high cost, and high risk have prevented oxygen metabolism measurement from becoming a routine procedure. Recent advances in MRI technologies have provided an opportunity to fill this gap. Over the past few years, a number of emerging techniques have been developed and extensively tested to a point that it is now feasible to measure human brain metabolism using completely noninvasive procedures on a standard 3-Tesla scanner.

CMRO₂ can be measured by combining several noninvasive measures obtained from MRI and pulse oximetry (Xu et al., 2009). The theoretical basis of the method is the Fick principle (Kety and Schmidt, 1948):

$$CMRO_2 = CBF \cdot (Y_a - Y_v) \cdot C_a$$

A graphical illustration of this relationship is shown in Figure 15.8a. In brief, arterial vessels deliver blood that has an oxygenation level of Y_a , the flow rate of which is denoted by CBF. When the blood transits through capillary beds, a portion of the carried oxygen is extracted by brain tissue for its metabolism, the rate of which is denoted by CMRO₂. The portion that remains in the blood will determine the venous oxygenation, Y_v , and is drained through veins. C_a is the amount of oxygen molecules that a unit volume of blood can carry, assumed to be 897 $\mu\text{mol O}_2/100$ ml blood based on physiology literature (Guyton and Hall, 2005). Therefore, once CBF, Y_a , and Y_v are experimentally measured, CMRO₂ can be determined using the Fick principle.

In the preceding equation, Y_a can be easily measured with noninvasive pulse oximetry on a fingertip. Note that arterial oxygenation is identical throughout the body; thus, measurement made at a finger can be used for brain calculation. A number of MR techniques are available for quantitative measurements of CBF. For global CBF, one can use a phase contrast MRI applied on the feeding arteries of the brain (Fig. 15.8b) (Aslan et al., 2010; Bonekamp et al., 2011; Lu et al., 2011; Xu et al., 2009). For region-specific CBF, a noninvasive technique, arterial-spin-labeling (ASL), can be used (Aslan et al., 2010; Dai et al., 2008; Detre and Alsop, 1999; Edelman et al., 1994; Golay et al., 1999; Kim, 1995; Kwong et al., 1995; Liu et al., 2011; Wong, 2007; Wu et al., 2007). The most challenging component is the measurement of Y_v , which has seen a great deal of technical development over the past several years.

One of the MRI approaches to quantify global venous oxygenation is based on the relationship between blood T2 and oxygenation and was termed T2-relaxation-under-spin-tagging (TRUST) (Lu and Ge, 2008). The TRUST MRI technique applies the spin labeling principle on the venous side and acquires control and labeled images, the subtraction of which yields pure venous blood signal (Fig. 15.8c). T2 value of the pure venous blood is then determined using nonselective T2 preparation pulses, minimizing the effect of flow on T2 estimation (Lu and Ge, 2008; Lu et al., 2012). Despite the lack of spatial information, this approach has the advantage of being fast and reliable (Liu et al., 2012). Intrasection and inter-session coefficient of variation (CoV) of this technique was $2.8\% \pm 1.3\%$ and $5.9\% \pm 1.6\%$, respectively, suggesting a high reproducibility of this technique. This CMRO₂ technique has so far been applied in studies of cognitive aging, Alzheimer's disease (AD), cocaine addiction, and multiple sclerosis (MS) (Ge et al., 2012; Lu et al., 2011). Another promising T2-based MRI method, quantitative imaging of extraction of oxygen and tissue consumption (QUIXOTIC) (Bolar et al., 2011), aimed to measure regional oxygenation. This technique uses velocity-selective spin tagging to separate venular blood from arterial blood and static tissue (Bolar et al., 2011). In combination with ASL MRI technique, absolute CMRO₂ map can, in principle, be generated.

Venous oxygenation can also be measured using susceptibility differences between oxygenated and deoxygenated blood. It has been shown that blood oxygenation in major blood vessels can alter the magnetic susceptibility difference between intravascular blood and surrounding brain parenchyma (Fernandez-Seara et al., 2006; Haacke et al., 1997). This concept has been extended to measure venous oxygenation in smaller vessels, which, in combination with regional CBF measured by ASL technique, yields regional CMRO₂ values (Fan et al., 2012). The major limitation of the susceptibility-based approaches is that the veins being measured need be parallel to the main magnetic field. The angle between vessel geometry and main magnetic field will cause bias to the oxygenation measurements.

Alternatively, calibrated fMRI has been shown to provide quantitative measurement of CMRO₂ as well. This approach is based on a generalized calibrated MRI signal model (Bulte et al., 2012; Gauthier et al., 2011). By having the subjects undergo

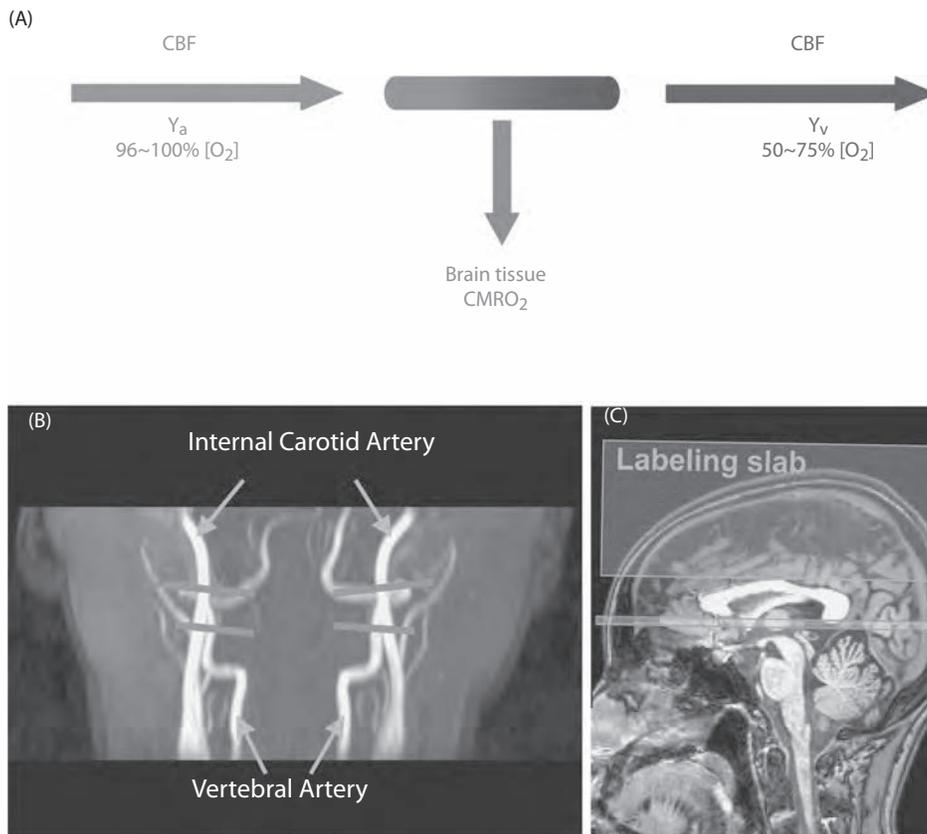

Figure 15.8 Illustration of cerebral metabolic rate of oxygen ($CMRO_2$) measurement using MRI techniques. (A) Relationship among physiologic parameters associated with oxygen demand and supply. (B) Slice locations of phase contrast MRI for the measurement of cerebral blood flow. Each of the imaging slices (gray horizontal) is placed at one of the four feeding arteries of the brain before they enter the skull. (C) Slice location of T2-relaxation-under-spin-tagging (TRUST) MRI for the measurement of venous oxygenation in superior sagittal sinus. Small rectangular slab—imaging slice. Large rectangular slab—labeling slab.

two physiologic challenges of hypercapnia and hyperoxia breathing, two forms of the signal equations can be obtained. Solving the two equations will provide parameters that can further yield $CMRO_2$ map (Gauthier and Hoge, 2012). A major limitation of the calibrated fMRI method is the complexity of experiment procedures, the subject burden to perform hypercapnia and hyperoxia breathing, and the large number of assumptions used in the model.

STRUCTURAL IMAGING USING MRI

With recent advances in high-field MR imaging technology and the development of parallel imaging acquisitions, structural MR images can be obtained with higher spatial resolutions and signal-to-noise ratio (SNR). Whole-brain images with a resolution of $1 \times 1 \times 1 \text{ mm}^3$ are now routinely acquired with scan durations of 4 to 8 minutes. This renders to MRI the capability of evaluating regional volumetric changes for various tissue types, such as gray matter, white matter, and CSF; this is especially useful for studies of psychiatric disorders because the involved brain regions may be relatively diffused and changes can be subtle. The typical MR pulse sequence used is called magnetization-prepared rapid acquisitions of gradient-echo (MPRAGE) (Mugler and Brookeman, 1991), and the resulting images are T1 weighted, with clear contrast

between gray and white matters. This technique is increasingly used to assess brain atrophy in longitudinal and cross-sectional studies. The MRI data can be analyzed using one of three different methods.

One method is to manually draw ROI on a slice-by-slice basis and to calculate the volume for each tissue type (Convit et al., 1997). The intersubject variability in head size can be corrected by dividing the ROI volume by the total intracranial volume. The advantage of such a method is that the procedure is relatively straightforward, and the results are less sensitive to SNR and image inhomogeneity. However, this approach is very time consuming, and the operators need to be well trained to produce consistent results. A less labor-intensive ROI approach is to use a semiautomatic procedure, in which a large ROI is selected based on simple landmarks; an algorithm is applied to segment the ROI into gray matter, white matter, and CSF; and the normalized tissue volume is used for atrophy comparison (Rusinek et al., 2003).

A second method is voxel-based morphometry (VBM). This processing strategy first uses spatial coregistration to normalize individual brains into the coordinates of a brain template (Ashburner and Friston, 2000; Rombouts et al., 2000; Wright et al., 1995), so that equivalent structures in different brains are roughly in the same location. Image segmentation is then performed to partition the normalized brain image into gray matter, white matter, and CSF. It is important to note

that, after the segmentation, the signal intensity in the original image is replaced by a value between 0 and 1, indicating the probability that the voxel belongs to gray matter, white matter, or CSF. These values are not influenced by the actual signal intensity in the raw MPRAGE image. This conversion from MRI signal to brain mask value is crucial in VBM as the scaling factor of the raw MRI signal is arbitrary and may be different for different participants. Therefore, a comparison of the signals in the MPRAGE image across participants is not meaningful. The next key step in VBM processing is the smoothing of the mask images. It is this step that creates the contrast between a normal brain and an atrophic brain, which can be used for statistical comparison. The spatial smoothing, in effect, allows the signal in a single voxel to reflect the concentration of the tissue in its surrounding areas. Therefore, a voxel in a thick gray matter layer will have a larger value than a voxel in a thin layer after smoothing, even though their values before smoothing were identical (e.g., both 1). In addition, the smoothing also reduces the effect of regional brain shape differences, which cannot be compensated for in the normalization step. Following smoothing, statistical comparison is performed on a voxel-by-voxel basis to detect the regions that show significant changes in tissue concentration. The advantage of the VBM method is that the processing steps are highly automated, and one can assess the atrophy for the entire brain easily. One disadvantage is that this processing requires the anatomical data to be of high quality, in terms of resolution and SNR, and data acquired using different MRI scanners or different imaging parameters may yield drastically different results.

A third method for analyzing structural images is deformation-based morphometry (Freeborough and Fox, 1998; Shen and Davatzikos, 2002). In this method, the brain image is transformed into the coordinates of a template brain or a baseline brain image. Then the information in the transformation matrix is used to determine whether the position of a particular brain structure is shifted or the shape has changed. Certain indices are often obtained from the transformation matrix (e.g., the Jacobian determinant), and they can be used for statistical analysis. The advantage of the deformation-based approach is that it does not use spatial smoothing to generate the volumetric information. On the other hand, the performance of this method would require the algorithm to be able to detect deformations at a very small scale.

AMYLOID IMAGING WITH POSITRON EMISSION TOMOGRAPHY

During the past decade, the neuroimaging community has seen the successful development of a few radiotracers for imaging of beta-amyloid (A β) (Jureus et al., 2010; Klunk et al., 2004; Koole et al., 2009; Zhang et al., 2005, 2007;), a hallmark protein in Alzheimer's disease (Hardy and Selkoe, 2002).

While a relatively large number of tracers have been reported to be capable of amyloid-specific imaging, two of them have made particularly large impact and are the foci of the discussion in this section.

Pittsburgh compound-B (PIB) is the most successful carbon-11-based radiotracer (Klunk et al., 2004). It is a benzothiazole agent that has high affinity to bind A β , and the tracer signal can be detected by PET scanners (Mathis et al., 2003). The PIB compound has been extensively tested in multisite studies (Klunk and Mathis, 2008). Validation studies comparing *in vivo* PIB imaging signal to postmortem tissue A β have also been reported, which showed strong correlations (Bacsikai et al., 2007; Ikonovic et al., 2008). Amyloid imaging using PIB has shown utility in many research areas such as Alzheimer's disease, mild cognitive impairment (Forsberg et al., 2008; Jack et al., 2008; Kemppainen et al., 2007; Pike et al., 2007), cerebral amyloid angiopathy (Johnson et al., 2007), cognitive aging (Aizenstein et al., 2008; Edison et al., 2007; Fotenos et al., 2008; Kemppainen et al., 2008; Mintun et al., 2006; Nelissen et al., 2007; Rodrigue et al., 2012), and Parkinson's disease (Johansson et al., 2008). Due to the large number of participants on whom PIB has been used and the extensive experience the field has gained on this tracer, it is now becoming a reference tracer that newly developed tracer is compared with (Klunk and Mathis, 2008). A limitation of PIB is that it is based on carbon-11 radioisotope, and the half-life of this agent is relatively short (~20 minutes). Therefore, in practice terms, the tracer would have to be generated on-site and be administered to the patient almost immediately. The equipment that is used to generate the carbon-11 radioisotope is called a cyclotron, and only less than 10% of the PET facilities in the United States have an on-site cyclotron. This requirement of PIB limits the use of this agent to the few medical centers and research institutions. Therefore, the impact of this agent so far has been mainly limited to the research realm.

The other tracer discussed in this section, Florbetapir, does not have this limitation. Florbetapir is based on fluorine-18 radioisotope, which has a half-life of about 110 minutes (Zhang et al., 2007). With this long half-life, it is feasible and practical for the agent to be synthesized at a centralized facility and then be shipped to various clinical and research PET facilities. This is a huge advantage in terms of practicality and scope of impact. On April 10, 2012, Florbetapir was approved by the U.S. Food and Drug Administration for use on adults who are being evaluated for Alzheimer's disease and other causes of cognitive decline. Therefore, the impact of amyloid imaging has evolved from research tools to clinical practice.

At present, the high costs associated with amyloid imaging remain to be the main obstacle to many researchers. It is estimated that the costs to obtain the amyloid imaging data are several times greater than that to collect the MRI data.

SUMMARY

It is clear that neuroimaging technologies will continue to contribute to our understanding of mental disorders and may emerge as a diagnostic tool and eventually be used for monitoring treatments. Many imaging biomarkers have already been proposed for the evaluation of diseases and to guide therapeutic procedures. Among neuroimaging modalities, MRI is a versatile technique in that it provides a variety of tools for *in vivo*

assessment of human brain, ranging from anatomical structure and neuronal functions to cerebral perfusion. Meanwhile, it is necessary to be cautious in interpreting and understanding MR data. Although MR images are often shown in high resolution and sometimes labeled in colors, investigators should always try to gain a full understanding of the results and be informed about potential uncertainties in the measurements and confounding factors in the quantification. PET imaging has the advantages of high specificity and sensitivity. With the development of new tracers, this imaging modality also has greater potentials in better understanding the neurobiology of mental illness.

16 | IMAGE-GUIDED BRAIN STIMULATION

MARK S. GEORGE, JOSEPH J. TAYLOR, AND JAIMIE M. HENDERSON

GENERAL ISSUES IN BRAIN TARGETING IN PSYCHIATRY

This chapter builds on the prior chapter, which described the new methods for imaging the brain. With our ability to image the brain's structure or function, we now have more sophisticated models, or maps, of how the brain works in health and disease. Luckily, in concert with the advances in brain imaging, there has been a steady expansion of new techniques that can focally stimulate the brain either invasively or noninvasively (Higgins and George, 2008). These new brain stimulation or neuromodulation methods work hand in hand with brain-imaging methods in order to determine where to stimulate or to examine the effects of stimulation (Sackeim and George, 2008). This chapter provides an overview of the ways in which the brain stimulation methods interact with, and even inform, brain imaging (Siebner et al., 2009). In particular, we will discuss the techniques where imaging is used to guide or target the stimulation. Before discussing the individual brain stimulation methods, there are several overview points needed in order to understand this exciting new area.

KEY POINT #1

In combining brain stimulation and imaging, is the stimulation being done offline after the imaging (guided by structure or function), or offline before and after imaging using imaging to assess the effects of stimulation, or are the imaging and stimulation online and truly interleaved? Figure 16.1 highlights an important point in understanding how to classify or conceptualize the different ways of integrating brain stimulation and brain imaging (from Siebner et al., 2009). “Offline” means that the stimulation and imaging are occurring on different occasions. “Online” means that stimulation and imaging are occurring simultaneously. In the neurosurgical literature, “offline” scans are also referred to as historical scans, as opposed to “online” real-time or intraoperative scans.

Perhaps the most common method to use imaging information to inform brain stimulation is to perform either a structural or functional scan on a patient or subject and then to use the offline scan to determine where to place the stimulation at a later time point. As we will discuss, there are many different ways to use an offline image to guide brain stimulation, and it is important to know the advantages and limitations of “image-guided” stimulation.

A less common offline approach is to perform the scan to assess the effects of the brain stimulation approach. This

can involve either a single scan after the stimulation, or a scan immediately before and then again after the stimulation, subtracting the two scans to determine the effect of the stimulation.

Finally, in some situations one can actually perform stimulation at the same time as the brain is being stimulated. This online stimulation allows one to visualize and understand the effects of stimulation. Currently this can be done with positron emission tomography (PET), single-photon emission computed tomography (SPECT), and functional magnetic resonance imaging (fMRI).

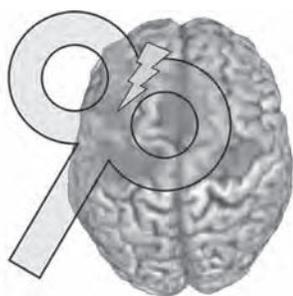

KEY POINT #2

When using scans to determine where to place the stimulation, it is important to remember that *there are differences between brain structure and function, and the two do not necessarily overlap*. Certain scans such as conventional computerized tomography (CT) or T1 MRI image the structure of the brain—its size and shape. Other scans reveal information about the function of the brain. These include images of blood flow (such as flow SPECT, oxygen [O15] PET, or the very common blood oxygen level-dependent [BOLD] fMRI technique) or metabolism (fluorodeoxyglucose [FDG] PET). It is important to realize that structure is not the same thing as function, and vice versa. One can have a brain region that appears normal structurally, but a small lacunar stroke at a distant location can make the function of broad areas of cortex change drastically. Similarly, one can have a vastly abnormal structural scan, say, congenital hemiatrophy, but with normal behavior and grossly normal brain function. It is thus important to understand which type of imaging information is present in a scan. Most commonly, areas of functional activation are overlaid onto a structural scan to allow more precise localization of function. Figure 16.2 depicts examples of different forms of imaging that can be used to guide or evaluate the brain stimulation methods.

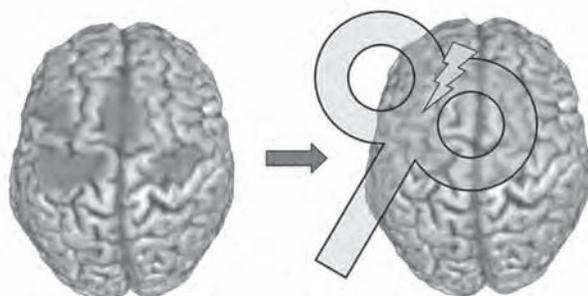

KEY POINT #3

In the case of cortical stimulation, *it can be difficult to identify homologous cortical structural sites across different individuals, in part due to morphological differences and varying gyral morphology*. Identification of highly conserved areas such as the motor strip and primary visual cortical regions is relatively straightforward with high-field MR imaging. However, gyral morphology varies greatly across individuals. About one third of humans have only two prefrontal gyri, and thus, they do not

(A) "Online" approach: concurrent TMS and neuroimaging

(B) "Offline" approach: neuroimaging before TMS

(C) "Offline" approach: TMS before neuroimaging

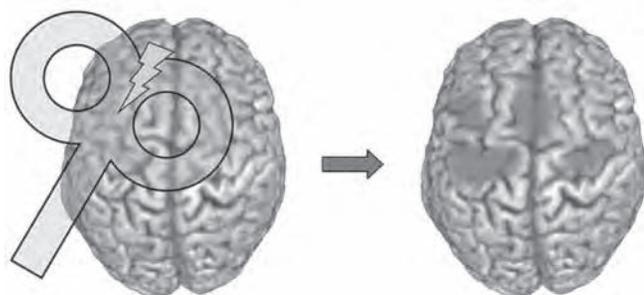

Figure 16.1 Different ways to combine imaging and stimulation. Image A shows the situation where the stimulation (in this case TMS) is being performed simultaneously with the imaging study. This is called "online" or real-time imaging. Image B shows the more common example where the information gathered in a separate scanning session, either structural or functional information, or both, is then used to position or target the location of the brain stimulation tool. This is called "offline imaging." Image C shows another example of offline imaging where imaging is done after the stimulation, in order to understand the effects of the stimulation. (Reprinted with permission from Siebner et al. 2009.)

by definition have a middle frontal gyrus. Even identical twins have widely varying gyral patterns (White et al., 2002). Thus, it may be difficult to guide brain stimulation methods to cortical regions based solely on a structural scan. For a full discussion of these issues (see Brett et al., 2002).

KEY POINT #4

Finally, should targeting of functional areas be performed using a single scan from a single individual, or using pooled group means from many scans mapped onto an individual's anatomy? On top of the variation in cortical structure, there is another problem where the functional location of a task varies as well across individuals. For example, the brain region that a given

individual uses to solve cognitive tasks can vary widely. In part the common practice of pooling group activation studies into a common group image, and then displaying that on a structural scan in a common brain space, may have led the field to "overphenologize" with respect to the cortical location, within individuals, that works to create a behavior. An example of this between-individual variation can be seen in Figure 16.3. Cigarette smokers were shown smoking-related cues while they were in an MRI scanner (Hanlon et al., 2012). Commonly these BOLD fMRI individual results would be averaged, and the results would be presented in a group image with one large area of mean activation. This would lead some to think that stimulation over the location in any given individual of the mean activation might actually influence craving. However, in Figure 16.2 we identified the actual peak locations for each individual. One can easily see the large variety of prefrontal brain regions used in this task. Thus, it may be that for certain behaviors we should do within-individual functional scanning in order to make sure that the stimulation method is in the correct location for that individual. There may be some locations that will stimulate a certain majority of individuals. There are additional concerns about the repeatability of the fMRI activation maps over time within individuals (Johnson et al., 2004), especially after they have learned or practiced a task.

With these guiding principles discussed or at least outlined, it is now worthwhile to examine exactly how the different brain stimulation methods have been combined with neuroimaging tools.

ISSUES FOR SPECIFIC BRAIN STIMULATION METHODOLOGIES

We will start with the least invasive of the brain stimulation methods, transcranial direct current stimulation (tDCS) and then proceed in terms of level of invasiveness, ending with deep brain stimulation (DBS). For each of these methods, we will discuss studies with offline scanning used to target or direct the device, then summarize studies with offline scanning illuminating what effect the device has on functional imaging scans, and finally discuss true online scanning.

TRANSCRANIAL DIRECT CURRENT STIMULATION

DESCRIPTION

tDCS involves placing two electrodes on the scalp and passing a small (usually 12 V) direct current between them. This remarkably simple technology has been around for over 100 years but has recently undergone a renaissance (Higgins and George, 2008). As current passes through the brain, it attempts to exit under the anode, causing the underlying cortex to become increasingly active (Nitsche et al., 2008). The opposite is true of the cathode. Areas under the cathode are largely inhibited in their function. If tDCS is applied to the scalp (and thus underneath to the brain), there is no immediately observable behavior change. In contrast to direct electrical stimulation, deep brain stimulation, or even transcranial magnetic stimulation (TMS), from the standpoint of changed external behavior,

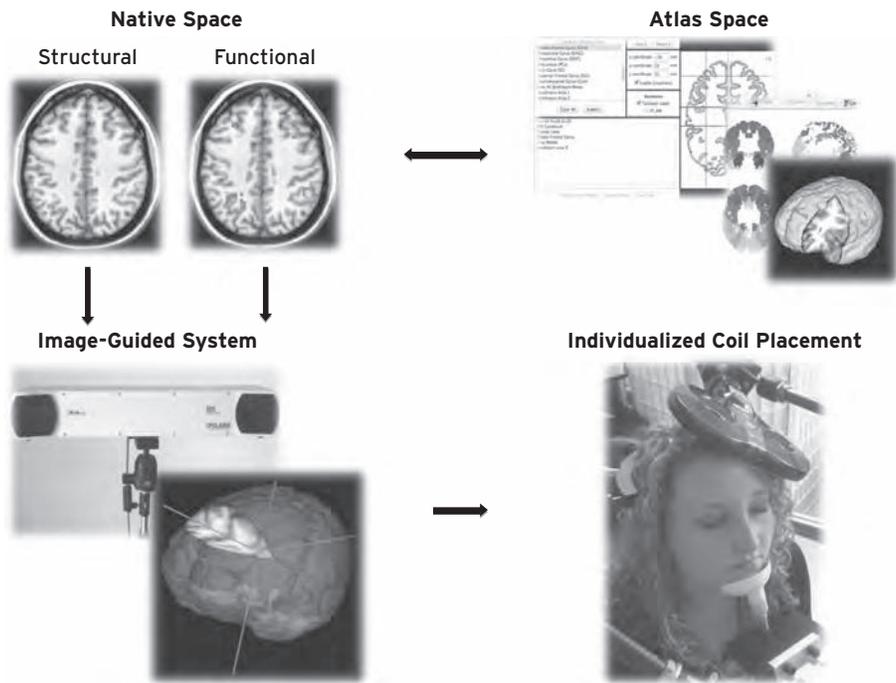

Figure 16.2 These are different ways that one can go from an image to targeting the stimulation method. At the far left is a structural scan. Commercial systems can then directly position the stimulation method over the skull in order to accurately stimulate the intended region. Because this image remains in the person's native space, there is little distortion and high fidelity. One can also overlay individual functional information directly onto the native space structural scan and use this to position the stimulation tool accurately for that person. Not uncommonly, however, researchers will have information gathered from multiple individuals. Because everyone's head varies in size, researchers then stereotactically normalize this information into a common brain atlas such as the Talairach atlas or the MNI atlas. In order to stimulate within an individual, this group information must be reverse transformed back into the person's native space and overlaid on their structural scan. This can then be targeted for brain stimulation using frameless stereotactic systems.

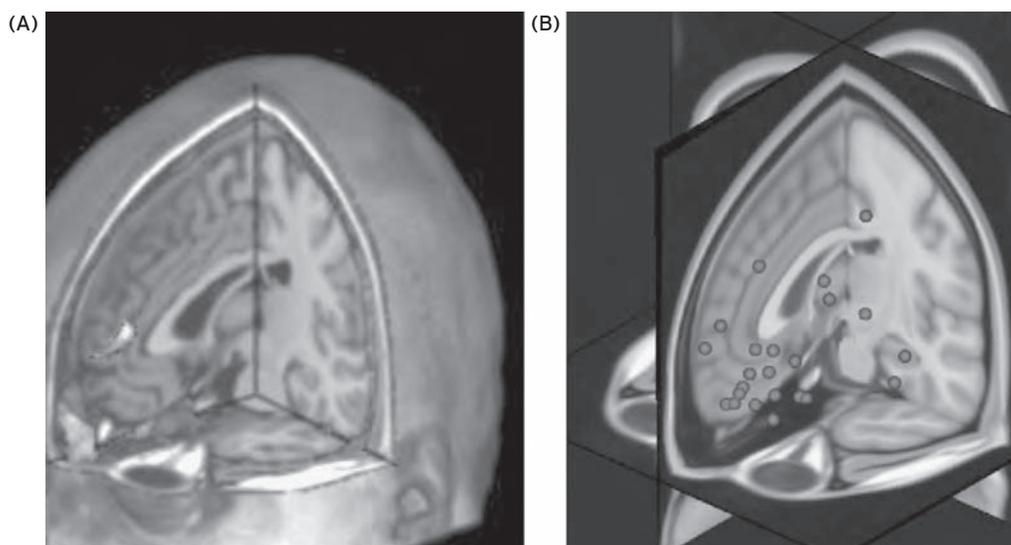

Figure 16.3 This figure illustrates the problem of between-individual variability in the functional location of various higher-order tasks. Much of the imaging literature consists of images like panel A on the left. This is the group mean area of activation for cigarette smokers who have been shown pictures of cigarettes. It is an area that is activated when they crave. It represents the mean, however. The panel to the right depicts each individual subject's major area of activation during the task. The image on the right is thus the raw data that creates the image on the left. If you were to stimulate the region in the left panel, many of the patients might not have a change in their craving, because their functional circuit varies widely from the group mean (seen on the scatter image to the right). This problem lies at the heart of how to use imaging to guide the brain stimulation treatments in a variety of disorders. (Reprinted with permission from Hanlon et al., 2012.)

nothing much happens during tDCS exposure. However, depending on the task being performed, and the region, tDCS can consistently either augment or subtly inhibit the activity within that brain region and thus influence performance and behaviors that rely on that brain region. Thus, tDCS is not really a brain stimulation method (stimulation here meaning directly causing neurons to depolarize due to an external stimulation) and is more of a neuromodulator (meaning that it changes the natural firing rates of a brain region). Some conceptualize the energy of tDCS like the effects of a catalyst on a chemical reaction. The presence of anodal tDCS requires less energy for the brain region to do its function (Molae-Ardekani et al., in press; Nitsche et al., 2007, 2008; Pena-Gomez et al., 2011; Stagg et al., 2011).

In general the pads are large, 2 × 2 cm sponges soaked in saline. These are secured on the head with straps. One group has developed a novel ring architecture that can provide more focal cortical stimulation, with the cathodes externally surrounding a central anode (Datta et al., 2008). However, even with this advance, tDCS is the most spatially crude of the current brain stimulation tools.

COMPUTER MODELS

Because of its simple design, with an MRI scan of a subject one can then model the likely flow of the tDCS current with different electrodes. This type of modeling was initially performed with time-intensive massive computers. Newer advances have reduced the time needed for these modeled maps.

OFFLINE TARGETING FOR PLACEMENT

Some investigators are using MRI image-generated maps to adjust the tDCS sponges in order to make sure current is flowing in the intended brain regions (see Datta et al., 2011; Turkeltaub et al., 2011)

OFFLINE IMAGING OF THE EFFECTS

Some of the most interesting imaging studies of tDCS have involved using MR spectroscopy to measure GABA or glutamate after subjects have received a standard tDCS dose. Excitatory (anodal) tDCS causes locally reduced GABA while inhibitory (cathodal) stimulation causes reduced glutamatergic neuronal activity with a highly correlated reduction in GABA (Stagg et al., 2009).

ONLINE INTERLEAVED SCANNING

There have not been many studies using tDCS during scanning, in part due to technical issues of artifacts, although there is one commercially available system (Pena-Gomez et al., 2011).

TRANSCRANIAL MAGNETIC STIMULATION

DESCRIPTION

Transcranial magnetic stimulation (TMS) allows for focal brain stimulation noninvasively from outside of the skull. An external electromagnet is pulsed and creates a powerful (1–3 T) magnetic field that passes unimpeded through the skull. When the magnetic field encounters neurons, it creates a charge in them and causes depolarization. Because the magnetic field

declines exponentially with distance from the coil, most TMS coils are only able to stimulate the superficial areas of the cortex. There is ongoing debate about how to design coils that can penetrate deeper into the brain. Most researchers agree that there is a depth/focality tradeoff, meaning that the deeper in the brain one penetrates with TMS, the less focal one can be (Deng et al., 2012; Peterchev et al., 2011).

A single TMS pulse over the motor area can produce a twitch or movement in the contralateral body. The electrical dose needed within the electromagnet to cause a thumb twitch (called the motor threshold [MT]) varies considerably across individuals but is remarkably constant within an individual over time. Early MRI structural studies found that about 60% of the between-individual variance in MT is accounted for by the distance from the skull to cortex (Kozel et al., 2000; McConnell et al., 2001). It is harder to determine how much TMS energy is needed to stimulate other “behaviorally silent” brain regions outside of the motor strip. In early MRI work with elderly subjects, we determined that 120% of the MT would likely result in a prefrontal dose of TMS sufficient to excite the prefrontal cortex, and thus 120% MT is commonly used in TMS depression treatment (Nahas et al., 2004).

COMPUTER MODELS

The Deng study cited earlier is the most extensive series of computer models to date of TMS. In early work in the field, researchers were able to actually use the MRI scanner to image the magnetic field distortions caused by the TMS coil (Bohning et al., 1997).

OFFLINE TARGETING FOR PLACEMENT

There are now several commercial systems available that allow a researcher or clinician to match (“register”) a structural MRI scan of a patient to the location of the TMS coil on the head surface, enabling real-time guidance of the TMS coil for a research study or treatment session. One of these systems (Nexstim, Helsinki, Finland) has been FDA (U.S. Food and Drug Administration) approved for presurgical mapping of the motor areas, allowing for safer resective surgery. The fidelity of this system is less than 7 mm difference from direct cortical stimulation. That is, the area actually stimulated by the TMS coil is within 7 mm of where the system indicates it to be on the scan, as confirmed with intraoperative direct electrical stimulation. This system also has a graphical interface that “knows” the field strength of the TMS coil, and then calculates based on the subject’s gyral orientation and can render an approximation of the induced electrical field generated by the TMS coil held over the scalp in a certain orientation.

While the technology exists to guide TMS to specific cortical regions, the neuroscience question of where to stimulate for a specific behavior is much more complicated. As discussed earlier, there are within-individual variations in the location, between-session changes due to plasticity or learning, and the fundamental problem that complex behaviors often depend on the coordinated activity of a network of regions.

This issue can be illustrated in the current controversy about where to stimulate with figure 8 TMS coils in order to treat depression. The early TMS clinical studies used a crude system called the “5 cm rule” to find the prefrontal cortex location for stimulating. One of us (M.S.G.) developed this with other researchers in the early 1990s by consulting the Talairach atlas and reasoning that 5 cm anterior and in a parasagittal line from the motor thumb area would place the coil in the center of the prefrontal cortex (Brodmann areas 9, 46). Thus, after finding the scalp location that best produced contralateral thumb twitching (which was needed in order to determine the motor threshold and determine the person’s dose), one could then put a cloth ruler on the scalp, find the prefrontal location, and proceed with treatment, without having to obtain an MRI and use formal image guidance. Unfortunately, this system did not take into account variations in head size or the location of motor cortex, and it likely results in 30% of patients being treated in the supplementary motor area, and not prefrontal cortex (Herwig et al., 2001). Thus, the field has now moved to systems using 6 cm, or based on the flexible EEG 10/20 system (Beam et al., 2009). An early analysis of imaging studies done in depression studies using the 5 cm rule found that more remitters received stimulation in anterior and more lateral locations (Herbsman et al., 2009) (see Fig. 16.4). A recent large study of the NIH OPT-TMS trial found that with the 5 cm rule, about 30% of patients needed the coil to be moved forward in

order to be over prefrontal cortex. Even with this nudge forward, 7 patients still had stimulation in premotor areas. None of these 7 patients remitted from their depression with TMS, suggesting but not proving that they were stimulated in the wrong location (Johnson et al., 2012).

Would personalized scanning be helpful in using TMS as a treatment for depression? This is an area where much more research is needed. A key issue is what task one would use to activate the intended treatment location. Affective regulation of response to pictures is one candidate that some researchers are exploring.

OFFLINE IMAGING OF THE EFFECTS

There have been many offline studies of the effects of TMS. It seems fairly clear that 10–20 minutes of treatment with high frequency TMS (10–20 Hz) causes increased activity (flow or metabolism) in local and connected regions in the brain. In contrast, 20 minutes of treatment with 1 Hz stimulation can cause the brain to temporarily decrease activity (Speer et al., 2000). These early PET studies mirrored the effects seen with TMS over the motor cortex measured electrophysiologically, and they are one of the cornerstones of knowledge about how to use TMS to temporarily excite or inhibit regional brain activity.

Additionally, important offline TMS studies include MRI scans performed before and after a course of treatment, showing no pathological changes in the brain as a function of treatment (Nahas et al., 2000). Finally, Baeken et al. (2011) performed PET scanning with a serotonin ligand before and after a course of daily left-prefrontal TMS. Successful rTMS treatment correlated positively with 5-HT(2A) receptor binding in the DLPFC bilaterally and correlated negatively with right-hippocampal 5-HT(2A) receptor uptake values. This type of imaging study reminds readers that the brain stimulation methods are really tools to change focal pharmacology (Baeken et al., 2011).

ONLINE INTERLEAVED SCANNING—COMBINING TMS WITH IMAGING

TMS can be performed inside the PET camera, producing truly interleaved online images of the local and distributed effects of the TMS pulse (Fox et al., 1997). Although there was initial controversy about the effect of the TMS pulse on the PET cameras, this has largely been resolved.

TMS can also be performed within an MRI scanner. This was initially thought to be impossible and unsafe, due to interactions between the TMS magnetic field and the MRI scanner’s field. There are some restrictions on what can be done (only figure 8 coils, biphasic pulses, etc.); however, truly interleaved TMS fMRI is possible (Bohning et al., 1999, 2000). These early imaging studies were important as they allowed researchers to determine the full brain effect of a TMS pulse. It appears that a TMS pulse results in brain metabolic changes that are similar in magnitude and extent to normal brain activity that results in a thought or produces a movement. Figure 16.5 shows the ways that interleaved TMS-fMRI can be used to precisely stimulate the appropriate region of the brain, and then, using the MRI scanner, to monitor the effects of the stimulation.

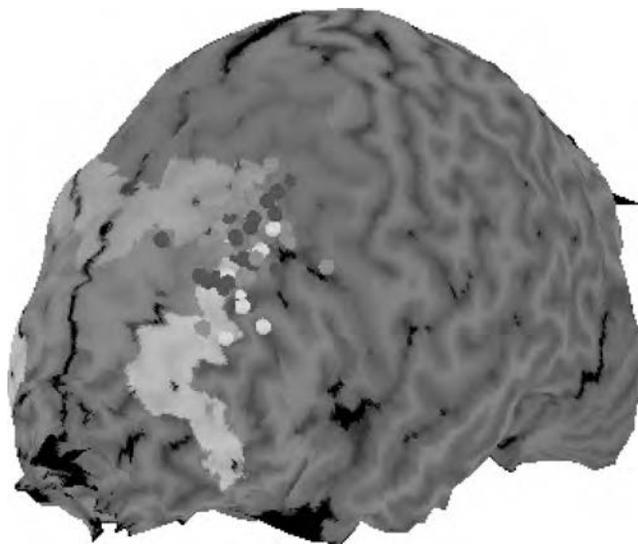

Figure 16.4 This figure illustrates the need for better positioning of the TMS coil for treating depression. David Avery and colleagues gathered structural MRI scans in all depressed patients being treated in double-blind trial of TMS for depression. The scalp location was determined using the rigid 5 cm rule, where the coil was placed 5 cm anterior from the best location for stimulating the thumb. Note the spread of the location when the data are all presented in a common atlas space. About one third of the patients were treated in supplementary motor areas (dark gray shaded areas). Patients who received placebo are in dark gray shaded circles. There were no placebo remitters. Patients who received active TMS are in light gray shaded circles, with active remitters in white shaded circles. The actively treated patients who remitted, on average, were treated at a location more anterior and more lateral than those who did not remit. This has led to adjustments in the way TMS coils are placed for treatment, with most methods now resulting in treatment more anterior and lateral than in early studies. (Reprinted with permission from Herbsman et al., 2009.)

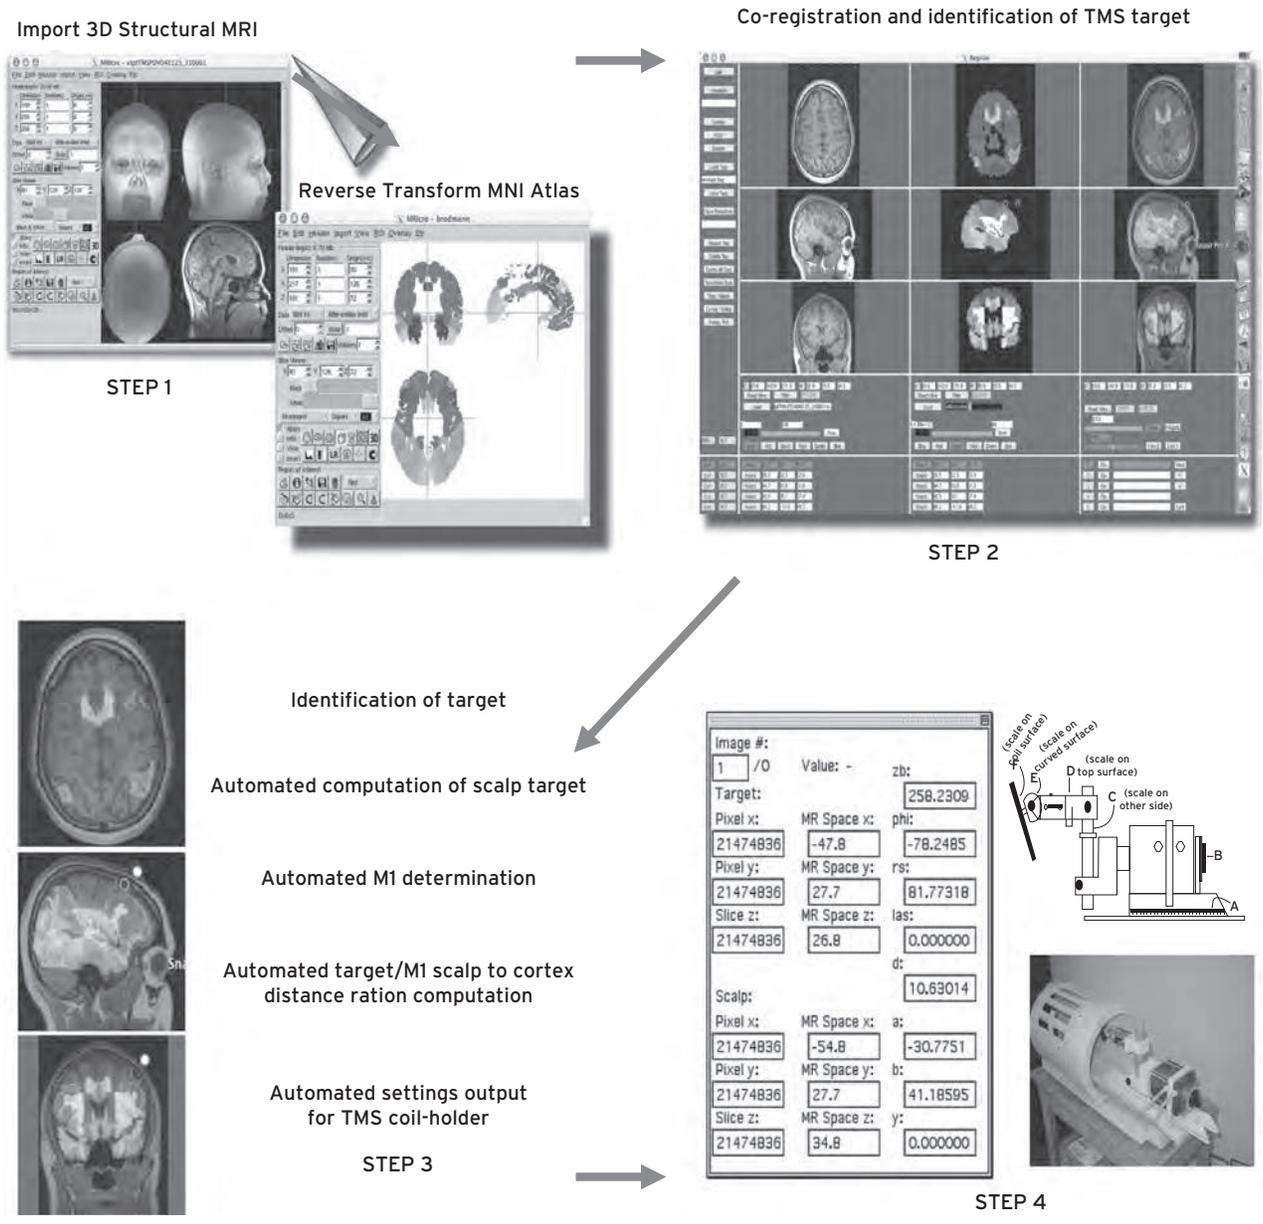

Figure 16.5 This image depicts how one can precisely position the TMS coil for accurate online stimulation within the scanner. Essentially, the person's native-space MRI scan is seeded with the data that describe the different Brodman areas. One can then determine on the person's scan, with the Brodman information loaded onto it, where to stimulate. These coordinates are then entered into a program that will calculate where on the scalp to position the coil, and that will then enter the correct adjustments to be made into the TMS coil holder. We call this "point and shoot." This approach has been reduced to a robot for PET studies. It is difficult, though not impossible, to build robots that work within the MRI suite that might do the same thing.

DBS

DESCRIPTION

Deep brain stimulation involves implanting electrodes into subcortical structures for the treatment of neurological and psychiatric disorders. It has been used in various forms since the 1950s, although it has only been since the late 1980s that chronically implanted systems have been widely available (Hariz et al., 2010). A linear array of electrodes (known as a "lead") is implanted into the target site using stereotactic surgical technique, and attached to an implantable pulse generator that provides continuous or intermittent pulsed electrical stimuli. Using an external programmer, the stimulation frequency,

pulse width, and amplitude can all be dynamically adjusted. DBS is approved by the FDA for the treatment of Parkinson's disease and tremor and is currently under investigation for use in the treatment of psychiatric disorders (Greenberg et al., 2008; Lozano et al., 2012).

COMPUTER MODELS

Stereotactic technique (from the Greek "στερεός," meaning "solid," and "τακτική," meaning "ability in disposition") is a method for introducing a therapeutic intervention to a particular three-dimensional location within the body, or more frequently, the brain. It involves correlating a target chosen

from preoperative image modality (either an atlas made from histological slices or a volumetric CT or MRI scan) with the analogous location in the target organ of interest. DBS is thus an inherently image-guided therapy.

OFFLINE TARGETING FOR PLACEMENT

DBS electrodes are most commonly introduced using a stereotactic frame, which mounts to the patient's head and provides mechanical adjustments in three orthogonal planes. A system of rods or markers, which can be imaged with MRI or CT (known as "fiducials"), provides a reference system that allows any point within the cranial volume to be precisely defined in three-dimensional space with reference to the base ring of the stereotactic frame. Once this target point is chosen, specialized software generates the settings for each axis, which are then entered into the frame. A burr hole is then made through the skull, and the lead is introduced to the target point using a trajectory guide mounted to the frame.

More recently, systems have been developed that provide real-time positional feedback without reliance on a stereotactic frame. Fiducial markers visible on both the patient and imaging studies are still required, but instead of defining an absolute coordinate system based on the frame, a process known as "registration" aligns the physical space of the operating room to the "image space" within the computer. Instruments are tracked through three-dimensional space by optical, sonic, or electromagnetic methods, allowing a less constrained approach to surgery. These so-called "image-guided" systems have been successfully used for DBS implantation (Henderson et al., 2004, 2005; Holloway et al., 2005).

OFFLINE IMAGING OF THE EFFECTS

DBS is commonly used as a continuous treatment modality, unlike rTMS or tDCS, which pulse intermittently, and thus could be thought of as being continuously "online." Imaging modalities such as PET collect data over relatively longer time-scales compared with fMRI or magnetic source imaging (MSI), and can be evaluated in both the on- and off-stimulation state. Many such studies have been carried out in patients undergoing DBS for various indications (Ballanger et al., 2009). PET has been successfully used to image the effects of DBS in the treatment of depression, showing normalization of prefrontal metabolic changes similar to those seen during other effective treatments (Mayberg et al., 2005).

ONLINE INTERLEAVED SCANNING

Since DBS systems consist of electrically conducting wires and electronic pulse generators, the introduction of strong magnetic fields such as those used for MRI scanning could induce current or heating. Patients with implanted DBS systems might thus be at risk for serious complications (Henderson et al., 2005), potentially limiting the use of functional MRI. Despite these concerns, several investigators have used fMRI to evaluate the effects of DBS in patients with movement disorders and chronic pain (Jech et al., 2001; Rezaei et al., 1999; Stefurak et al., 2003). fMRI has thus far not been performed in patients undergoing DBS for the treatment of psychiatric disorders.

CONCLUSIONS AND THE FUTURE

The brain stimulation methods are now making an impact in clinical neuropsychiatric practice, with prefrontal TMS FDA approved for treating acute depression, and DBS approved for medication-resistant Parkinson's disease. We have reviewed in this chapter how imaging informs the use of the stimulation methods. Brain images can either provide the road map that guides the placement of the stimulator or assess the effects of the stimulation. The two—imaging and stimulation—go hand in hand. Each improves the other. "Knockout or temporary lesion" stimulation studies can sometimes confirm or reject a brain behavior relationship suggested by pure imaging studies, which have problems attributing causality (Rorden et al., 2008). Just because a certain brain region is active on a scan at the same time as someone performs a behavior does not mean that that brain region is causing the behavior. The region could be causing the behavior, or responding to the behavior, or it could have nothing to do with the behavior and be merely correlational. Augmenting imaging studies with temporary knockout noninvasive stimulation studies can help in understanding how the brain works.

TOWARD A NEUROPSYCHIATRIC "CATH. LAB?"

In cardiology, rapid advances occurred when physicians were able to perform an intervention (placing a stent or expanding an artery) while simultaneously examining the effects of the stimulation. In the catheterization lab, cardiologists are constantly using fluoroscopy to image the heart while they are interacting with it. They are able to diagnose, intervene, reimagine, reintervene, and so on, until they achieve full blood flow (or deem that a full open-heart bypass surgery is needed). Imagine where the field of cardiology would be without this fundamental ability to intervene and image simultaneously in the cath. lab. Is it possible to have a "neuropsychiatric cath. lab"? To a simple extent, this is already possible, and neurosurgeons or interventional neuroradiologists do investigate aneurysms and strokes in a catheter lab environment. But problems with blood flow are not the main issue in many neuropsychiatric diseases that are not caused by acute problems with blood flow. Rather, the problem is one of abnormal or pathological activity of a circuit or system (e.g., the fear circuitry in anxiety disorders, mood regulation circuitry in depression, motor movement in Parkinson's disease, craving circuits in the addictions). Imagine having an imaging tool (like BOLD fMRI) that could quickly assess circuit behavior within an individual, and the psychiatrist or neurologist can then stimulate within the scanner in a manner that will produce long-term potentiation (LTP)-like or long-term depression (LTD)-like changes that would alter the function of the circuit. One could then immediately reimagine the activity of the circuit with real-time output (Johnson et al., 2012) and continue to intervene until the circuit behaved normally. The studies reviewed in this chapter demonstrate that for some issues the field is not far from creating such an environment. However, in other areas, there is much work to be done before such a dream could be realized.

Only more research will tell us if combined imaging/stimulation approaches might eventually treat some, many, or most psychiatric diseases.

DISCLOSURES

Dr. George has no equity ownership in any device or pharmaceutical company.

He does occasionally consult with industry, although he has not accepted consulting fees from anyone who manufactures a TMS device, because of his role in NIH and DOD/VA studies evaluating this technology. His total industry-related compensation per year is less than 10% of his total university salary.

Current or Recent (within past two years)

Pharmaceutical Companies

None

Imaging and Stimulation Device Companies

Brainsonix (TMS): Consultant (unpaid)

Brainsway (TMS): Consultant (unpaid), Research Grant

Cephos (fMRI deception): Consultant (unpaid), MUSC owns patent rights

Mecta (ECT): Consultant (unpaid), Research Grant

Neuronetics (TMS): Consultant (unpaid), company donated equipment for OPT-TMS trial, VA antisuicide study

Cervel/NeoStim (TMS): Consultant (unpaid), Research Grant

NeoSync (TMS): Consultant (unpaid), Research Grant

PureTech Ventures (tDCS, others): Consultant

Publishing Firms

American Psychiatric Press: Two recent books

Elsevier Press: Journal Editor

Lippincott: One recent book and a second edition

Wiley: One recent book

MUSC has filed eight patents or invention disclosures in my name regarding brain imaging and stimulation.

Mr. Taylor has no conflicts of interest to disclose. He is funded by NIDA (1F30DA033748-01).

Dr. Henderson serves on the Advisory Board of Nevro Corp. (stock options) and Circuit Therapeutics (stock options). He has also served in a consulting role for Proteus Biomedical (stock options). Stanford University receives support from Medtronic, Inc. for education of a trainee in Stereotactic and Functional Neurosurgery, which Dr. Henderson directs.

SECTION III | PSYCHOTIC DISORDERS

PAMELA SKLAR

Psychotic disorders disturb particularly human aspects of perception and cognition. The overall burden of suffering for patients, family, and society are huge, and these disorders have seemingly proven refractory to the best neurobiological and genetic experimental strategies. We remain without fundamental clarity regarding many key issues that could lead to improved diagnosis and treatment. There is now cause for optimism. In the last decade we have moved from knowing nothing about the types and number of genetic loci involved in these diseases to having a substantial understanding of rare and common variants that increase disease risk. The purpose of this section is to discuss the current state of research and understanding in nosology, genetics, genomics, biology, imaging, cognition, and pharmacology of psychotic disorders. Organizationally, the first five chapters cover the basic science and phenomenology of psychosis, the subsequent three chapters delve into animal and cellular models, and the final chapters address theoretical models and clinical aspects of psychosis and the neurobiology of bipolar disorder.

In Chapter 17, Morris Smith, Meisinger, and Malaspina discuss the historical evolution of the term “psychosis” and its prototypical disorder, schizophrenia, as well as its relationship to other mental illnesses with prominent psychotic symptoms such as bipolar disorder and schizoaffective disorder. They explain the development of current diagnostic schema, criteria, and reliability, as found in the American Psychiatric Association’s *Diagnostic and Statistical Manual of Mental Disorders* (DSM) and the *International Statistical Classification of Diseases and Related Health Problems* (ICD). Importantly, since the current nosology is phenomenological and symptom-based, they discuss directions for the future and ways in which genetics and neurobiology are likely to drive a more refined understanding of the disease categories.

In Chapter 18, Sklar covers the current status of the genetics of psychotic disorders, in particular schizophrenia and bipolar disorder. While both disorders have been repeatedly demonstrated to be familial, until recently they have proven unyielding to standard genetic tools. This has dramatically changed over the last half decade, and several aspects of the underlying architecture—the type and number of genetic changes that lead to liability—are now well established. This chapter explores the role of structural variation and common and rare single nucleotide variation. The overall focus is on understanding that the genetics of these disorders is highly complex, being both polygenic and multifactorial, with the strong prediction that psychotic disorder genetics will be ultimately defined through future research.

In Chapter 19, genomic syndromes in psychotic disorder are discussed by Kirov, O’Donovan, and Owen. One of the most fertile areas of genetic discovery over the last five years has been identifying structural lesions, copy number variants (CNVs), in the genome that predispose individuals to schizophrenia, bipolar disorder, and autism. These lesions generally have strong effects, harbor many genes, and result in multiple phenotypes; the current understanding of the most robustly associated CNVs are reviewed. However, understanding the role of these lesions is a rapidly changing area that will be influenced by neurobiology, clinical studies, and integration with other types of genomic data.

In Chapter 20, the applications of neuroimaging techniques to study the brain in schizophrenia are explored. Heckers, Woodward, and Ongur synthesize a vast literature that includes computed tomography (CT), single photon emission computed tomography (SPECT), positron emission tomography (PET), magnetic resonance imaging (MRI) of a variety of types, magnetic resonance imaging spectroscopy (MRS), and diffusion tensor imaging (DTI). Consistent observations regarding brain volume, connectivity, chemistry, and activation during psychosis have been observed and replicated, but the future lies in the exciting possibilities for deriving diagnostic markers by connecting neuroimaging with neurobiology, genetics, and clinical treatment.

In Chapter 21, Anticevic, Dowd, and Barch focus not on the psychotic symptoms such as delusions and hallucinations, but on abnormalities in cognitive functions that are responsible for some of the most debilitating aspects of schizophrenia and bipolar disorder. Over the years many direct tests of cognitive processing abnormalities in patients and controls have been made. Critical observations regarding working memory deficits in both its encoding and maintenance phase are leading to a deeper understanding of this aspect of schizophrenia. The direct connections that can be made through the use of functional neuroimaging are described and point to the involvement of the dorsolateral prefrontal cortex. In addition, dysfunction within reward and motivation systems are reviewed. Finally, exciting potential links with underlying biology and circuitry, particularly as they relate to the balance of excitatory and inhibitory signaling are drawn that should ultimately unravel the circuit changes responsible for symptom production and disease.

In Chapter 22, Pletnikov and Ross discuss the progress and limitations of using mouse models in studying psychotic disorders. The current generation of models is based largely on environmental exposures, drug-induced behaviors that

correlated with pharmacological developments, or lesion studies, and mimic aspects of the phenotype, but not the underlying pathophysiology convincingly. However, there is great hope for the future in applying the mature and advanced transgenic tools and animal models to newly emerging, validated loci from genetic and genomic studies.

In Chapter 23, Curley and Lewis explore the cellular details of inhibitory neurotransmission, its role in the synchronized firing of cells and networks, and the strong connections with schizophrenia. They discuss the elegant studies that have led to understanding the basic structure of inhibitory neurons, their subtypes, transmitters, contacts, and organization, as well as the mechanisms used for controlling and timing the activity of large numbers of cortical pyramidal cells. Numerous intriguing observations regarding GABA signaling as well as interneuron abnormalities and upstream NMDA-receptor signaling that have been observed in patients with schizophrenia emphasize the importance of inhibitory signaling in the pathology of schizophrenia.

In Chapter 24, exploration of cellular aspects of brain function continues with a focus on synaptic physiology. In this chapter, Grant focuses attention on the billions of contacts through which nerve cells communicate. Understanding the neurotransmitter receptors, ion channels, and membrane proteins that are in play at the synapse, as well as disruptions in rare neurological and developmental disorders, is likely to point to common pathways that will also be relevant to schizophrenia and other psychotic disorders.

In Chapter 25, Kwon, Soda, and Tsai discuss the developmental theory of schizophrenia. They particularly focus on a series of developmental factors that have not been discussed

elsewhere in this section including the environment, the role of myelin development, and pathways that are critical to neuronal development and neuronal migration.

In Chapter 26, Gur follows up the neurodevelopmental focus of the previous chapter with a clinical discussion of the proneness to psychosis. Identifying individuals with early symptoms that represent a “psychosis risk syndrome” is being helped forward through following neurobehavioral outcomes such as cognition in high-risk patients. This approach is complemented by detailed imaging measures investigating aspects of brain physiology, and increasingly, brain circuitry. These studies are frequently longitudinal, and the early work has largely been focused on, and will be discussed in relationship to, prodromal schizophrenia.

In Chapter 27, Tamminga and Ivleva review the neurochemical models of these illnesses. The evidence for and against the long-standing theories, including dopamine hyperfunction, glutamatergic hypofunctions, and altered inhibitory neurotransmission, are elucidated. The relation of these theories to treatment modalities is made clear, as well as a review of the current status of molecular targets for both the positive psychotic symptoms and cognitive dysfunction.

In Chapter 28, Burdick, Haggarty, and Perlis review the neurobiology of bipolar disorder. While there are genetic loci that overlap between schizophrenia and bipolar disorder, there are substantial differences between the two syndromes as well. In this chapter, the particular aspects of the clinical syndrome and neurobiology that appear more distinct from schizophrenia are covered, including evidence for involvement of circadian systems, mitochondrial function, and epigenetics.

17 | DIAGNOSIS OF THE PSYCHOSES

LIANNE MORRIS SMITH, JULIE W. MESSINGER, AND DOLORES MALASPINA

INTRODUCTION

Despite the currently accepted practice of separating textbook discussions of the non-affective (“schizophrenia-spectrum”) psychoses from the affective psychoses, this chapter considers both illnesses. The schizophrenia spectrum disorders (specifically, schizophrenia and schizoaffective disorder) were combined with bipolar disorder in this section because the diagnostic boundary between the non-affective and affective psychoses is an active topic of debate. This debate, initially sparked in the 19th century by observations of clinical contrasts between *dementia praecox* (now denoted schizophrenia) and manic-depressive insanity, continues to be fueled by mounting scientific evidence of overlap and dissimilarities in the epidemiology, genetics, neuroanatomy, and neuropsychiatry between and within the categories (for review, see Crow, 1995, and Moller, 2003). In order to provide the reader with a broad appreciation of the theories underlying the diagnostic grouping and separation of the categories, their clinical characteristics (as typified by schizophrenia and bipolar disorder) will be reviewed both individually and jointly. The clinical entity of schizoaffective disorder will also be a primary topic of discussion as it represents a bridging of the affective and non-affective psychoses. The scope of this section will be limited to schizophrenia, schizoaffective disorder, and bipolar disorder to allow greater depth of discussion, as most studies of psychosis have focused on these illnesses with relatively less data on other psychotic disorders (e.g., brief psychotic disorder, schizophreniform disorder, and delusional disorder).

THE CONCEPT OF PSYCHOSIS

Psychosis, a mental state characterized by impaired reality testing, is manifested by a constellation of symptoms that have been eloquently described since the age of Hippocrates (c. 460 B.C.–c. 370 B.C.). Schizophrenia is the best known of the psychotic disorders, and many of the classic symptoms of psychosis were originally described in patients that would today be diagnosed as having schizophrenia. Eugen Bleuler (1857–1939), the Swiss psychiatrist who coined the term *schizophrenia* (from the Greek *skhizein* “to split” and *phren* “mind”), summarized the schisms in behavior, thought, and emotion that he observed in patients with schizophrenia which are now mnemonically known as “the four As”: affect, associations (particularly the loose associations characteristic of a thought disorder), autism, and ambivalence. Kurt Schneider (1887–1967), a German

psychiatrist, later compiled a core group of “hallmark” disturbances of behavior and thought, termed *first rank symptoms* (FRSs) including delusions and hallucinations, which he emphasized were not meant to be diagnostic of schizophrenia but a useful guide in identifying the disorder. Schneider additionally described a list of *second rank symptoms* that were also intended as an aide in the particular diagnosis of schizophrenia versus other psychotic disorders. One of the most popular systems for categorizing symptoms of schizophrenia is the positive/negative grouping. The British neurologist John Hughlings Jackson (1835–1911) provided one of the earliest and the most extensive applications of the positive and negative symptom model to psychosis (a model he initially developed in the context of evolutionary theory). Jackson hypothesized that the brain is organized into strata of higher (more civilized) and lower (more primitive) layers. He proposed that delusions and hallucinations, the positive symptoms of psychosis, were “release” phenomena seen when impaired higher cortical regulators allowed emergence of unchecked activity from lower cerebral levels. Negative symptoms (e.g., affective blunting and avolition) were “dissolution” phenomena reflecting loss of functioning in higher centers. Multiple subsequent studies, using statistical techniques such as factor analysis, have found that the symptoms of schizophrenia, the classic disease of psychosis, do not fit into two disparate categories. Andreasen et al. (1995), for example, found that the symptoms of schizophrenia fell into three natural categories; they separate into psychotic and disorganized dimensions, and negative symptoms.

Although schizophrenia is considered the classic psychotic disorder and is the source of many of the original descriptions of psychosis, it was recognized as early as the 19th century that psychosis manifests across a broad range of other non-schizophrenic mental conditions including, most prominently, the affective disorders. It was also evident that the symptomatology presented by different patients with schizophrenia is a highly heterogeneous combination of the aforementioned positive and negative symptoms. This observation led to the concept of “the group of schizophrenias.” Emil Kraepelin’s (1856–1926) dichotomous distinction between *dementia praecox* and manic-depressive insanity (modern-day schizophrenia and bipolar disorder, respectively), which he primarily differentiated by differences in episodicity of symptoms and the long-term outcome, was one of the earliest attempts to categorize mental illnesses based on observable behavioral phenomena, which practice continues to the current day.

Phenomenology, a philosophical school founded by Austrian mathematician Edmund Husserl (1859–1938), was

formally applied to psychopathology, including the psychoses, by the German psychiatrist and philosopher Karl Jaspers (1883–1969) (Burg, 2008). Jaspers’s phenomenology focused on detailing descriptive accounts of a patient’s current subjective experiences heavily based on his/her self-report (unlike Kraepelin, he deemphasized longitudinal course), and emphasized the form of symptoms rather than content (e.g., the experience of visual hallucinations rather than the actual visions) in the diagnosis of a mental illness. In the more modern, Anglophone interpretation, phenomenology refers to diagnosis based on the observation of externally observable phenomena (Burg, 2008), with a less strict emphasis on the subjective experience of the patient.

The nosology, or diagnostic categorization, of psychotic disorders has been and continues to be heavily based on phenomenological (behavioral) descriptions of signs and symptoms, with considerably less focus on etiology. An area of particularly heated debate in psychiatric nosology is the distinction between the functional psychoses, schizophrenia and bipolar disorder, which can both present with severe psychosis. Despite the propensity for psychosis in both types of disorders, schizophrenia has been considered a primary psychotic disorder with minimal fluctuations in affective symptoms. By contrast, psychosis for those with affective illnesses (bipolar disorder and depression) is considered to be a secondary phenomenon (reviewed in Ivleva et al., 2008). However, the clinical distinction between “primary” psychosis and psychotic affective illness is often diagnostically unclear, as evidenced by the eventual designation of the nosologic category of schizoaffective psychosis in 1933 by Jacob Kasanin. Although Kraepelin’s dichotomy holds in the formal diagnostic literature, the validity of this distinction has been in question since the 1890s. Recent studies demonstrating the evidence for significant overlap in genetic liability for affective disorders and schizophrenia is discussed in chapter 18.

Another significant hindrance to clarity and reliability in the nosology of psychosis was an initial lack of a common language to describe mental illnesses. The widespread embrace of Freudian psychoanalytic theory in the early- to mid-20th century, which may have had the greatest impact in the United States, considerably shifted the goal of work with patients from nosology and diagnosis via the detailed observation of behaviors to the identification and exploration of intrapsychic conflicts (Andreasen, 2007). The landmark United States–United Kingdom Study (Zubin and Gurland, 1977) provided a needed and striking illustration of the heterogeneity in diagnostic practices between regions that resulted from inconsistent definition and utilization of specific diagnostic criteria. The study found that while there were similar total admissions rates for mental disorders in the United Kingdom and United States, there was a fourfold higher first admission rate for schizophrenia compared to affective psychosis in the United States versus the United Kingdom. The authors attributed this disparity to the “free-wheeling psychiatric interviews” and prevailing “psychiatric culture” of symptom interpretation in each country. Furthermore, they found that the United States and United Kingdom schizophrenia-affective psychosis diagnostic ratios converged significantly when clinicians used a

structured clinical interview which combined the Present State Examination (Wing et al., 1974) and the Psychiatric Status Schedule (Spitzer et al., 1970). Zubin and Gurland’s study served to highlight the improved reliability of standardized diagnoses based on operational criteria. It also underscored the underlying similarities between the affective psychoses and schizophrenia related psychosis.

THE DIAGNOSIS OF PSYCHOTIC DISORDERS BY THE FEIGHNER CRITERIA AND THE RESEARCH DIAGNOSTIC CRITERIA

Despite the American Psychiatric Association’s first *Diagnostic and Statistical Manual of Mental Disorders* (DSM-I), published in 1952, and second version (DSM-II) released in 1968, there remained significant concern in the scientific and clinical communities that the DSM and other standard glossaries of the time did not contain explicit criteria for psychiatric diagnoses that distinguished schizophrenia, schizoaffective disorder, and affective psychoses. The inconsistency and unreliability in diagnosis that was exemplified in the United States–United Kingdom study (Zubin and Gurland, 1977) remained despite the new environment of rekindled interest in nosology and the movement toward standardization. These circumstances led to the publication of the Feighner Criteria (Feighner et al., 1972), developed by a group of researchers based at the Washington University School of Medicine in St. Louis, Missouri. The Feighner Criteria provided diagnostic criteria for 15 mental illnesses, based on the most current evidence (clinical description, follow-up studies, and family investigations) at the time. Of particular interest to our topic, of course, was the categorization of the functional psychoses. In the Feighner system, mania was classified along with depression under the Primary Affective Disorders, while schizophrenia formed its own separate group, in accordance with Kraepelin’s dichotomy. Schizophrenia was marked by chronicity of delusions, hallucinations, or a thought disorder, lasting at least six months, with evidence of a fixed deterioration of psychosocial functioning (see Table 17.1A). There was relatively little detail provided on positive, negative, and disorganized symptoms, in contrast to later glossaries. Additionally, the criteria did not mention bipolar disorder, although mania (see Table 17.1B) was described with a requirement of at least two weeks duration of classic mood and behavioral symptoms, and a listing of exclusion criteria (including no prior episodes of schizophrenic illness). Schizoaffective disorder was also not included although in clinical practice it was considered under the category Undiagnosed Psychiatric Illness. The authors acknowledged the omission of several categories of illness that were coded in the DSM-II based on insufficient clinical data for diagnostic validation (Feighner et al., 1972).

Following the publication of the Feighner Criteria, the Research Diagnostic Criteria (RDC; Spitzer et al., 1978) were developed as a collaborative project of investigators from the Washington University School of Medicine and the New York State Psychiatric Institute. The RDC, published just ahead of the release of the *Diagnostic and Statistical Manual of Mental*

TABLE 17.1A. Feighner criteria for diagnosis of schizophrenia

For a diagnosis of schizophrenia, A through C are required.

A. Both of the following are necessary:

- (1) A chronic illness with at least 6 months of symptoms prior to the index evaluation without return to the premorbid level of psychosocial adjustment
- (2) Absence of a period of depressive or manic symptoms sufficient to qualify for affective disorder or probable affective disorder

B. The patient must have had at least one of the following:

- (1) Delusions or hallucinations without significant perplexity or disorientation associated with them
- (2) Verbal production that makes communication difficult because of a lack of logical or understandable organization (In the presence of muteness the diagnostic decision must be deferred.)

C. At least three of the following manifestations must be present for a diagnosis of "definite" schizophrenia, and two for a diagnosis for "probable" schizophrenia:

- (1) Single
- (2) Poor premorbid social adjustment or work history
- (3) Family history of schizophrenia
- (4) Absence of alcoholism or drug use within one year of onset of psychosis
- (5) Onset of illness before age 40

TABLE 17.1B. Feighner criteria for diagnosis of mania

For a diagnosis of mania, A through C are required.

A. Euphoria or irritability

B. At least three of the following symptom categories must also be present:

- (1) Hyperactivity (includes motor, social, and sexual activities)
- (2) Push of speech (pressure to keep talking)
- (3) Flight of ideas (racing thoughts)
- (4) Grandiosity (may be delusional)
- (5) Decreased sleep
- (6) Distractibility

C. A psychiatric illness lasting at least 2 weeks with no preexisting psychiatric conditions such as schizophrenia, anxiety neurosis, phobic neurosis, obsessive compulsive neurosis, hysteria, alcoholism, drug dependency, antisocial personality, homosexuality and other sexual deviations, mental retardation, or organic brain syndrome

Disorders III (DSM III; American Psychiatric Association, 1980), were "developed to enable research investigators to apply a consistent set of criteria for the description or selection of samples of subjects with functional psychiatric illnesses" (Spitzer et al., 1978: p. 773). They were initially developed as a National Institutes of Mental Health (NIMH)-sponsored collaborative project on the psychobiology of depressive disorders. However, they were adopted by a variety of other research groups and also had a significant impact on clinical work since several of the definitions, criteria, and semistructured interviews stemming from the study were utilized in DSM-III. The RDC, which was partially an elaboration of Feighner's Criteria, defined 25 major diagnostic categories and significantly expanded psychosis diagnoses. The definition of schizophrenia was modified and subcategories were delineated (see Tables 17.2A and 17.2B). Of note, the Feighner Criteria minimum duration of six months was reduced

TABLE 17.2A. Research diagnostic criteria (RDC) for schizophrenia, schizoaffective disorder, and bipolar disorder

SCHIZOPHRENIA
 Course:
 Acute-subacute-subchronic-chronic
 Subtypes:
 Paranoid
 Disorganized
 Catatonic
 Mixed (undifferentiated)
 Residual

SCHIZOAFFECTIVE DISORDER-MANIC OR DEPRESSED
 Course:
 Acute-chronic
 Subtypes:
 Mainly schizophrenia
 Mainly affective

BIPOLAR AFFECTIVE DISORDER
MANIC DISORDER
HYPOMANIC DISORDER
BIPOLAR WITH MANIA
BIPOLAR WITH HYPOMANIA

TABLE 17.2B. The research diagnostic criteria (RDC) for schizophrenia

A through C are required for the period of illness being considered.

A. During an active phase of the illness (may or may not now be present), at least two of the following are required for definite and one for probable:

- (1) Thought broadcasting, insertion, or withdrawal
- (2) Delusions of being controlled (or influenced), other bizarre delusions, or multiple delusions
- (3) Somatic, grandiose, religious, nihilistic, or other delusions without persecutory or jealous content lasting at least 1 week
- (4) Delusions of any type if accompanied by hallucinations of any type for at least 1 week
- (5) Auditory hallucinations in which either a voice keeps up a running commentary on the patient's behavior or thoughts as they occur or two or more voices conversing with each other
- (6) Nonaffective verbal hallucinations spoken to the patient
- (7) Hallucinations of any type throughout the day for several days or intermittently for at least 1 month
- (8) Definite instances of marked formal thought disorder accompanied by either blunted or inappropriate affect, delusions or hallucinations of any type, or grossly disorganized behavior

B. Signs of the illness lasted at least 2 weeks from the onset of a noticeable change in the patient's usual condition (current signs of the illness may not now meet criterion A and may be the residual symptoms only, such as extreme social withdrawal, blunted or inappropriate affect, mild formal thought disorder, or unusual thoughts or perceptual experiences).

C. At no time during the active period of illness being considered (delusions, hallucinations, marked formal thought disorder, bizarre behavior, etc.) did the patient meet full criteria for either probable or definite manic or depressive syndrome to such a degree that it was a prominent part of the illness.

(Spitzer et al., [1978] from *Neurobiology of Mental Illness*, 3rd Edition)

to two weeks in order to exclude the brief reactive psychoses and to include non-chronic cases. To exclude borderline and paranoid states, the "A criteria" symptoms were expanded to better reflect Schneider's (1959) first rank symptoms. Schizophrenia was also

subtyped according to temporality of symptoms (acute-chronic) and phenomenology of the episode (paranoid, disorganized, catatonic, mixed/undifferentiated, residual). Schizoaffective disorder (SAD) was newly included but as its own category of illness, given its unclear relationship to schizophrenia. Schizoaffective disorder was separated into manic and depressive subtypes in the RDC, with further qualifiers of temporality (acute-chronic) and phenomenologic characteristics (mainly schizophrenic versus mainly affective). The authors were not reticent in declaring the limitations of their diagnosis of SAD, stating:

There is no consensus on how to diagnose this condition, or even whether or not it represents a variant of affective disorder, schizophrenia, or a separate condition... we define this class symptomatically, requiring some temporal overlap of both the active signs of schizophrenia and the full depressive or manic syndrome.

(SPITZER et al., 1978: p. 776)

They also hypothesized that the acute form of SAD may be a form of atypical mood disorder, whereas the chronic form may be more related to schizophrenia.

The RDC also expanded the number of categories addressing bipolarity, with the inclusion of Manic Disorder and Bipolar Depression with Mania (Bipolar I). They note that Manic Disorder might be the more appropriate diagnosis for some “excited” patients formerly diagnosed with paranoid schizophrenia, and provide exclusion criteria to delineate it from SAD, manic type. Hypomanic Disorder and Bipolar Depression with Hypomania (Bipolar II) were also newly included but with the caveat that hypomania excludes psychotic features.

THE DIAGNOSIS OF PSYCHOTIC DISORDERS IN DSM-IV AND ICD-10

The fourth edition of the DSM (DSM-IV) was published in 1994, with a subsequent text revision (DSM-IV-TR) released in 2000. The DSM-5 is scheduled for publication in 2013, and with minimal alterations will replace DSM-IV-TR as the primary reference used for the diagnosis of psychiatric disorders in the United States. To the extent that it is possible, more harmony was sought between the DSM-5 and the 10th edition of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10; World Health Organization, 1992b), which is more commonly used in other countries. Both systems of diagnosis provide a categorical classification of mental disorders based on sets of defined phenomenological criteria. The definitions of schizophrenia, schizoaffective disorder, and bipolar disorder according to the DSM-IV-TR and ICD-10 are defined and contrasted later in this section.

In the DSM-IV-TR, schizophrenia is grouped under Schizophrenia and Other Psychotic Disorders. The diagnosis of schizophrenia requires the presence of at least two characteristic positive and negative signs and symptoms (“A” criteria) for a significant period over a 1-month interval (or less if successfully treated). No “A” criterion symptom is considered pathognomonic for schizophrenia, other than bizarre delusions

(the authors acknowledge that bizarreness can be challenging to judge) or auditory hallucinations involving running commentary or two voices conversing. The positive symptoms include delusions and hallucinations, as well as disorganized thoughts and behavior; three main negative symptoms (affective flattening, alogia, avolition) are specified, with other negative symptoms listed under Associated Features and Disorders. The B criterion specifies the need for significant impairment in psychosocial functioning. Criterion C specifies that the total duration of the behavioral change must be present for at least 6 months, and may include prodromal or residual periods when only negative symptoms are expressed or positive symptoms are seen in an attenuated form. Criteria D, E, and F are exclusion criteria, requiring rule-out of schizoaffective and mood disorders, substance-induced or causative medical conditions, and pervasive developmental disorders. The subtypes of schizophrenia (paranoid, disorganized, catatonic, undifferentiated, residual) are discontinued in the DSM-5.

In the ICD-10, schizophrenia is described under the category Schizophrenia, Schizotypal, and Delusional Disorders. Similar to the DSM-IV, the ICD-10 lists signs and symptoms, including classic Schneiderian first-rank and second-rank phenomena. The ICD-10 provides a more considerably detailed list of phenomena (see Table 17.3); for example, “persistent hallucinations in any modality, when occurring every day for at least 1 month, when accompanied by delusions (which may be fleeting or half-formed) without clear affective content, or when accompanied by persistent overvalued ideas” can be compared to the DSM’s simply listed requirements for “delusions” or “hallucinations.” The ICD-10 requires at least one item from a list of four symptoms, or two items from a second list of symptoms, which includes negative symptoms. The former list is akin to the DSM-IV specification that the presence of either bizarre delusions or voices dialoguing or providing running commentary alone is, with appropriate satisfaction of the Criteria B–F, diagnostic of schizophrenia. The most significant difference between the DSM and the ICD-10 is in the duration criteria. ICD-10 requires a one-month period of active symptoms, while DSM requires a one-month duration of active symptoms in the context of at least six months of the behavioral disturbance. Individuals with an overall duration of behavioral disturbance lasting between one and six months would meet criteria for a diagnosis of schizophreniform disorder in the DSM, whereas they would meet criteria for schizophrenia in the ICD-10.

In the DSM, schizoaffective disorder is listed under Schizophrenia and Other Psychotic Disorders. Schizoaffective disorder is defined as a chronic, uninterrupted illness in which mood (manic, mixed, or depressive) episodes overlap for a substantial portion of time with the active or residual symptoms of schizophrenia. It is divided into manic and depressive types, which require a history of a manic/mixed or exclusively depressive episodes, respectively. Criterion A specifies that the phase in which the mood and psychotic symptoms coincide must involve the full symptomatic and temporal criteria for the active phase symptoms of schizophrenia (see Criterion A for schizophrenia) and for the particular mood episode. The illness must also include at least a two-week period of positive psychotic symptoms (delusions or hallucinations) in the

TABLE 17.3. ICD-10 Diagnosis of schizophrenia, schizoaffective disorder, and bipolar disorder

SCHIZOPHRENIA
<p>G1. Either at least one of the syndromes, symptoms and signs listed under (1), or at least two of the symptoms and signs listed under (2), should be present for most of the time during an episode of psychotic illness lasting for at least one month (or at some time during most of the days).</p> <p>(1) At least one of the following:</p> <ul style="list-style-type: none"> a) Thought echo, thought insertion or withdrawal, or thought broadcasting b) Delusions of control, influence, or passivity, clearly referred to body or limb movements or specific thoughts, actions, or sensations; delusional perception c) Hallucinatory voices giving a running commentary on the patient's behavior, or discussing him between themselves, or other types of hallucinatory voices coming from some part of the body d) Persistent delusions of other kinds that are culturally inappropriate and completely impossible (e.g. being able to control the weather, or being in communication with aliens from another world) <p>(2) or at least two of the following:</p> <ul style="list-style-type: none"> a) Persistent hallucinations in any modality, when occurring every day for at least one month, when accompanied by delusions (which may be fleeting or half-formed) without clear affective content, or when accompanied by persistent over-valued ideas b) Neologisms, breaks, or interpolations in the train of thought, resulting in incoherence or irrelevant speech c) Catatonic behavior, such as excitement, posturing, or waxy flexibility, negativism, mutism, and stupor d) "Negative" symptoms such as marked apathy, paucity of speech, and blunting or incongruity of emotional responses (it must be clear that these are not due to depression or to neuroleptic medication) <p>G2. Most commonly used exclusion criteria: If the patient also meets criteria for manic episode or depressive episode, the criteria listed under G1.1 and G1.2 must have been met before the disturbance of mood developed</p> <p>G3. The disorder is not attributable to organic brain disease (in the sense of F0), or to alcohol- or drug-related intoxication, dependence, or withdrawal</p> <p>Comments: In evaluating the presence of these abnormal subjective experiences and behavior, special care should be taken to avoid false-positive assessments, especially where culturally or sub-culturally influenced modes of expression and behavior, or a subnormal level of intelligence, are involved.</p>
TYPES
<p>Paranoid, Hebephrenic, Catatonic, Undifferentiated, Post-schizophrenic depression, Residual schizophrenia, Simple schizophrenia</p>
SCHIZOAFFECTIVE DISORDER
<p>Note: This diagnosis depends upon an approximate "balance" between the number, severity, and duration of the schizophrenic and affective symptoms.</p> <p>G1. The disorder meets the criteria of one of the affective disorders of moderate or severe degree, as specified for each sub-type.</p> <p>G2. Symptoms from at least one of the symptom groups listed in the following, clearly present for most of the time during a period of at least two weeks (these groups are almost the same as for schizophrenia):</p> <ul style="list-style-type: none"> (1) Thought echo, thought insertion or withdrawal, thought broadcasting (2) Delusions of control, influence, or passivity, clearly referred to body or limb movements or specific thoughts, actions, or sensations (3) Hallucinatory voices giving a running commentary on the patient's behavior, or discussing him between themselves; or other types of hallucinatory voices coming from some part of the body (4) Persistent delusions of other kinds that are culturally inappropriate and completely impossible, but not merely grandiose or persecutory, e.g. has visited other worlds; can control the clouds by breathing in and out; can communicate with plants or animals without speaking, etc. (5) Grossly irrelevant or incoherent speech, or frequent use of neologisms (6) The intermittent but frequent appearance of some forms of catatonic behavior, such as posturing, waxy flexibility, and negativism <p>G3. Criteria G1 and G2 must be met within the same episode of the disorder, and concurrently for at least some time of the episode. Symptoms from both criteria G1 and G2 must be prominent in the clinical picture.</p> <p>G4. Most commonly used exclusion criteria: the disorder is not attributable to organic brain disease, or to psychoactive substance-related intoxication, dependence or withdrawal.</p>
TYPES
<p>Schizoaffective disorder, manic type Schizoaffective disorder, depressive type Schizoaffective disorder, mixed type Other schizoaffective disorders Schizoaffective disorder, unspecified</p>
MANIA WITH PSYCHOTIC SYMPTOMS
<p>A. The episode meets the criteria for mania without psychotic symptoms with exception of criterion C.</p> <p>B. The episode does not simultaneously meet the criteria for schizophrenia (F20) or schizo-affective disorder, manic type (F25.0).</p> <p>C. Delusions or hallucinations are present, other than those listed as typical schizophrenic in G1.1b, c, and d (i.e. delusions other than those that are completely impossible or culturally inappropriate, and hallucinations that are not in the third person or giving a running commentary). The commonest examples are those with grandiose, self-referential, erotic, or persecutory content.</p> <p>D. Most commonly used exclusion criteria: the episode is not attributable to psychoactive substance use (F1) or any organic mental disorder, in the sense of F0.</p>

(Continued)

TABLE 17.3. (Continued)

A fifth character may be used to specify whether the hallucinations or delusions are congruent or incongruent with the mood:
Mania with mood congruent psychotic symptoms (such as grandiose delusions or voices telling the subject that he has superhuman powers)
Mania with mood incongruent psychotic symptoms (such as voices speaking to the subject about affectively neutral topics, or delusions of reference or persecution)

ICD-10 SUBTYPES OF SCHIZOPHRENIA, SCHIZOAFFECTIVE DISORDER, AND BIPOLAR DISORDER

F20 SCHIZOPHRENIA

- F20.0 Paranoid schizophrenia
 - F20.1 Hebephrenic schizophrenia
 - F20.2 Catatonic schizophrenia
 - F20.3 Undifferentiated schizophrenia
 - F20.4 Post-schizophrenic depression
 - F20.5 Residual schizophrenia
 - F20.6 Simple schizophrenia
 - F20.8 Other schizophrenia
 - F20.9 Schizophrenia, unspecified
- A fifth character may be used to classify course:
- Continuous
 - Episodic with progressive deficit
 - Episodic with stable deficit
 - Episodic remittent
 - Incomplete remission
 - Complete remission
 - Other
 - Course uncertain, period of observation too short

F25 SCHIZOAFFECTIVE DISORDER

- F25.0 Schizoaffective disorder, manic type
 - F25.1 Schizoaffective disorder, depressive type
 - F25.2 Schizoaffective disorder, mixed type
 - F25.8 Other schizoaffective disorders
 - F25.9 Schizoaffective disorder, unspecified
- A fifth criteria may be used to classify the following subtypes:
- Concurrent affective and schizophrenic symptoms only
 - Concurrent affective and schizophrenic symptoms, plus persistence of the schizophrenic symptoms beyond the duration of the affective symptoms

F31 BIPOLAR AFFECTIVE DISORDER

- F31.0 Bipolar affective disorder, current episode hypomanic
- F31.1 Bipolar affective disorder, current episode manic without psychotic symptoms
- F31.2 Bipolar affective disorder, current episode manic with psychotic symptoms
 - With mood-congruent psychotic symptoms
 - With mood-incongruent psychotic symptoms
- F31.3 Bipolar affective disorder, current episode mild or moderate depression
 - Without somatic syndrome
 - With somatic syndrome
- F31.4 Bipolar affective disorder, current episode severe depression without psychotic symptoms
- F31.5 Bipolar affective disorder, current episode severe depression with psychotic symptoms
 - With mood-congruent psychotic symptoms
 - With mood-incongruent psychotic symptoms
- F31.6 Bipolar affective disorder, current episode mixed
- F31.7 Bipolar affective disorder, currently in remission
- F31.8 Other bipolar affective disorders
- F31.9 Bipolar affective disorder, unspecified

(From the World Health Organization, 1993, used with permission)

absence of mood symptoms. This latter specification primarily serves to differentiate schizoaffective disorder from mood disorders with psychotic features. Criterion C specifies that the mood symptoms must have been present for a “substantial portion” of the illness as determined by “clinical judgment.” In the DSM-5, the “substantial portion” of mood disturbance necessary for schizoaffective diagnosis is greater than 50% from the

illness onset. Criterion D excludes symptoms due to the direct effects of a substance or medical condition.

Similarly, schizoaffective disorder is classified under the Psychotic Disorders section of the ICD-10. The ICD-10 criteria are similar to those of DSM-IV-TR as they both require positive and/or negative symptoms and affective symptoms for diagnosis, and specify manic, mixed, and depressive types.

CHANGES IN THE DSM-5

However, the requirement for a temporal dissociation of symptom types is specified differently. According to the ICD-10 diagnostic guidelines, “a diagnosis of schizoaffective disorder should be made only when both definite schizophrenic and definite affective symptoms are prominent simultaneously, or within a few days of each other, within the same episode of illness” (World Health Organization, 1992a: p. 90). This contrasts with the relatively specific DSM requirement for at least two weeks of psychotic symptoms in the absence of affective symptoms. Consequently, there would be some cases (without the required temporal dissociation of symptoms) classified as schizoaffective disorder by the ICD-10 and a psychotic mood disorder by the DSM (Jager et al., 2011).

Bipolar Disorder is categorized under the Mood Disorders section of the DSM-IV. The category of Bipolar Disorder includes Bipolar I Disorder, Bipolar II Disorder, Cyclothymia, and Bipolar Disorder Not Otherwise Specified. The focus here will be on bipolar disorder I, as it is the category that is most consistently associated with psychotic features, with half of bipolar disorder cases experiencing psychosis and/or thought disorder. A diagnosis of bipolar I disorder requires a history of at least one episode of mania or, more commonly, a history of recurrent mood disturbances meeting criteria for at least one episode of mania with additional episodes of mixed features, hypomania, or major depression. There are six different criteria sets that specify the nature of the most recent episode, which include Single Manic Episode, Most Recent Episode Hypomanic, Most Recent Episode Manic, Most Recent Episode Mixed, Most Recent Episode Depressed, and Most Recent Episode Unspecified. The remainder of the bipolar I disorder criteria sets apply to individuals who have had recurrent episodes of mania or mania and depression. A characteristic of bipolar disorder that usually differentiates it from the schizophrenia spectrum disorders is its episodic nature with symptom-free intervals associated with a significant improvement in psychosocial function; this contrasts with the classically more chronic course of schizophrenia and schizoaffective disorder, which is usually associated with a greater impairment in and poor prognosis for psychosocial function.

In the ICD-10, bipolar I disorder is similarly categorized as a Mood (Affective) Disorder. The congruence between the DSM-IV and ICD-10 diagnoses of bipolar I disorder is relatively good compared to the diagnostic congruence for schizophrenia and schizoaffective disorder. For example, Cheniaux et al. (2009) found congruence levels (as measured by Cohen’s kappa values) between the DSM-IV and ICD-10 diagnoses of bipolar disorder of 0.83 compared to lower scores in schizophrenia (0.61) and schizoaffective disorder (0.37). Both classification systems require a history of episodic disturbances in mood and activity levels, including at least one episode of mania. However the ICD-10 requires a history of at least two mood episodes, at least one of which is manic, for a diagnosis of Bipolar Affective Disorder. This contrasts with the DSM-IV in which a single manic episode qualifies for a diagnosis of Bipolar I Disorder, Single Manic Episode. The ICD-10 acknowledges this discordance, stating that a single episode of mania is “distinguished from bipolar and other multiple episode disorders because substantial proportions of patients have only one episode of illness” (World Health Organization, 1992a: p. 94).

As described previously, no particular psychotic symptom or single illness feature can be used to distinguish who will receive a diagnosis of a bipolar or other psychotic affective disorder versus a schizophrenia-related psychosis; of course this process presumes that medical, substance-related, and other exclusionary causes of psychosis have been ruled out. The diagnostic categorizations of “the psychoses” in the DSM-5 will entail the clinician’s determination of the relative duration and overlap of any manic and/or depressive episodes as they occurred with psychotic symptoms. The duration will extend from the estimated onset of the disorder to the time of the current diagnosis and not just consider the current episode, as was often practiced in previous considerations of the schizoaffective diagnosis. For individuals meeting the A criterion of schizophrenia and continually having mood symptoms that meet the criteria for affective syndromes, or where the affective symptoms are successfully treated, the appropriate diagnosis will be a psychotic mood disorder. By contrast, if the bipolar or depressive syndrome accompanies less than 50% of the entire illness duration of psychosis, the DSM-5 criteria will specify a schizophrenia diagnosis. Schizoaffective disorder is reserved for cases who have at least 2 weeks of non-affective psychosis meeting the A criteria for schizophrenia; they must also have had concurrent affective syndromes for more than 50% of their illness course. In DSM-IV, schizophrenia and schizoaffective disorder were distinguished by the imprecise clinical determination of whether or not the symptoms meeting criteria for a mood episode were present “for a substantial part of the overall duration of both the active and residual period of the illness” (American Psychiatric Association, 2000: p. 323). The concept of “substantial” was so variably interpreted that the reliability of a schizoaffective diagnosis was quite poor. Schizophrenia quite commonly includes mood features, which do not necessarily change the appropriate diagnosis to schizoaffective disorder in DSM-5.

Notably, the implicit acceptance of the overlap of bipolar and schizophrenia conditions is not disputed in the DSM-5, but the convention of separating the chapters on bipolar disorder and schizophrenia is consistent with the decision to make only conservative changes to the DSM-5. The need to improve diagnostic reliability for schizophrenia, schizoaffective disorder, and psychotic affective conditions will contribute to the evolution of evidence-based studies by improving the reliability for categorical diagnoses, such as the 50% determination. The overlap of bipolar and schizophrenia conditions is certainly evident in the frequent longitudinal instability of an individual’s diagnosis, which commonly shifts among schizophrenia, bipolar or other affective psychosis, and schizophrenia. These common shifts in diagnosis for a patient, between affective and schizophrenia diagnostic categories, puzzle both patients and clinicians, but neither treatment nor prognosis is altered by these designations. It is expected that the most appropriate diagnosis will shift over time, but that the cross-sectional assessments by different clinicians will be more reliable and fewer schizophrenia cases should be misdiagnosed as having schizoaffective disorder based on the DSM-5 criteria requiring

that an affective syndrome is present for more than 50% of the entire illness for a schizoaffective diagnosis.

Other possible approaches to addressing the substantial overlap of bipolar disorder and schizophrenia for the DSM-5 were suggested. On one hand, subdivisions of a psychotic illness into separate epochs of psychosis related to schizophrenia, bipolar disorder, major depressive psychosis, and substance-induced psychosis are appealing to some groups, but have a weak evidence base. On the other hand, quantifying the different symptom domains of all severe mental disorders by dimensional metrics is very compelling; that is, providing separate ratings for psychosis, mania, depression, cognitive limitations, avolition and diminished emotional expression, anxiety, and other dimensions depending on the disorders at a specific time point. These domain scores could shift over time with treatment, brain development, and symptom evolution, but would provide an anchor for description and intervention at specific time points, rather than the constrained longitudinal categorical diagnoses. Again, there is an insufficient database to support this large departure from current practice in the DSM-5.

Other changes in the schizophrenia chapter of the DSM-5 include an elevation of the catatonia concept, such that the condition may stand on its own or accompany a host of other conditions; the consideration of a period of attenuated psychotic symptoms in the appendix, as a route to better understand the adolescent and young adult transitions to psychotic disorders; and limiting the negative symptoms to those that can be observed rather than inferred, namely, avolition/asociality, and diminished emotional expression rather than anhedonia and other negative symptom constructs. The essential “A criteria” for schizophrenia will include two (or more) of the following, each present for a significant portion of time during a one-month period (or less if successfully treated). At least one of these should include 1, 2, or 3: (1) delusions; (2) hallucinations; (3) disorganized speech; (4) grossly abnormal psychomotor behavior, including catatonia; (5) negative symptoms, for example, diminished emotional expression or avolition. The special consideration for bizarre delusions is discontinued in the DSM-5. The “B criteria” specify deterioration in function, or failure to achieve expected levels for those with earlier onset; the “C criteria” set the disturbance duration of at least 6 months (or less if successfully treated), including periods of prodromal or residual symptoms. Durations less than a month indicate brief psychotic disorder and 1 month to up to 6 months are noted as schizophreniform disorder, which may have good or bad prognostic signs of likelihood to become a chronic condition. Changes to the bipolar disorder section in the DSM-5 are notable for the new inclusion of increased energy/activity as a core symptom of Manic Episodes and Hypomanic Episodes.

THE MAJOR RATING SCALES FOR PSYCHIATRIC DIAGNOSIS

Distinguishing between different psychotic illnesses in a reliable way is often challenging for clinicians and researchers. Numerous structured and semistructured diagnostic interviews

have been developed to provide standardized ways for clinicians to collect the information necessary to make a differential diagnosis, thus increasing reliability across clinician diagnoses. The most common of these interviews are the Structured Clinical Interview for DSM Disorders (SCID; Spitzer et al., 1992), the Diagnostic Interview for Genetic Studies (DIGS; Nurnberger et al., 1994), and the Schedule for Affective Disorders and Schizophrenia (SADS; Endicott and Spitzer, 1978), all of which have demonstrated reliability (Keller et al., 1981; Lobbestael et al., 2011; Nurnberger et al., 1994).

While these interviews all provide structured questions and prompts aimed at gathering the same basic data (e.g., identifying information, developmental history, psychiatric history, medical history, and current symptomatology), the interviews differ in the diagnostic criteria to which the information corresponds. For example, the SCID was initially developed based on DSM-III criteria and had to be revised following the publication of the DSM-IV in 2000. Similarly the SADS was developed based on the Research Diagnostic Criteria (RDC). As a result the SCID most directly corresponds to DSM criteria and the SADS most directly corresponds to the RDC criteria, which may present a challenge for clinicians who want to apply the information obtained from these interviews to a different set of diagnostic criteria. An advantage that the DIGS has over the other two interviews is that the questions and prompts were written to collect information that allows clinicians to make diagnoses based on multiple diagnostic criteria. The Operational CRITERia (OPCRIT; Craddock et al., 1996), which is embedded in the DIGS, is a checklist of criteria from all of the major diagnostic classification systems that can be entered into computerized software, which then allows for the generation of diagnoses across the major diagnostic systems. This system allows for easy, standardized, and reliable comparison of diagnosis across multiple diagnostic systems and has demonstrated good to excellent agreement with multiple clinician consensus diagnoses.

RESEARCH DOMAIN CRITERIA: THE FUTURE OF PSYCHIATRIC DIAGNOSIS

Given the overlap of phenomenology, genes, neurobiology, risk factors, and course between the bipolar and schizophrenia-related disorders, it is clear that the categorical diagnoses are not optimal. Nonetheless these are standard instruments for diagnosis, insurance, utilization reports, clinical trials, and even for the Federal Drug Association (FDA). Their use in research, however, may have stymied our progress in discerning the etiology and finding optimal interventions for individual illness features, which can be called “domains” of behavior. The RDoC is a strategy proposed by the National Institute of Mental Health to find a synergy between behavioral analysis and neuroscience that can serve to deconstruct the current and former categorical mental illnesses into their component specific observable behaviors for research. These domains of psychopathology will cut across disorders and will even be identified, to a variable extent, in people who do not meet criteria for any psychiatric diagnosis (www.nimh.nih.gov). The RDoC considers that

a disruption in behavior may be driven by changes in one or more genes that impact a specific neurocircuitry. The major constructs encompassing the domain will encompass motivation, cognition, and social behavior in the first iteration of the RDoC. The specific domains will include Negative Valence Systems (i.e., systems for aversive motivation), Positive Valence Systems, Cognitive Systems, Systems for Social Processes, and Arousal/Regulatory Systems. Each domain is expected to be definable by different classes of variables reflecting neurobiological and clinical approaches; including neurochemistry, cellular systems, neurocircuitry, behavioral tasks, and self-reports. It is furthermore expected, given the lifelong development and remodeling of the brain, that many or most behaviors and their underlying neurobiology will be developmentally modified, as observed for most symptom phenomena in psychiatric patients. RDoC will not immediately be a useful clinical tool, but it will gather the knowledge that is essential for the clinical diagnostic schemes of the future.

CONCLUSION

Over the past century the concept of psychosis has shifted from a unitary model, in which psychosis was considered a single illness, to the current model, in which it is recognized that psychosis manifests across a broad range of separate psychiatric disorders. Current diagnostic criteria (DSM-IV and ICD-10) are largely consistent with Kraepelin's dichotomy and the Feighner Criteria in making a distinction between primary psychotic illnesses (e.g., schizophrenia) and the functional/affective psychoses. Recognition of overlap between these two categories is seen in schizoaffective disorder, a diagnosis given to individuals who simultaneously meet criterion A for schizophrenia and criteria for an affective episode for "a substantial part of the overall duration of both the active and residual period of the illness" (American Psychiatric Association, 2000: p. 323). The diagnostic criteria for schizoaffective disorder are refined with the publication of the DSM-5 to clarify vague wording and increase diagnostic reliability, such that the diagnosis will be reserved for individuals who meet criterion A for schizophrenia and meet criteria for an affective episode for more than 50% of their illness course. Still, there remains great overlap between phenomenology, genes, neurobiology, and risk factors across all psychotic disorders. New behavioral domain approaches to psychopathology research, such as the NIMH's RDoC initiative, will provide approaches to assessment that are not bound by diagnostic categories, which may help further clarify these diagnostic categories over time.

18 | GENETICS OF SCHIZOPHRENIA AND BIPOLAR DISORDER

PAMELA SKLAR

INTRODUCTION

This chapter provides an overview of the genetics of schizophrenia and bipolar disorder. Over the last 100 years or so genetic studies have included the epidemiology of families and twins, traditional genetic linkage and positional cloning in pedigrees, and candidate gene association studies. The evolution of genetic information rapidly expanded as we entered the genomic era with important new insights from genome-wide microarray and sequencing studies.

We can expect this expansion in genetic knowledge to continue and likely escalate. This chapter will cover information supporting several basic ideas. First, that there is strong and consistent evidence that both disorders are genetic. Second, neither disorder is caused by a *single* abnormal gene. Third, biological candidate genes and traditional linkage studies proved inadequate to identify genetic causes for reasons that are now largely understood. Fourth, copy number variation plays an important role in schizophrenia. Fifth, genome-wide association studies have identified multiple significant loci for schizophrenia and bipolar disorder. Sixth, next generation sequencing studies are beginning to catalog rare variants and their potential role in schizophrenia and bipolar disorder. Finally, integration of all of the various sources of genetic risk information will be difficult and will require interdisciplinary work and new biological strategies.

GENETIC EPIDEMIOLOGY

Schizophrenia and bipolar disorder are both strongly familial. It is only over the last ~120 years that they have been investigated as separate, distinct disorders. This distinction, based on clinical observations and symptoms, was codified by Emil Kraepelin in the late 1890s. As highlighted in Chapter 20, many clinical and phenotypic aspects of the diseases have long been known to overlap. Genetic, imaging, and some cognitive observations have increasingly converged, and thus bipolar disorder genetics will be discussed along with schizophrenia, rather than among the mood disorders.

Recent systematic re-review of extant literature confirms that the lifetime risk of schizophrenia is approximately 1% and that there is evidence for a modest variation in prevalence when investigated by latitude (McGrath et al., 2008). The incidence is elevated in migrants over native-born individuals (4.6-fold). Several recent studies of schizophrenia using Scandinavian hospital registers suggest the prevalence may be somewhat lower (Lichtenstein et al., 2009). Estimating the lifetime risk of bipolar

disorder is more difficult as diagnostic schemes have changed significantly over the last 100 years particularly with the formulation of bipolar II disorder in DSM-III-R in 1987. Subsequent changes have tended to broaden the diagnostic scope and the larger spectrum of symptoms has increased the overall prevalence. However, discussing the accuracy and potential impacts of these diagnostic changes is beyond the scope of this chapter (Yutzy et al., 2012). Recent population-based studies in the United States find roughly a 1% lifetime prevalence for bipolar I disorder (Merikangas et al., 2007), with some differences between countries (Merikangas et al., 2011). Prevalence of bipolar II disorder was estimated at 1.1 (Merikangas et al., 2007). Most genetic studies focus on bipolar I disorder only or bipolar I disorder and bipolar II disorder.

FAMILY AND TWIN STUDIES IN SCHIZOPHRENIA

As described in Chapter 12, the first step in gene mapping is to establish whether a trait or disease has a genetic liability, typically undertaken through family and twin studies. The first family study of schizophrenia was carried out almost one hundred years ago by Ernst Rudin. Even though his work predated the development of modern statistical methods for analyzing these data, he was able to appreciate that schizophrenia ran in families, although not in a manner consistent with Mendel's laws. Since then the rates of transmission in hundreds of families have been studied with consistent results. In fact, even application of modern statistical methods to Rudin's original data confirm these observations (Kendler and Zerbin-Rudin, 1996). The relative risk for first-degree relatives (λ) of an individual with schizophrenia is ~10. This has recently been confirmed and extended in a large Swedish population registry-based study of 32,536 individuals with schizophrenia and their family members. The size of this study allowed for examination of a wider variety of familial relationships and again the familial relative risks for parents, siblings, and children were 8.6–10.3 (Lichtenstein et al., 2006). Further investigation using twin studies supports underlying genetic factors for the observed familial clustering. The concordance rate (the likelihood that the second twin will develop the disorder once the first is diagnosed) between genetically identical monozygotic twins is high (41%–65%) and substantially lower for dizygotic twins (0%–28%) (Cardno and Gottesman, 2000). A meta-analysis of 12 twin studies derived a heritability estimate of 81% (Sullivan et al., 2003). Heritability estimates based on Swedish and Danish registry data were somewhat lower (67%) and may represent diagnostic differences in the newer

studies. However, the larger registry based studies are likely to be more broadly representative of the types of samples that are used in the genome-wide studies discussed below (Wray and Gottesman, 2012).

It is frequently stated that most patients with schizophrenia do not have affected relatives and are thus “sporadic” in nature. However, Yang and colleagues have demonstrated that a low rate of affected relatives would be expected with a disease that is uncommon (1% prevalence), highly heritable, and highly polygenetic with risk mediated by many common variants of small effects (Yang et al., 2010). Thus, the lack of close relatives alone is insufficient to support an exclusively sporadic, or non-inherited component to the etiology of schizophrenia.

FAMILY AND TWIN STUDIES IN BIPOLAR DISORDER

Early family studies of bipolar disorder did not distinguish individuals with depressive episodes only, or what is now classified as major depressive disorder, from individuals with depressive episodes as well as manic episodes, what is now classified as bipolar disorder. More recent studies have done so, and the most recent have further included separate analyses of bipolar II disorder. In the modern studies that included control populations and that used a population risk of 1%–2%, the relative risk for first-degree relatives (λ) of bipolar patients is approximately 7–10 (Barnett and Smoller, 2009). Family studies of bipolar II disorder are indeterminate. This is likely because bipolar II disorder symptomatically resembles both major depression and bipolar I disorder and may be genetically related to one, or both. Complicating this is a lower interrater reliability for the diagnosis of bipolar II disorder as well as the small samples sizes available (Smoller and Finn, 2003). Family studies also point to familial enrichment of several other phenotypes that may prove useful in refining genetic studies once genes and loci have been identified. These include observing evidence for familial clustering of early age-of-onset, mania versus depression on first onset, mood episode frequency, psychosis, lithium-responsiveness, rapid-cycling, and panic disorder (Barnett and Smoller, 2009). Like schizophrenia, twin studies of bipolar disorder support a genetic underpinning to the family study results. The most recent studies find the concordance rate for monozygotic twins is higher (0.5–0.6) than for dizygotic twins (0.39–0.43) resulting in heritability estimates of 79%–93% (Kendler et al., 1995; McGuffin et al., 2003; Kieseppa et al., 2004).

EPIDEMIOLOGICAL OVERLAP BETWEEN SCHIZOPHRENIA AND BIPOLAR DISORDER

For the traditional linkage studies that will be described below, families with the clearest inheritance of either schizophrenia or bipolar disorder, but not both, were sought. Supporting this focus were two family studies from the early 1990s that indicated there was no genetic overlap in families (Kendler et al., 1993; Maier et al., 1993). However, two more recent studies have suggested that this was not a settled

issue. Researchers found increased risks of affective disorder in the families of schizophrenia patients (Mortensen et al., 2003), and one found the reverse (Maier et al., 2002). Several small twin studies came to similar contradictory conclusions. However, in 2009 a very large population-based study was reported that was able to take advantage of the quality of information in the Swedish Hospital Discharge Registry to more definitively answer the question of the familial relationships (Lichtenstein et al., 2009). Analyzing data on over 35,000 patients with schizophrenia, 40,000 patients with bipolar disorder, and their family members, they were able to calculate the relative risk for a wide variety of family and adoptive relationships. Table 18.1 displays these results. For schizophrenia probands, the relative risk of schizophrenia was highest for first-degree relatives, but the relative risk of developing bipolar disorder was also elevated, although not as high. The reverse applied to bipolar disorder probands, where they had increased risks of both bipolar disorder and schizophrenia in their first-degree relatives. In fact, there was sufficient power in this study to look at a variety of adoptive relationships confirming earlier studies that adopted away children with a biologic parent with schizophrenic or bipolar are at increased risk of developing the same disease as their biological parent.

The nature of the genetic relationship between schizophrenia and bipolar disorder is also highlighted by patients with schizoaffective disorder, often referred to as a schizophrenia spectrum disorder. Patients with the manic/bipolar subtype meet diagnostic criteria for both schizophrenia and bipolar disorder, while those with the depressed subtype meet criteria for schizophrenia and major depressive disorder. Some work suggests increased familial risk of bipolar disorder and schizophrenia for each subtype, respectively. However, not all family and twin studies concur. Molecular genetic overlap that will be discussed below reinvigorates the discussion and may provide additional data to improve nosology (Craddock et al., 2009; Hamshere et al., 2009).

ENVIRONMENTAL AND NON-INHERITED GENETIC FACTORS

Several non-genetic risk factors for schizophrenia have been reproducibly identified and have been reviewed (Brown, 2011). The most well documented of these include obstetrical complications, urban birth, season of birth, famine while *in utero*, migration, prenatal infections, and cannabis use. Advancing paternal age has also been shown to be associated with increased risk of schizophrenia (Miller et al., 2011). Patients with schizophrenia have decreased reproductive fitness as measured by reduced fecundity measured as a fertility ratio in comparison to siblings, particularly in males (23% vs. 47% in females), that is not offset by increased fecundity in siblings (Power et al., 2012). This implies that negative selection is at work, and that there is a supply of new mutations that are occurring that are contributing to the risk of schizophrenia. In a whole genome sequencing study in Iceland, paternal age was estimated to explain most of the increased *de novo* mutation rate observed (Kong et al., 2012), providing

a potential molecular correlate. There are fewer studies investigating environmental factors in bipolar disorder. However, there is some evidence of effects on risk of seasonality of birth, advanced paternal age, and stressful life events (Alloy et al., 2005; Frans et al., 2008; Disanto et al., 2012), environmental factors that overlap those observed in schizophrenia and major depressive disorder.

EARLY GENETIC STUDIES/TRADITIONAL GENETIC METHODS

LINKAGE ANALYSES

The genetic observations described above led to searches for the responsible genes. As genome-wide markers became available in the 1980s, they were used for linkage studies in families with schizophrenia or bipolar disorder. As was discussed in Chapter 12, linkage analysis follows the transmission of disease and particular genetic markers in families to identify chromosomal segments for closer follow-up and has primarily been successful in diseases caused by mutations with large effect sizes in a single or small number of genes. Many linkage studies of both disorders have been performed. The overall conclusion that can be drawn is that no genomic loci are likely to harbor large effect genes that account for a substantial portion of genetic liability. Even a meta-analysis of 32 independent linkage studies using data from 7,413 schizophrenia cases in 3,255 pedigrees was not able to identify

significant chromosomal regions linked to schizophrenia at above the chance level (Ng et al., 2009). While the overall number of linkage studies in bipolar disorder is more modest, the overall observation was the same in the meta-analysis of 18 studies of 2,437 bipolar cases in 592 pedigrees (Segurado et al., 2003). This was recently extended using a linkage panel of 6,000 single nucleotide markers to achieve more complete linkage information across the genome in 2,782 bipolar disorder cases without producing significant results (Badner et al., 2012). Phenotypic heterogeneity and diagnostic inaccuracy have often been postulated as a primary explanation for lack of clear success in linkage studies. However, similar diagnostic methods and patient samples were used in the genome-wide association studies (GWAS) of common variants and rare copy number variants with strikingly different results that will be described below. Furthermore, it is often argued that there are some suggestive regions that overlap in several studies and might contain loci, however the most likely explanation for the overlap is random chance resulting from the large number of studies performed and the relative lack of fine scale genomic resolution of linkage analysis.

Despite this, positional cloning, the process whereby specific genes are identified within a linkage peak, has been carried in some linkage regions, particularly on chromosomes 8p12 and 6p22.3. In those regions, two candidate genes were of particular focus, neuregulin1 (*NRG1*) and dysbindin (*DTNBP1*), respectively. Disrupted in Schizophrenia 1 (*DISC1*), is a gene interrupted by a balanced chromosomal translocation between chromosomes 1 and 11 (t(1;11) (q42;q14)), that segregates in

a single Scottish family with schizophrenia, bipolar disorder, and major depression. No other families with translocations, or other segregating structural abnormalities in *DISC1* have been found. Numerous association studies have focused on this gene in both schizophrenia and bipolar disorder with inconsistent results. A meta-analysis of data from 11,626 cases and 15,237 controls did not find evidence for association for any of the 1,241 SNPs in *DISC1* that were tested (Mathieson et al., 2012). In addition, studies have generally not found an excess of rare variants at this locus. Despite the paucity of evidence for a major role in genetic risk of schizophrenia, there have been many interesting biological studies of this gene that will be described in later chapters.

CANDIDATE GENES STUDIES OF SCHIZOPHRENIA AND BIPOLAR DISORDER

Hundreds of candidate gene association studies have been performed over the last decade. Most were defined as candidates based on biological theories from pharmacological observations or secondary to abnormalities observed in postmortem human brain tissue from patients. Taken as a whole, the results of these studies are inconsistent and may represent poor candidate choices because of our fundamental lack of understanding

of the underlying biology and/or poor gene coverage and/or small sample sizes. Numerous detailed publications review the status of the most frequently studied of these genes, and a list of them is maintained by the schizophrenia research forum (see <http://www.szgene.org>). It is of note that initial results from GWAS do not find the prior biological candidate genes enriched among significant or nearly significant loci (Collins et al., 2012). The most extensively investigated are covered in other chapters of this section. Candidate genes in bipolar disorder have focused on *BDNF*, circadian genes, phosphoinositide signaling, and Wnt/GSK3beta signaling (Martinowich et al., 2009). As with schizophrenia, initial results from GWAS do not find the prior biological candidates enriched among significant or nearly significant loci (Seifuddin et al., 2012).

COPY NUMBER VARIATION

Copy number variants (CNVs) are deletions or duplications of genetic material and can range from several base pairs (often called “indels”) to 100,000s to millions of bases. The risk of developing schizophrenia is markedly elevated in the presence of certain CNVs (Table 18.2). A large body of work reviewed in detail elsewhere (Malhotra and Sebat, 2012) has defined

TABLE 18.2. Disease-associated copy number variants

the following principles of the CNVs associated with schizophrenia from studying over 10,000 samples initially using array-comparative genomic hybridization and subsequently SNP microarrays.

- Genome-wide rates of large (>100 kb), rare (<1%) CNVs are elevated.
- Rates of *de novo* CNVs are elevated.
- CNVs generally contain many genes and confer large relative risks (2.1–49.5)
- SCZ associated CNVs are often found in multiple additional disease phenotypes including most commonly ASD, LD, and epilepsy.
- Specific genomic locations are recurrent sites of these CNVs (see Table 18.2)
- CNVs are enriched in neuronal functions particularly those that are involved in synaptic activity and neurodevelopmental processes. Additional support for proteins enriched in synaptic signaling has been found in recent work on *de novo* CNVs.

Characteristics of the individual loci, genes, and phenotypic overlaps are discussed in Chapter 19.

The role of CNVs in bipolar disorder has been less well studied and remains somewhat controversial, with some studies findings increased rates and others not (Malhotra and Sebat, 2012; Olsen et al., 2011). Overall, the association of rare CNVs is less prominent, and only one specific CNV (3q29) is reported with an effect size > 5 for bipolar disorder, although a study of 185 proband-parent trios found a rate of *de novo* CNVs that was 4.8-fold higher than controls and similar to what was observed in schizophrenia (Malhotra et al., 2011).

GENOME-WIDE ASSOCIATION STUDIES

Development of the technology for simultaneously genotyping hundreds of thousands of SNPs as well as the positional information regarding the sites of almost all common SNPs has allowed for progressively more informative GWAS studies. These studies have the advantage of being unbiased with respect to prior biologically driven theories, but of course have well-known limitations. The theoretical underpinnings of GWAS have been discussed in an earlier chapter, and the specific implications for psychiatric disease covered in several excellent reviews (PGC, 2009; Sullivan et al., 2012).

SCHIZOPHRENIA

There are now >10 published GWAS studies of European samples (Table 18.3) (Lencz et al., 2007; O'Donovan et al., 2008; Sullivan et al., 2008; Need et al., 2009; Purcell et al., 2009; Shi et al., 2009; Stefansson et al., 2009; Athanasiu et al., 2010; Schizophrenia Psychiatric Genome-Wide Association

Study (GWAS) Consortium, 2011; Shi et al., 2011; Steinberg et al., 2011; Bergen et al., 2012; Hamshere et al., 2012; Rietschel et al., 2012). Other studies have included African American and Japanese samples, but sample sizes remain small at present. A large sample has been reported by the Psychiatric Genomics Consortium (PGC). This consortium was formed in 2007, recognizing that individual studies that utilized only several thousand individuals would be underpowered and that sharing of data and rapid meta-analysis would significantly accelerate the gene discovery process. An international group of scientists from over 60 institutions and 19 countries continues to work together and timely updates will be provided on their website (<https://pgc.unc.edu/>). An overlapping group of European scientists from seven European institutions work together as part of the SGENE consortium (<http://www.sgene.eu/>).

A stringent and well-accepted criteria for genome-wide significance takes into account the total number of independent SNPs tested (approximately 1 million) and thus should be equal to or below 5×10^{-8} (Pe'er et al., 2008). If we assume that most common variant loci have modest effect sizes (<1.5-fold), then the power to detect loci using stringent thresholds that adjust for the total genome-wide testing burden is low. Thus, while many groups began by using their own samples, they rapidly proceeded to replication of the best loci through collaboration with additional groups. This can easily be appreciated by reviewing Table 18.3, noting that most of the primary or stage 1 samples did not detect associated loci, but that following either replication/stage 2 or large meta-analysis (e.g., PGC or SGENE) several loci were convincingly associated.

Since linkage disequilibrium varies across the genome, the associated regions vary in size; some contain multiple genes, some one, or even none. Table 18.4 contains genome-wide significant findings as of November 2012. The most significant individual marker is listed along with the nearest gene, the study in which it was first reported, and the study in which it has been reported in the largest overall sample size. The first regions were identified in a series of studies published in 2008 and 2009. O'Donovan and colleagues first reported a locus *ZNF804A*, a transcription factor of unknown function (O'Donovan et al., 2008). This was followed by three studies published simultaneously that analyzed over 3,000 cases each. These studies reported an association across the large region of the major histocompatibility complex (MHC) on chromosome 6. Two additional regions, each of which pointed to specific genes, were reported by the SGENE consortium, transcription factor 4, *TCF4*, and neurogranin, *NRGN* (Stefansson et al., 2009). The largest study, undertaken by the Schizophrenia Psychiatric Genome-Wide Association Study Consortium, assembled and directly analyzed genotype data from 17 individual samples for a total of 8,394 cases and 12,462 in the primary analysis. Overall, five new loci were detected (1p21.3, 2q32.3, 8p23.2, 8q21.3, and 10q24.32). A graphical representation of the data is displayed in Figure 18.1. In the replication study of the 81 most associated SNPs, a strongly positive deviation from expectation in the number of results detected in the same direction as

^aReplication and Stage 2 samples often tested only a subset of the most associated SNPs in the larger sample. ^bLarge Chinese sample; ^cenlarged sample based on Stefansson, 2009, only subset of SNPs tested in primary study; GWS = genome-wide significant

the original effect (but not independently genome-wide significant) was found. This means that sample sizes are insufficient and that as they grow additional associated loci will be found. The PGC is completing meta-analysis of case and control samples that is 2–3 times larger than those previously reported. The expectation, based on simulations that compare the rates of identification of additional loci in other genetically complex traits such as height, is that there will be a dramatic increase in genome-wide significant loci. Thus, the loci listed in Table 18.4 are provisional. Ultimately this list may also contain some of the prior biological candidate genes, albeit with effects sizes that are more modest than those originally observed.

It is important to note that the relative risk conferred by each individual variant listed in the table is small and thus, even in aggregate, contributes a negligible amount to the overall heritability. Rather than jump to the conclusion that the genetic causes of schizophrenia must be either rare, or *de novo* as many authors have, the International Schizophrenia Consortium tested whether there were many variants, even thousands of variants, each contributing a very small amount to the overall liability of developing schizophrenia. Individually, none of these variants was able to generate a signal, but taken in groups of 10s or 1000s of SNPs they were able to predict aggregate risk of having schizophrenia in independent samples (Fig. 18.2). The Consortium developed score profiles from groups of SNPs that were below a variety of more and more

relaxed *P* value thresholds. This was done in order to be able to include SNPs with very small effect sizes. Using the derived profiles and applying them to independent schizophrenia samples, they found that for all the thresholds tested, they were highly significantly associated, as a group, in the independent schizophrenia samples, but critically, not in a wide variety of other non-psychiatric genetic diseases like Crohn's disease and diabetes. These results cannot be explained by rare variants alone, or by other artifacts such as population stratification, and thus indicate there are meaningful contributions from many common variants to the overall liability to schizophrenia. These results have subsequently been replicated in several larger samples. A recent study estimated the proportion of variation in the susceptibility to schizophrenia that had been explained by GWAS SNPs was ~25%–30% using some of the largest GWAS studies (Lee, DeCandia, et al., 2012). A highly polygenic model suggests that genetically influenced individual differences across domains of brain development and function may form a diathesis for major psychiatric illness, perhaps as multiple growth and metabolic pathways influence human height.

While GWAS does not identify specific functional variants and genes, several interesting observations have already emerged from this early work. The MHC is an exceedingly gene-rich region, including both HLA genes as well as a family of histones, an olfactory receptor cluster, and a number of brain-related genes. To complicate matters, the MHC is a

multi-megabase region of unusually extensive linkage disequilibrium and gene density, making it impossible to attribute the association signal to particular genes, or to a particular HLA haplogroup. One of the strongest new associations is over 100 kb from the nearest protein-coding gene, but is within the transcript for *MIR137*. Prior work has identified a role for *miR137* in several important areas of brain development including neurogenesis and neuronal maturation. While there is an additional gene, dihydrophyrimidine dehydrogenase (*DPYD*), in which rare *de novo* functional mutations were found in two schizophrenia patients (Xu et al., 2012), the connection

between *MIR137* is strengthened by the observation that four schizophrenia associated genes at the genome-wide significant level are *MIR137* targets. Of course, both may be contributing to the phenotype. In general, one reasonable, although not proven, hypothesis is that associated loci will fall into meaningful biologic pathways with explanatory power for the disease. Many methods have been developed for this (e.g., ALIGATOR: Holmans et al., 2009; INRICH: Lee, O'Dushlaine, et al., 2012; DAPPLE: Rossin et al., 2011; and GRAIL: Raychaudhuri et al., 2009), and there are a wide variety of databases with curated gene sets (e.g., Gene Ontology-GO: <http://www.geneontology.org>).

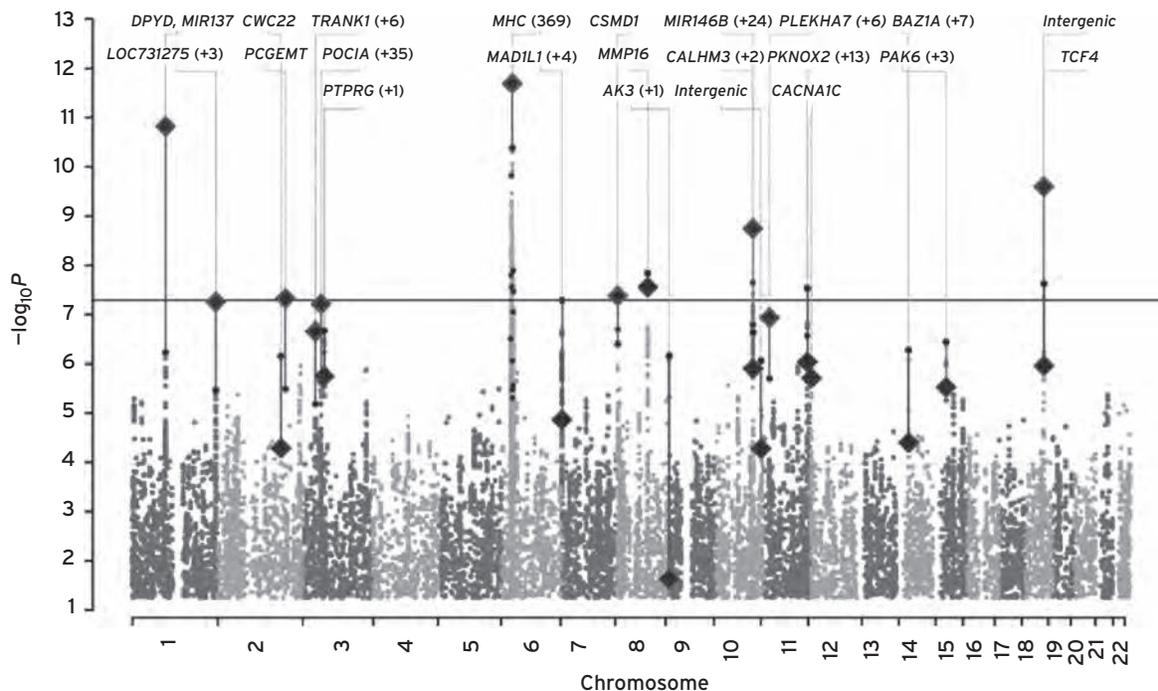

Figure 18.1 Manhattan plot adapted from Schizophrenia Psychiatric Genome-Wide Association Study (GWAS) Consortium, 2011. Each point represents either a directly genotyped or imputed SNP. SNPs are plotted on the x-axis starting from the p arm of chromosome 1 to chromosome 22. The y-axis displays the statistical significance as the $-\log_{10}P$ value of the association results for each SNP. For the stage 1 results, 16 regions with one or more SNP achieving $P < 10^{-6}$ are highlighted and labeled with the name of the nearest gene. SNPs selected for stage 2 replication are highlighted, with the resulting combined P value after replication (i.e., after incorporation of stage 2 results) indicated by the large diamonds. Diamonds above highlighting indicate SNPs that were more significantly associated after replication, and diamonds below highlighting indicate SNPs that were less significantly associated after replication. P values below 0.05 are not shown adapted from Ripke et al., 2011 (Consortium 2011).

org/; Kyoto Encyclopedia of Genes and Genome-KEGG: <http://www.genome.jp/kegg/>). However, currently these databases are likely underrepresented in human brain pathways, just those that should be most useful for schizophrenia studies. Furthermore, consensus has not been achieved on proper thresholds for statistical significance for these studies given the wide variety of methods, and numbers and types of genes and pathways that may be analyzed. Application of these methods to GWAS data have not yet identified consistent and replicable loci, most likely because the overall number of input loci has been too small to have adequate power.

Ultimately, developing etiological validation of genetic observations is important, and one method is through testing their effects on gene expression. Microarray based gene expression studies using postmortem tissue from schizophrenia patients have identified regional brain abnormalities, as well as abnormalities in several biological processes such as synaptic transmission, inhibitory neurotransmission, and myelination (Horvath et al., 2011). Furthermore, sequence dependent gene expression abnormalities have been reported in a variety of the biological candidate genes or those that emerged from earlier linkage studies such as *NRG1*, *DISC1*, and *DTNBP1*. As discussed earlier, there is no evidence for a predominant role in genetic liability for these genes. However, systematic surveys of the presence of common and rare human variation on protein coding genes and gene expression found that the genome contains a surprising number of functional alleles that profoundly alter gene expression (Kang et al., 2011; MacArthur et al.,

2012). The role of the gene expression changes in the etiology of schizophrenia will require understanding whether genes or pathways with statistically compelling risk associations are among this group. As a first step in this direction, several groups have investigated whether associated loci are enriched for expression quantitative trait loci (eQTLs). Using gene expression microarray data from 163 control postmortem brain samples, polygenic schizophrenia risk alleles derived from large-scale GWAS were statistically enriched for cis-eQTLs (Richards et al., 2011). Gene expression data from several developmental and spatial transcriptional atlases of the human brain have recently been made available (NCBI Gene Expression Omnibus GSE25219 and GSE30272). Comprehensive next generation sequencing surveys are also in progress for human postmortem samples from hundreds of schizophrenia patients. Integration of these resources and other complex datatypes that are emerging from the Encyclopedia of DNA Elements (ENCODE) project with DNA variation will enable an understanding of the biological role of disease associated variation.

BIPOLAR DISORDER

There are also ~10 published studies of GWAS genotyped Europeans. Table 18.5 lists GWAS studies of bipolar disorder, many of which included both types 1 and 2. As in schizophrenia, it is in the largest studies or the replication and stage 2 samples that genome-wide significant loci were identified. A particular difficulty in the early bipolar disorder GWAS

literature occurred because many of the samples used partially overlapping case and controls. The first small study that used pooled genotyping, reported a genome-wide significant association to *DGKH* that has subsequently not been replicated in the larger studies that followed (Baum et al., 2008). Subsequently, Ferreira and colleagues (Ferreira et al., 2008) identified the region of *ANK3* (encoding ankyrin 3) and *CACNA1C* (encoding the alpha subunit of the L-type calcium channel) and those from a third reported an association to *NCAN* (encoding neurocan) (Cichon et al., 2011), while other studies did not report genome-wide significant loci (Scott et al., 2009; Sklar et al., 2008; Smith et al., 2009, 2011). The PGC Bipolar Disorder Working Group reported results from the largest study to date (Psychiatric GWAS Consortium Bipolar Disorder Working Group, 2011). Genotype data were assembled from 11 samples and a combined analysis of 16,731 samples and 46,912 replication samples identified two genome-wide significant loci, *CACNA1C* and a new locus, *ODZ4* (encoding a human homolog of the *Drosophila* pair-rule gene *ten-m* (*odz4*)). Of note, strong association (but not genome-wide significant) was reported by Scott in 2009 in the region of *NEK4-ITIH1-ITIH3* on chromosome 3; this region was recently shown to be genome-wide significant in follow-up studies of schizophrenia, and has a replication *P* value below 0.05 for bipolar disorder in an independent sample (Hamshere et al., 2012).

As we discussed for schizophrenia, there is strong evidence that increasing the sample sizes for bipolar disorder will make it possible to identify additional loci. In the replication portion of the PGC-BD study, 34 of the most associated SNPs were tested in an additional 4,496 cases and 42,422 controls. Of those tested, 31 of the 34 SNPs had a signal in the same direction of effect as the original—highly unlikely to have occurred by chance ($P = 3.8 \times 10^{-7}$). However, not all loci were independently replicated—in particular, two significant loci

in the stage 1 samples, *ANK3* and *SYNE1*. These results may represent the “winner’s curse” with smaller real effects sizes and larger samples needed for replication or with false positive associations. This will become clearer as data from additional samples becomes available.

The PGC-BD group also provided direct evidence for a polygenic component in bipolar disorder. Performing the same score profile analysis, but starting with bipolar disorder samples to define the score, they showed a highly statistically significant enrichment of putatively associated bipolar disorder score profile alleles across a wide variety of *P* value thresholds. These data are consistent with the presence of many common susceptibility variants of relatively weak effects.

Pathway analysis in the PGC-BD sample showed significant enrichment in the GO category of voltage-gated calcium channel activity (GO:0015270) in an analysis that controlled for many of the potential biases caused by not accounting for SNP density, gene density, and gene size. Three calcium channel subunits were included in this category, *CACNA1C*, *CACNA1D* and *CACNB3*. The first two encode the major L-type alpha subunits found in the brain, consistent with prior literature regarding the role of ion channels in bipolar disorder, the mood stabilizing effects of ion channel modulating drugs, and the specific treatment literature suggesting direct efficacy of L-type calcium channels blockers in the treatment of bipolar disorder (Casamassima et al., 2010). *ODZ4*, located on chromosome 11, encodes a member of a family of cell surface proteins, the teneurins. These genes are likely involved in cell surface signaling and neuronal pathfinding. *NCAN* is an extracellular matrix glycoprotein that is brain expressed. *Ncan*^{-/-} mice show abnormalities in a variety of behavioral paradigms, some of which are often used as models of mania, such as increased exploratory behavior and increased amphetamine-induced hyperactivity (Miro et al., 2012). *ANK3* codes for a multi-functional protein, which forms a critical component of the

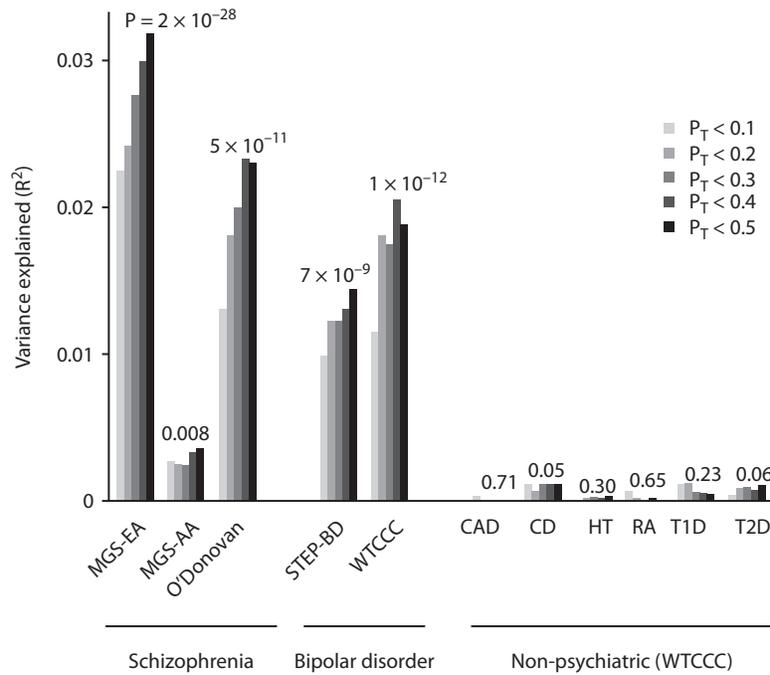

Figure 18.2 Variance explained in the target samples on the basis of score profiles derived in the entire ISC for five significance thresholds ($P_{\text{Value}_{\text{Threshold}}} < 0.1, 0.2, 0.3, 0.4, \text{ and } 0.5$, plotted left to right in each study). The y-axis indicates Nagelkerke's pseudo R^2 ; the number above each set of bars is the P value for the $P_{\text{Value}_{\text{Threshold}}} < 0.5$ target sample analysis. axon initial segment and of nodes of Ranvier with described functions in the developmental and physiological regulation of neural activity including the assembly of voltage-gated sodium channels. As in schizophrenia, enrichment of cis e-QTL were found when testing the top ~1,000 SNPs in novel human cerebellar postmortem brain tissue ($P < 0.001$).

Phenotypic aspects, such as clinical symptom dimensions, of the categorical disease diagnosis are beginning to emerge. These have included negative mood delusions, mood incongruent psychotic symptoms, suicidality, and temperament, and while some have reported signals that just achieve genome-wide significance, they need to be interpreted with caution (Goes et al., 2012; Greenwood et al., 2012; Meier et al., 2012; Willour et al., 2012). These studies are necessarily smaller in size and thus confronted with low statistical power and problems from the lack of replication samples, since detailed phenotyping is not widely available.

GWAS OVERLAP BETWEEN SCHIZOPHRENIA AND BIPOLAR DISORDER

Overlap in both specific genetic vulnerability loci as well as an overlap in polygenic background has been observed. Large-scale GWAS have found strengthened signals that are also genome-wide significant when combining results from schizophrenia and bipolar disorder for *ZNF804A*, *ITIH3-ITIH4*, *ANK3*, and *CACNA1C*. In Fig. 18.2, the score profile that was defined using a schizophrenia case-control sample was also able to statistically significantly discriminate between bipolar disorder cases and controls in two independent bipolar disorder samples. This is a strong demonstration

that there is a large molecular overlap in vulnerability alleles for the two disorders. The strength of these observations differs from earlier indications from linkage and candidate gene studies because of the sample sizes, statistical significance, and replication status of the results. Graphical representations of genes and regions of interest from GWAS results have been made publicly available through the easy to use program RICOPIILI (<http://www.broadinstitute.org/mpg/ricopili/>). It is hoped that this will facilitate translation of genetic findings into neurobiological and clinical follow-up by interested scientists. Examples of loci in schizophrenia and bipolar disorder are shown in Fig. 18.3.

LARGE-SCALE SEQUENCING STUDIES

Several observations imply that cataloging rare single nucleotide variants (SNVs) enriched in patients is important. As with the CNVs discussed earlier, advanced paternal age is associated with increased risk of schizophrenia (age 45–49 relative risk = 1.24; >50 = 1.79) suggesting a role for *de novo* mutations. We know, conclusively, that rare large structural mutations, many of which are *de novo* or relatively new in the population, such as that deletions of hundreds of kilobases, have a large effect on the SCZ risk. In addition, work described previously from the genome-wide studies of common variants strongly supports a threshold liability model, which by definition will include inherited variants on the rare end of the spectrum. Integrating between and across multiple sources of variation will be a large-scale challenge for the future. Already several studies are pointing to hints from new and segregating

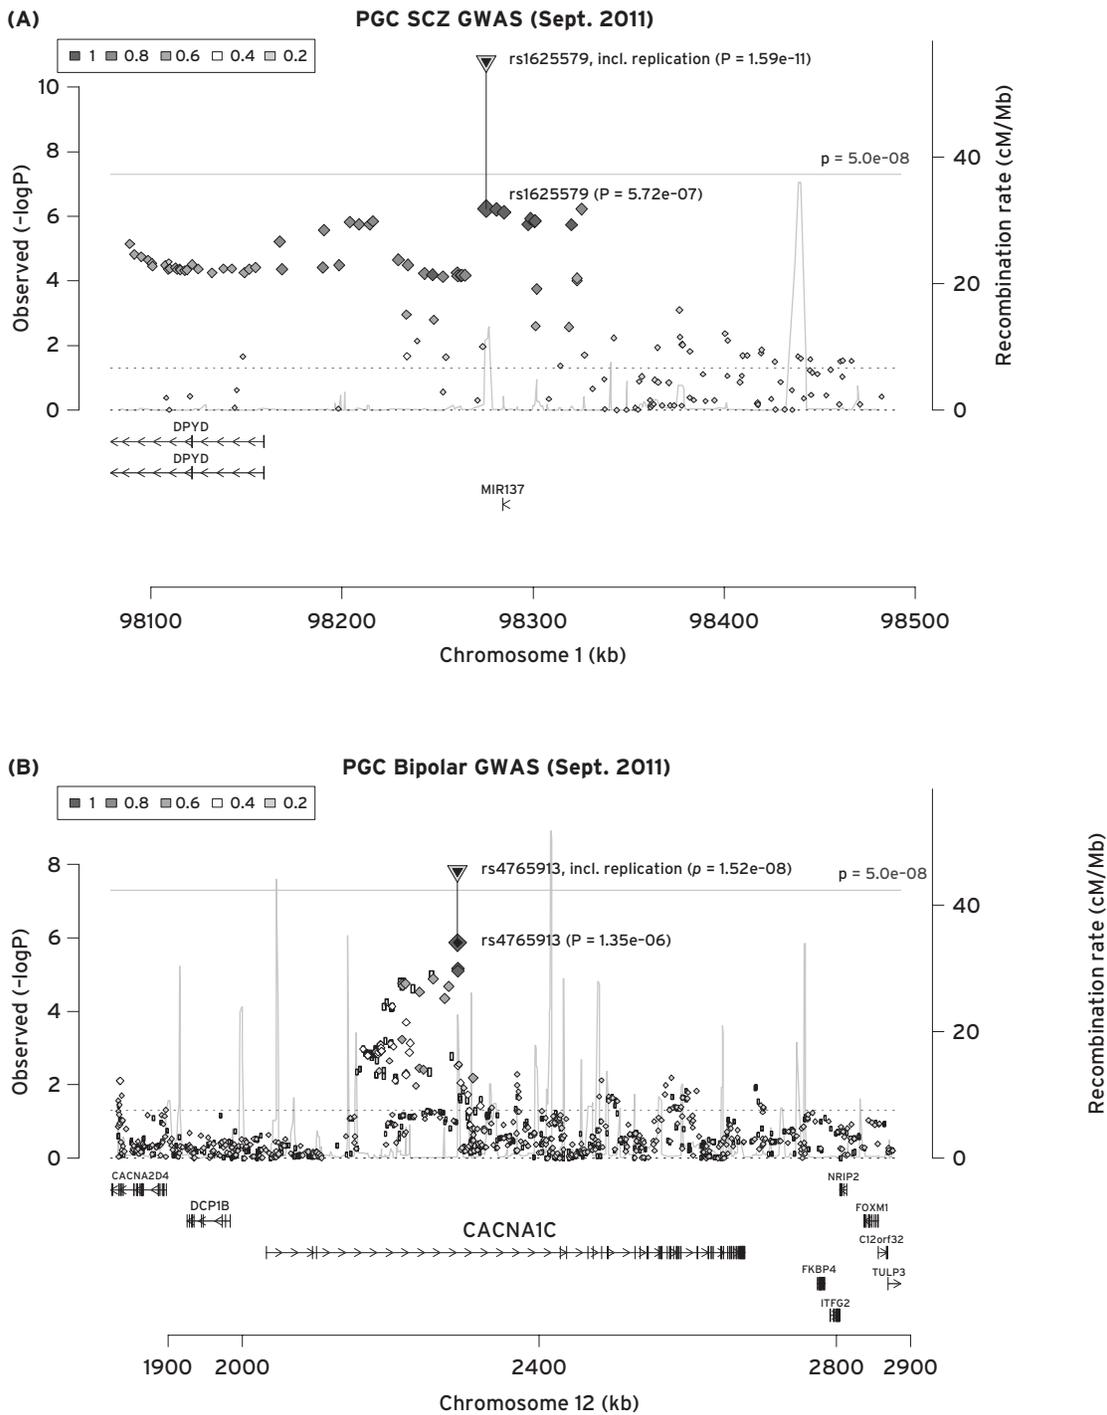

Figure 18.3 Representative regional plots in schizophrenia and bipolar disorder. (A) Top association signal in schizophrenia on chromosome 1 in PGC-SCZ; (B) Top association signal in bipolar disorder on chromosome 12 in PGC-BD. Each point represents either a directly genotyped or imputed SNP. SNPs are plotted on the x-axis starting surrounding the gene or SNP of interest 5' to 3'. The y-axis displays the statistical significance as the $-\log_{10}P$ value of the association results for each SNP. Genes are indicated and exons marked with vertical lines. The horizontal line at 5×10^{-3} marks the genome-wide significance threshold. Linkage disequilibrium (r^2) with most significant SNP is indicated as shading of each SNP according to the legend in the upper left of each graphic. Graphic produced by Ricopili.

variants, that will require replication in large samples. The field is in its infancy, but similar to GWAS studies it can be broken into genome-wide, candidate, and single gene studies.

Prior to the availability of high-throughput sequencing machines, identifying mutations or rarer variants could only be accomplished by sequencing single or modest numbers

of genes, usually based on biologically driven hypotheses (Table 18.6). As part of the Synapse-to-Disease Project, the coding regions of 401 genes found in the synapse, with ~30% located on the X chromosome, were sequenced in 143 schizophrenia samples and 285 population controls (Wing et al., 1990). Following confirmation as new mutations, by sequencing

(Xu, Roos, et al., 2011). Note that several studies of the *DISC1* used a pooled DNA sequencing strategy and single gene sequencing studies in fewer than 100 cases are not included in this table. Ms-missense, Ns-nonsense.

both parents, they found 8 *de novo* changes in patients, and 1 in the controls. Amino acid altering mutations were found in several genes previously highlighted in autism or in structural variant pathways including *SHANK3, NRXN1, GRIN2B,* and *KIF7*. The coding regions of 10 genes selected to have some biological and genetic evidence (predating genome-wide association studies) for a role in schizophrenia were sequenced in 727 cases and 733 controls (Crowley et al., 2012). In this study genotyping follow-up of 92 variants, including all rare, novel nonsense, missense, or splice site variants in an independent sample of 2,191 cases and 2,659 controls. Although the replication sample was only modestly powered, no evidence was found suggesting that these genes are enriched for rare coding variation for either the individual variants, or when the variants from a single gene were analyzed together. This is in line with the results from common genomic variants as discussed above for biologically chosen candidate genes. Of note, *DISC1* was included and did not show evidence for an association with rare variants.

Four exome sequencing studies have been reported using next generation, high-throughput technology, and many more will emerge (Table 18.6). Two studies investigated whether there is an increased rate of *de novo* mutations by sequencing the coding regions (exome sequencing) using hybrid capture followed by next generation sequencing, and both used filtering strategies to arrive at a small set of novel mutations for validation (Girard et al., 2011; Xu et al., 2012). In the first study of 14 schizophrenia probands and both parents, 15 *de novo* mutations were found in 8 of the probands, with a notable

number of them being nonsense mutations. An initial small study by Xu et al. reporting 53 cases was followed in 2012 with a larger study of 231 SCZ trios (Xu et al., 2012). In the larger study, the point mutation rate of the exome sequence tested did not differ between cases and controls, but there were differences in the rate and ratios of specific types of mutations, some of which could have a larger functional potential. The missense to silent ratio was elevated 4.84-fold over controls, and no nonsense or canonical splice site mutations were observed in controls. Caution in interpreting these early results is indicated. Recent work from the larger scale studies of *in silico* predicted loss of function mutations indicate that not all nonsense and consensus splice site mutations are functional (MacArthur et al., 2012). Of note, however, only 50% of the patients carried even one potentially functional SNV. Even more surprising was that observation of lack of the same gene being affected by recurrent *de novo* mutations across studies. Only a single gene, dihydropyrimidine dehydrogenase (*DPYD*) contained more than one highly likely functional mutation. The hope that mutations would fall easily into pathways or recur repeatedly in a specific subset of genes is not likely.

In a population-based study, exome and whole genome sequencing of 166 cases of schizophrenia and 307 controls (Need et al., 2012) was followed by genotyping of ~5,000 of the best candidates in additional unrelated cases ($n = 2,617$) and controls (1,800). No individual SNV was significant, given the low power of the primary sample for rare variation. However, even in the follow-up sample no variants were significant. This

study indicates that there may not be very many moderately rare variants (1%–5%) of large effects (>2-fold). Similarly, three candidate genes studies did not find differences between cases and controls in the number of rare variants observed.

Taken together these very early results suggest that rare variation, like common variation, will play a role in liability, but effect sizes may be smaller than hoped and the number of variants larger than hoped, and thus considerably larger sample sizes will be needed to evaluate this. To date no genome-wide deep sequencing studies have been published, however, at the time of writing this chapter, several large studies are in progress whose results will enrich the understanding of the overall architecture.

NEAR FUTURE NEEDS

In the last decade, we have moved from knowing nothing about the types and number of genetic loci involved in these diseases to having a substantial understanding of rare and common variants that increase disease risk, and the path forward is clear for further, future locus identification. Many types of variants of weak effects will be involved, and thus large samples will be necessary regardless of whether common or rare loci are sought. What has not advanced as rapidly is the translation of these findings into biological experimentation. In this respect we are no worse off than with many Mendelian diseases, where the gene cloning is not followed rapidly by insights into pathophysiology and novel treatments (Huntington's disease and Cystic Fibrosis are two examples). For schizophrenia and bipolar disorder, this is in large part because the number and type of loci is much greater than ever anticipated, and because our long history of powerful reductionist science is well developed to study single genes rather than pathways and circuits. However, the large size of the risk gene pool should ultimately allow for more shots on goal as we consider choosing targets for novel drug development.

Many areas of investigation in the near term should prove fruitful in improving our ability to detect causal pathways and relatively more important genes. For common and rare variants, the initial genetic identification generally does not lead to an obvious functionally testable hypothesis regarding the relationship with disease. In the case of common SNPs they may be intergenic, or only related to the functional SNP; in the case of SNVs, the identified variants may have no obvious function, or may be in a seemingly irrelevant gene. In particular, strategies that seek to integrate genetic data with the wealth of biological information publicly available through the Encyclopedia of DNA Elements (ENCODE) and Roadmap to Epigenomics projects, databases of protein interactions, biological pathways, and gene expression will be able to increase the signal to noise ratio. For example, intersecting between different types of genetic variants by evaluating the burden of rare variants in loci identified in CNVs and/or *de novo* SNVs is likely to improve the detection of consistent underlying pathways. Similarly, integrating genotype data with RNA expression and neuroimaging should likewise be helpful and be employed to build predictive models. Any models derived from this work will need to be experimentally validated, and here there is great

hope that human stem cells—induced human pluripotent stem cells derived from patients, that recapitulate the human genetic background—can be differentiated into the tissue of interest, and manipulated experimentally, and this will prove a powerful intermediate for developing and testing pathophysiological understanding (Brennand and Gage, 2012).

Finally, the studies reviewed in this chapter have focused on European samples because those have the largest sample sizes and thus have had the greatest power. These studies need to be extended to additional ethnic groups to begin to elucidate both the shared loci as well as those that are specific.

SUMMARY

This chapter has reviewed strong and convincing genetic evidence that indicates a contribution of many DNA changes to the risk of becoming ill. For schizophrenia, there are large contributions of rare copy number variants and common single nucleotide variants, with an overall highly polygenic genetic architecture. There is a role for rare single nucleotide variation as well as *de novo* genetic variation being pointed to in new sequencing studies, but their overall contribution to risk is less clear. For bipolar disorder, the role of copy number variation appears to be much less pronounced. Specific common single nucleotide polymorphisms are associated, there is evidence for polygenicity, but as yet no deep sequencing surveys have been published. Several intriguing biological pathways are suggested by these genetic findings related to microRNAs and calcium channel signaling. Several surprises have emerged from the genetic data that indicate there is significantly more molecular overlap in copy number variants between autism and schizophrenia, and in common variants between schizophrenia and bipolar disorder. Translating these results into biological and etiological understanding has not yet advanced, and will likely only do so when experimental methods are developed that can address the large numbers of genes and variants within them that, along with environmental and stochastic effects, result in the development of disease for a particular person.

19 | GENOMIC SYNDROMES IN SCHIZOPHRENIA

Overlapping Phenotypes

GEORGE KIROV, MICHAEL C. O'DONOVAN, AND MICHAEL J. OWEN

ABBREVIATIONS

CNV	copy number variant
DD	developmental delay
CM	congenital malformations
ASD	autism spectrum disorders
SCZ	schizophrenia
ADHD	attention-deficit hyperactivity disorder
LCR	low copy repeat
NAHR	non-allelic homologous recombination

BACKGROUND

Chromosomes can be impacted by events that result in the duplication, deletion, or inversion of segments of DNA as well as other more complex rearrangements. When the affected segments are relatively large (several million bases of DNA), they can often be seen by light microscopy, a process known as karyotyping. Smaller rearrangements are only detectable by molecular genetic techniques, for example fluorescence in situ hybridization (FISH). Using these approaches, a number of rare causes of severe forms of developmental delay (DD) have been identified that involve whole chromosomes (e.g., Down's syndrome) or relatively large segments of chromosomes (e.g., Prader-Willi/Angelman syndrome, Smith-Magenis syndrome, and the 1p36 deletion syndrome). In schizophrenia (SCZ), these low resolution approaches made two striking findings. Thus carriers of the 2.3Mb deletion of 22q11.2 that causes the DiGeorge/Velo-Cardio-Facial syndrome (VCFS) have been shown to be at very high risk of the disorder (Murphy et al., 1999), and so were members of a single large pedigree who carry a balanced translocation involving chromosomes 1 and 11, the translocation breakpoint on chromosome 1 intersecting the eponymously named Disrupted in Schizophrenia gene (*DISC1*). However, with the introduction of technology with better resolution, including comparative genomic hybridization (CGH), high density genotyping microarrays, and more recently, whole genome sequencing, it is now possible to undertake genome-wide screens for much smaller deletions and duplications, with the resolution offered by sequencing being at the single nucleotide level.

Chromosomal deletions and duplications above 1,000 bases in size have been called DNA copy number variants (CNVs). Some CNVs are common and are not thought to play a major

role in human disease. Others are rare, and, while many may be non-pathogenic, a subset of these cause uncommon phenotypes known as genomic disorders (Lupski, 1998, 2009), the name arising from the fact that the disorders are caused via changes to genome structure rather than sequence, and that the genome architecture incites an instability of the genome. The alterations in the genome can occur through recombination between highly homologous stretches of DNA, known as low copy repeats (LCRs), that is, non-allelic homologous recombination (NAHR, Stankiewicz and Lupski, 2002), although other mechanisms have been recognized since (Lupski, 2009). There is now compelling evidence that CNVs also play a role in common disorders, among which SCZ is a prime example.

SCZ is a chronic mental disorder with a lifetime risk of ~1% and a strong genetic component, indicated by heritability estimates of 60–80% and a ~10-fold elevated recurrence risk in first-degree relatives (Gottesman, 1991; Lichtenstein et al., 2009) (see Chapter 18, Pamela Sklar). Despite the evidence for a strong genetic component, until recently there had been very few confirmed genetic susceptibility factors. This picture changed with the publication of a number of genome-wide SNP and CNV studies based on large samples of cases and controls.

Here we summarize the findings for loci for which we consider the evidence of involvement in SCZ as virtually indisputable. Such evidence arises mainly from strong statistical support, replication in independent studies (Table 19.1), and evidence that they are pathogenic for other neurodevelopmental disorders. We will also summarize the evidence for involvement of these loci in other disorders.

THE MAJOR SOURCES OF EVIDENCE CONSIDERED IN THIS REVIEW

The main primary sources of data we consider in this review come from the largest studies on SCZ. The ISC study (ISC, 2008) investigated 3,391 cases and 3,181 controls from six European populations, genotyped with Affymetrix 5.0 or 6.0 arrays. The authors filtered out loci that were common in the sample (>1%) and CNVs <100 kb in size, as they are less reliable for calling. Another team, Stefansson et al. (2008), started off by identifying *de novo* occurring CNVs in the Icelandic population, and then examined their frequencies in a total of 4,718 cases and 41,199 controls from nine European countries and China. Kirov et al.

(2009) examined 471 cases and 2,792 controls who took part in the Wellcome Trust Case Control Consortium study (WTCCC) study and were genotyped with the early version Affymetrix 500K arrays. A large collaborative study on European and African Americans was published by Levinson et al. (2011). It analyzed 3,945 subjects with SCZ or schizoaffective disorder and 3,611 comparison subjects. We also use the main papers that implicated several specific loci: Mulle et al. (2010) for deletions at 3q29; ISC (2008) and Stefansson et al. (2008) for deletions at 15q11.2 and 15q13.3; Kirov et al. (2009) for deletions at *NRXN1*; Moreno-de-Luca et al. (2010) for deletions at 17q12; Ingason et al. (2011a) for duplications at 16p13.1; Ingason et al. (2011b) for maternal duplications at the PWS region on 15q11.2-q13.1; and McCarthy et al. (2009) for duplications at 16p11.2. We have taken care to exclude any overlapping samples. Data on additional ~10,000 controls from the UK population was published by Grozeva et al. (2012), and that paper will be used extensively, as it also summarizes the findings in these loci.

Every CNV that has been robustly implicated in SCZ (Table 19.1) has also been evaluated in large datasets of subjects referred for genetic testing because they had intellectual disability, DD, congenital malformations (CM), or autism spectrum disorders (ASD). Two very large non-overlapping datasets on such patients were reported recently. Girirajan et al. (2012) reported on a sample of 32,587 cases with DD/CM/ASD, and Kaminsky et al. (2011) reported results gathered by a large consortium of cytogenetic laboratories on another very large sample of 15,749 subjects. Combined with the availability of data from other large studies of candidate CNVs in specific disorders, those data permit a reasonable estimation of the frequencies in other neurodevelopmental disorders of what are extremely rare events. A caveat is that these samples comprise a heterogeneous mixture of conditions ascertained through referral for genetic testing, and consequently, the data on each disorder of potential interest (e.g., ASD or DD) may be limited. However, a large proportion of these cases were known to suffer from intellectual disability, DD, and/or ASD, and evidence for the involvement of most of the loci has also come from smaller datasets recruited specifically for the presence of ASD, so we regard the estimates in Table 19.1 as giving a good approximation of the true rates in both DD and ASD.

REVIEW OF INDIVIDUAL CNV LOCI

All coordinates in this chapter are according to the genome build NCBI36/hg18.

DELETIONS AT 1q21.1 (144,9–146,3 Mb)

Deletions at 1q21.1 were independently implicated in SCZ by the first large-scale genome-wide CNV studies of the disorder (ISC, 2008; Stefansson et al., 2008). In a recent review of the published data (Grozeva et al., 2012), we identified 20 reported deletions among over 11,000 cases compared with 11 deletions in almost 60,000 controls. These rates differ highly significantly between the groups ($P = 2.9 \times 10^{-9}$) and correspond to an odds ratio (OR) of 9.2 for the deletion. Shortly after the

findings in SCZ, deletions at this locus were reported to be enriched among a heterogeneous group of individuals who had been referred for genetic testing (Brunetti-Pierri et al., 2008; Mefford et al., 2008). Among the variable phenotypes in carriers, most consistently present were autism, heart defects, and cataracts. Of particular interest, the deletion was also associated with microcephaly, while the reciprocal duplication was associated with macrocephaly. Intriguingly, the region contains the *HYDIN2* gene, a paralog of *HYDIN*. Since disruption of *Hydin* causes hydrocephalus in mouse, this has led to speculation that the head size phenotype might be related to altered copy number state of *HYDIN2* (Brunetti-Pierri et al., 2008; Mefford et al., 2008), although it is unclear that *HYDIN2* is translated and it is currently annotated as a pseudogene.

The studies by Girirajan et al. (2012) and Kaminsky et al. (2011) found the deletion at very similar rates of 0.31% and 0.35% respectively, in large samples of people referred to diagnostic laboratories because of DD, intellectual disability, ASD, and various CM. The combined rate of the deletion among such subjects is 0.32%, which is higher than the 0.18% found in SCZ. It is not yet possible to conclude whether this rate is statistically higher in DD/ASD, as the above cohorts included other (non-neurodevelopmental) phenotypes where this CNV has also been specifically implicated, such as congenital heart disease. An excess of duplications in SCZ cases has also been suggested by Levinson et al. (2011). Such an increase in SCZ looks even more likely, as the rate of these duplications is also increased in cases with DD/ASD/CM in the series of Girirajan et al. (2012) and Kaminsky et al. (2011).

DELETIONS IN *NRXN1*

NRXN1 encodes neurexin 1, which is one of a family of pre-synaptic transmembrane proteins that bind with postsynaptic proteins called neuroligins. They are the only cell adhesion molecules known to be specific to synapses, where they mediate essential interactions between pre- and postsynaptic structures (Südhof, 2008). *NRXN1* has been shown to have a vital role in the formation, maintenance, and release of neurotransmitters at synapses. In the first published study to implicate CNVs in *NRXN1* in SCZ, we and colleagues found a deletion that spanned the promoter and the first exon of the gene which was transmitted to two affected siblings (Kirov et al., 2008). While the statistical evidence that this deletion was disease relevant was weak, the observation in our study of a case with a *de novo* CNV spanning *APBA2* (coding for a protein known to interact with neurexin 1) provided some circumstantial support. Subsequently a strong body of evidence has emerged for the involvement in SCZ of exonic deletions at *NRXN1*, as reviewed by Kirov et al. (2009).

Unlike the other CNVs discussed in this chapter, those affecting *NRXN1* are not flanked by LCRs and therefore deletions at this locus come in various sizes and disrupt different parts of the gene. Currently, and as first noted by Rujescu et al. (2008), compelling evidence ($P = 3.7 \times 10^{-6}$) for the involvement of CNVs at *NRXN1* concerns specifically exon spanning deletions which have a substantial effect on risk (OR = 7.44; 95% CI = 3.2–17.2) (Kirov et al., 2009). Duplications affecting *NRXN1* are surprisingly rare and have not been associated with diseases.

TABLE 19.1. CNV loci that can be regarded as increasing risk to develop SCZ. The numbers of carriers and the total number of subjects in each study are presented (nn/nn). The sources used to derive the figures are abbreviated with just the names of the first authors and are listed in the references as follows: Grozeva et al. (2012); Girirajan et al. (2012); Kaminsky et al. (2011); Kirov et al. (2009); Ching et al. (2010); Glessner et al. (2009); Ballif et al. (2008); Burnside et al. (2011); de Kovel et al. (2010); Ingason et al. (2011b); Levinson et al. (2011); Dibbens et al. (2009); Nagamani et al. (2011); Williams et al. (2010); Kuang et al. (2011); McCarthy et al. (2009); Rees et al. (2011); Schaaf CP et al. (2012). Genomic coordinates are according to NCBI36/hg18

Two large studies on DD/ASD/congenital anomalies/epilepsy found deletions in *NRXN1* at higher rates than in controls: Schaaf et al. (2012) found 17 carriers of exonic CNV among 8,051 individuals, and reported that 93% of the patients with exonic deletions manifested DD or intellectual disability, 56% had ASDs, and 59% had infantile hypotonia, while congenital malformations and dysmorphic features appeared only infrequently. Proband with epilepsy were also highly overrepresented among the carriers, at 53%, and ADHD was found in 41%. Ching et al. (2010) reported a similar rate of 12/3,540 exonic deletions among another cohort of probands with similar phenotypes. The combined rate of these two studies (29/11,591) is 0.25%, slightly higher than the 0.16% found in SCZ. Deletions in *NRXN1* have also been found in cases recruited specifically for the presence of ASD (Glessner et al., 2009), again at the somewhat higher rate of 0.36%, compared to SCZ (Table 19.1). Here the sample sizes are smaller than those for SCZ, and so the estimate of the prevalence in ASD is less exact to allow a conclusion as to whether these CNVs are more specific for SCZ or ASD.

DELETIONS AT 3q29 (197,4–198,8 Mb)

These deletions span 21 genes and, after anecdotal observations in some studies, were reported to be associated with SCZ by Mulle et al. (2010). The finding was confirmed by Levinson et al. (2011). In a synthesis of the data (Grozeva et al., 2012), deletions were shown to have been found in about 1 in 1,000 cases, a rate 50 times higher than in controls, a highly significant increase ($P = 4.2 \times 10^{-7}$, OR = 49.5, 95% CI = 6.9–2168). Three large studies reported on the rate of this deletion in other neurodevelopmental disorders (Table 19.1). Ballif et al. (2008) reported the highest rate of 14/14,698 cases affected with CM/mental retardation. The deletion was found in 20 cases out of 32,587 people affected with DD/CM/ASD in the Girirajan et al. (2012) series, and in 9 among the 15,749 subjects of the Kaminsky et al. (2011) series. This gives a total frequency of 0.068% (43/63,034) among such disorders, slightly lower than the 0.097% found among SCZ cases. The near absence of this deletion among controls (a single observation so far in >50,000 controls) suggests a high pathogenicity. This is reflected by the very high selection coefficient of 0.81 estimated for this locus (discussed later in the section “Mutation Rates and Selection Coefficients”).

DELETIONS AT 15q11.2 (BP1-BP2, 20,3–20,8 Mb)

There are five documented LCRs near the centromere of chromosome 15 that can instigate NAHR and give rise to CNVs. These LCRs have been called breakpoints (BP) and in the literature are designated BP1 to BP5. Several CNVs arising between different BPs in this region have been implicated in SCZ and other neurodevelopmental disorders. Deletions at 15q11.2 are the most centromeric of these CNV loci and involve the region between BP1 and BP2. The first report that deletions at this locus are risk factors for SCZ came from the work of Stefansson et al. (2008). CNVs at this locus are the most common of those discussed in this review, indeed in the study of the ISC, they surpassed the threshold for exclusion (>1% for deletion and duplication combined) and as a

result, this locus was not considered in that initial report (ISC, 2008). We have recently summarized the results of all published large studies (Grozeva et al., 2012): deletions have been reported in 68 out of 11,863 cases (0.57%) and in 160 of 60,367 controls (0.27%), Fisher Exact Test $P = 5.7 \times 10^{-7}$.

Despite the very low p-value, this locus confers only a modest OR for SCZ of 2.2 (95% CI = 1.6 to 2.9). Additional support for the pathogenic role for this deletion in human disease has come from work on other neurodevelopmental disorders. Burnside et al. (2011) found 69 cases with deletions here among 17,000 subjects referred for genetic testing, a rate of 0.4%. Phenotypes in carriers of the 15q11.2 deletion included autism, DD, motor and language delays, and behavioral problems. Girirajan et al. (2012) found a somewhat higher rate in their study, CNV deletions occurring here in 0.71% of their sample. Together, these two studies report the deletion in 235 out of 40,380 subjects affected with unexplained DD/intellectual disability/physical anomalies/ASD, a rate of 0.58%. This is almost identical to the rate reported in SCZ (0.57%), and twice that in controls.

High rates of this deletion have also been reported in subjects with epilepsy: De Kovel et al. (2010) found a rate of 1% among 1,234 patients with idiopathic generalized epilepsy. The sample size here is too small to accept this estimate of frequency as accurate, and the main finding in epilepsy remains to be replicated.

The chromosomal segment between BP1 and BP2 contains four highly conserved genes that are expressed in the brain: *TUBGCP5*, *NIPAI1*, *NIPAI2*, and *CYFIP1*. *CYFIP1* is a gene encoding a postsynaptic protein involved in regulating postsynaptic sensitivity at glutamatergic NMDAR receptors. As reported in their study of *de novo* and case-control CNVs (Kirov et al., 2012) genes that encode such proteins are enriched among CNVs found in those with SCZ, suggesting the hypothesis that *CYFIP1* may be the gene relevant to the disorder at this locus. Details on the role of the postsynaptic density complex in SCZ, and of the involvement of CNVs containing genes that code for proteins embedded within that complex, are presented in Chapter 24 (Seth Grant).

DUPLICATIONS AT 15q11.2-q13.1 (BP2-BP3, 21,2–26,2 Mb)

This 4Mb region is known as the Prader-Willi/Angelman syndrome critical region (PWS/AS). Due to differential methylation of paternal and maternal chromosomes in this region, a phenomenon known as imprinting, some genes are only expressed from the maternally transmitted chromosome, others from the paternally transmitted one. Accordingly, CNVs at this locus functionally impact on different genes depending on the transmitting parent, and as a result, the phenotype also differs by parent of origin. Deletions of the paternal chromosome cause PWS, while deletions of the maternal chromosome cause AS. Duplications of this region are also involved in human disease; indeed they have been claimed to be one of the most common causes of autism (Glessner et al., 2009), where the majority are maternally derived.

It is of note that PWS patients who have maternal uniparental disomy (lacking the paternal chromosome but having inherited two maternal copies) have high rates of psychosis, usually of a

schizoaffective or cycloid type (Verhoeven et al., 1998), whereas those with the usual PWS (lacking the paternal chromosome, but having only a single maternal chromosome in this locus) do not. This suggests that excess expression of a gene in this region (normally expressed only on maternal chromosomes) might contribute to psychosis. Compatible with this, Ingason et al. (2011b) reported four duplications of this region of maternal origin among 7,582 patients affected with SCZ. The rate of this maternal duplication in SCZ is approximately 0.05%, which is more than five times higher than the rate in controls but is much lower than in autism (0.68%). Coupled with the high rate of psychosis in PWS patients with maternal uniparental disomy, it seems very likely this duplication is involved in psychotic disorders.

DELETIONS AT 15q13.3 (BP4-BP5, 29–30,3 Mb)

This 1.3Mb deletion was independently implicated as a risk factor for SCZ in both of the first large CNV studies of the disorder (ISC, 2008; Stefansson et al., 2008). The rate of the deletion in those with SCZ is 0.19% (21/10,887), about 10 times higher than that of controls, $P = 2.7 \times 10^{-9}$, OR = 8.3 (95% CI = 4–18.2) (Grozeva et al., 2012).

Similar to the other CNVs discussed here, this deletion can present with a range of phenotypes. Thus, the overall rate of 0.28% in DD/CM/ASD is similar, and possibly higher to that of SCZ, with similar rates reported in the two largest studies: Girirajan et al. (2012) found 85 deletions in 32,587 subjects referred for DD/CM/ASD, and Kaminsky et al. (2011) found 46/15,749 in their series. Ben-Shachar et al. (2009) pointed out the incomplete penetrance and highly variable expressivity associated with this deletion in a series of 14 children with the deletion, who had been identified from a series of 8,200 individuals referred to medical genetics for diagnostic testing. Phenotypes in the children carrying this CNV included DD, mental retardation, ASD, speech delay, aggressiveness, and attention-deficit hyperactivity disorder (ADHD). Deletions were observed in several phenotypically normal parents and siblings, confirming its incomplete penetrance.

This deletion is also highly likely to be pathogenic for epilepsy. Two studies of generalized idiopathic epilepsy reported a rate of about 1% in patients (combined results of the two studies): 16/1,639 patients (de Kovel et al., 2010; Dibbens et al., 2009). Epilepsy also appears to be more common than expected among carriers of the deletion who also suffer with mental retardation (Sharp et al., 2008). Overall, this CNV seems to be most highly enriched in those with epilepsy than it is for other developmental phenotypes, although as before, a caveat is that sample sizes used in the epilepsy studies are more than an order of magnitude smaller than those for SCZ and DD/CA. It is also of note that very few of the SCZ patients who had this deletion had documented epilepsy.

DUPLICATIONS AT 16p13.1 (15.0–16.2 Mb)

The pathogenicity of this CNV locus was first suggested by Ullmann et al. (2007), who found duplications in four male patients with severe autism. Ingason et al. (2011a) subsequently reported a threefold increase in the rate of this duplication in

4,345 cases with SCZ, which is in line with, although slightly larger than, what we find in a review of the literature in which we reported a prevalence of 0.28% (20/7,075) in cases compared with 0.13% in controls (63/47,854) in controls, $p = 0.005$, OR = 2.1 (95% CI = 1.2–3.6).

Following the pattern of the other CNVs, increased rates of this duplication have been reported in other disorders. Williams et al. (2010) found an increased rate of 0.84% in ADHD. The rates reported in DD/CM/ASD are similar to those in SCZ (Table 19.1): 0.29% among 15,749 subjects in the study by Kaminsky et al. (2011), 0.3% among 32,587 subjects in the study by Girirajan et al. (2012), and 0.40% among 14,000 subjects in the study by Nagamani et al. (2011). Phenotypic manifestations in the three studies listed above included behavioral abnormalities, cognitive impairment, congenital heart defects, and skeletal defects. Another phenotype is aortic dissection, with a carrier rate of ~1% (Kuang et al., 2011), although given the size of the sample, this study is underpowered for accurate estimation of frequency and requires replication.

The reciprocal deletion has not been confidently implicated in SCZ yet, although a non-significant trend was reported in the Ingason et al. (2011a) study, where deletions were present in 0.12% of cases and 0.04% of controls ($P > 0.05$). The deletion appears to also confer high risk for DD and ASD. Thus, in the study by Girirajan et al. (2012), deletions at 16p13.1 were found in 0.14% of the 32,587 subjects. Intriguingly, very high rates of this deletion have been reported in people with epilepsy, with one study (Heinzen et al., 2010) reporting a 0.6% rate (23/3,812).

DUPLICATIONS AT 16p11.2 (29,5–30,1 Mb)

This gene-rich duplication (24 genes) was first implicated as a risk factor for autism, where it is regarded as one of the most frequent chromosomal abnormalities (e.g., Glessner et al., 2009; Sanders et al., 2011), with a rate of 0.45% (reviewed in Rees et al., 2011). A meta-analysis of studies on SCZ (McCarthy et al., 2009) also found a highly increased rate of duplications at this locus in SCZ: 0.3% (26/8,590), while the latest estimate of the control rate is 0.031 (12/38,665), an almost 10-fold increase in SCZ: OR = 9.8, 95% CI = 4.8–21.3, $P = 1.8 \times 10^{-11}$ (Grozeva et al., 2012). This CNV is also present at high rates in DD/CM: Girirajan et al. (2012) and Kaminsky et al. (2011) found it in a total of 122 out of 48,446 subjects referred for genetic testing, a rate (0.25%) similar to but somewhat lower than in ASD and SCZ. Carriers were typically microcephalic, a phenotype that through studies of zebra fish and of mouse, appears to be attributable to dosage of *KCTD13* (Golzio et al., 2012). *KCTD13* encodes polymerase delta-interacting protein 1, which has been speculated to have a role in cell cycle during neurogenesis, although it is not clear yet from human studies that this gene per se is involved in SCZ.

The rate of the reciprocal deletion is markedly increased in DD/CM: Girirajan et al. (2012) found it among 125/32,587 cases (0.38%) and Kaminsky et al. (2011) in a similar rate of 67/15,749 (0.43%) a more than 10-fold increase over the 0.03% in controls (McCarthy et al., 2009). However, as yet there is no evidence that the prevalence of this deletion is increased in people affected with SCZ (McCarthy et al. 2009).

DELETIONS AT 17q12 (31,8–33,3 Mb)

Deletions of 1.5Mb at this region have been implicated in SCZ (Moreno-De-Luca et al., 2010), and in autism/neurocognitive impairment (Loirat et al., 2010; Moreno-De-Luca et al., 2010). This CNV can also present with various medical conditions including macrocephaly, genitourinary tract anomalies such as renal cysts, recurrent infections, and diabetes (Moreno-De-Luca et al., 2010; Nagamani et al., 2010). The rate among individuals referred for genetic testing in the combined datasets of Girirajan et al. (2012) and Kaminsky et al. (2011) is 0.09% (44/48,336), an approximately 30-fold increase compared to controls, where it has been detected in only two out of 58,188 controls (0.003%). As this CNV is very rare, and has not been tested in sufficiently large cohorts of SCZ, the evidence for its involvement in SCZ is still modest and requires further evaluation, it having been reported so far in only 4/6,340 cases (0.06%) a rate that is still about 20-fold higher than in controls, $p = 0.001$, OR = 18.4 (95% CI = 2.6–203).

DELETIONS AT 22q11.2 (17,4–19,8 Mb)

This was the first CNV of established pathogenicity in psychosis, for which it still confers the highest known elevation in risk of any molecular lesion. It has been extensively reviewed in the literature (e.g., Murphy et al., 1999). Small studies have reported substantial variation in prevalence in the disorder, but the best estimate is 0.31% (35/11,400) (Levinson et al., 2011), compared with zero observations among 55,620 controls. Around 80% of cases are due to *de novo* mutations (reviewed by Rees et al., 2011). Around 30% of carriers develop psychosis, but despite this incomplete penetrance, the deletion carriers are not found in control populations, probably because they can also develop cardiac anomalies, mild mental retardation, or other behavioral abnormalities, leading to their exclusion from control populations. About 40% of carriers have mild mental retardation, and the mean IQ is in the range of 70–80. Around 30% of deletion carriers have ASD. The rate among referrals for genetic testing for DD/CM/ASD is 0.55% in the combined datasets of Girirajan et al. (2012) and Kaminsky et al. (2011), with virtually identical rates between the two studies: 175/32,587 (0.54%) and 93/15,749 (0.59%) respectively. This is approximately twice the rate found in SCZ.

Despite intensive investigation over more than a decade, and a number of intriguing candidates, the gene(s) within this CNV relevant to psychosis have not been unequivocally established. The role of the reciprocal duplication is much less clear, with increased rates reported in DD/ASD/CM (Girirajan et al., 2012; Kaminsky et al., 2011), but not in SCZ.

COMPARISON BETWEEN RECIPROCAL DELETIONS AND DUPLICATIONS OF THE REGIONS

As can be seen from Table 19.1, the specific deletion or duplicated CNVs that have been implicated in SCZ have also been implicated in DD and or ASD. However, whereas most of the reciprocal CNVs in Table 19.1 have also been implicated in DD and/or ASD, there are to date no instances where both deletion

and duplication at a given locus have been confidently confirmed to increase risk of SCZ. This could be due to lack of power of these studies, and indeed increased risk for duplications at 1q21.1 and deletions at 16p13.1 has been suggested and awaits replication (Ingason et al., 2011a; Levinson et al., 2011). Of the three duplications listed in Table 19.1, the reciprocal deletions at 15q11.2–q13.1 are known to cause Prader-Willi or Angelman syndromes (depending on parental origin), while deletions at 16p11.2 and 16p13.1 are found at high rates in DD/ASD. The same applies to rearrangements at 7q11.23, where deletions cause Williams Beuren syndrome, while duplications have been implicated in SCZ (Kirov et al., 2012) and are known to cause ASD (Sanders et al., 2011). Similarly the reciprocal duplications of the deleted loci from Table 19.1 (except for 1q21.1) have not yet been implicated as increasing risk for SCZ, although many have been found at increased rates in the Girirajan et al. (2012) and Kaminsky et al. (2011) series with DD/CM (e.g., duplications at 1q21.1, 3q29, 15q13.3, 17q12, 22q11.2). The absence of association at most of the reciprocal loci could be due to lack of power in the SCZ studies, but could also reflect a degree of specificity in the role of CNVs in SCZ and DD/ASD.

Figure 19.1 (based on Table 19.1) shows the frequencies of each CNV at SCZ implicated loci in SCZ, DD/CM/ASD, and controls. At several of the loci (1q21.1, *NRXN1*, 15q13.3, duplications at the PWS/AS region and deletions at the VCFS region on 22q11.2), the CNV frequencies are substantially higher in DD/CM/ASD compared with SCZ, but at none is the frequency markedly higher in SCZ than in DD/CM/ASD. We have not attempted a formal statistical analysis of these comparisons given the data have been generated and analyzed with very different methods and platforms. Nevertheless, it appears that with some exceptions the SCZ-associated CNVs are either similar in frequency or are even more common in DD/ASD than in SCZ.

At present, it is premature to do direct comparisons between SCZ and samples ascertained specifically for studies of ASD (as opposed to general referral for molecular genetics testing), as those studies are still too small to allow confident comparisons. However, tentatively, the available data suggest a more prominent role in autism than in SCZ for maternally inherited duplications of the PWS/AS region (0.68%), deletions at *NRXN1* (0.36%), and possibly duplications at 16p11.2 (0.45%), but larger studies of ASD (without CM/DD) are required to resolve this question.

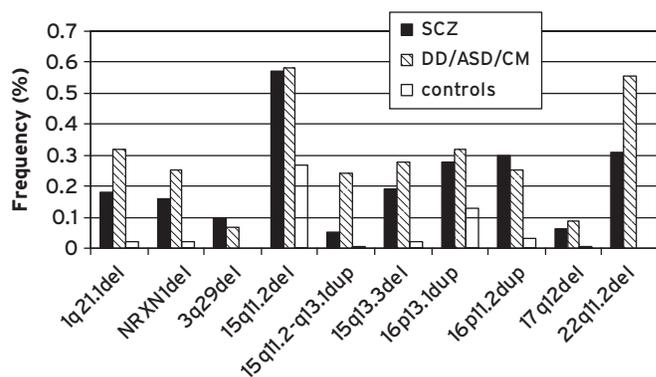

Figure 19.1 Comparison of the rates of the reviewed CNVs in SCZ, DD/ASD/CM, and controls.

As highlighted in the previous sections, several CNVs result in increased risk to develop DD/CM/ASD, but not SCZ, but the converse is not true. If we accept that SCZ represents a milder phenotype based on later age at onset and less impaired cognition, this may suggest that those that do not cause SCZ have higher pathogenicity. In support of this hypothesis, we would note that there are many other CNV loci that we do not discuss in this chapter, that cause severe DD, intellectual deficit, and some recognized syndromes, for example 1p36 syndrome, Sotos or Smith-Magenis syndrome. These CNVs are not known to include SCZ as a phenotype, although the identification of such CNVs in a proband with SCZ or ASD should raise the question of causality.

There was an expectation that these CNVs will also increase risk to develop bipolar affective disorder, as the two disorders share genetic factors (Lichtenstein et al., 2009). Several studies failed to find such links and the overall rate of large and rare CNVs in bipolar disorder was found to be similar to that among controls (e.g., Grozeva et al., 2010). However, the rate of *de novo* CNVs is increased in bipolar patients compared to controls, at 4.3%, which is nearly as high as the rates reported in SCZ (Malhotra et al., 2011), indicating that certain CNVs also increase risk to develop this disorder. This might apply especially to large duplications (Malhotra et al., 2011), such as the duplication at 16p11.2 (McCarthy et al., 2009).

MUTATION RATES AND SELECTION COEFFICIENTS

SCZ is associated with substantially reduced fecundity, estimated at less than half compared to healthy controls. As a result, genetic variants that confer high risk to SCZ might be expected to be subject to strong negative selection and therefore be eventually excluded from the population. If the prevalence of SCZ is stable in the population, and the evidence suggests it is, or at least it has not decreased to the current rate from a much higher level, it is a reasonable first proposition that the high penetrance variants that are excluded by selection should be replenished by new (*de novo*) mutations (though other explanations are also possible). In the case of CNVs, studies of proband parent trios (reviewed by Rees et al., 2012) have shown that this is indeed true. An early study (Xu et al., 2008) found that a *de novo* CNV occurred in 10% of individuals with SCZ who had no family history of SCZ in a close family member, but the rate of *de novo* CNV occurrence in SCZ has dropped somewhat as sample sizes have enlarged. Thus, recent estimates are in the order of around 5% compared with a rate in controls of around 1% or 2% (summarized by Kirov et al., 2012). The *de novo* CNVs were also much larger than those found to be transmitted, another indication that they are under selection pressure (otherwise their properties would be similar to those of CNVs that are neutral and segregating in the population at large). Moreover, that the observed *de novos* represent a replenishing of schizophrenia risk CNVs is supported by the fact that a large number of the 34 *de novo* CNVs we reported (Kirov et al., 2012) were either in some of the confirmed SCZ loci discussed in this chapter, or in loci for which there is a high index of suspicion for their involvement

in SCZ, such as the duplication at the WBS region and the DLG2 gene.

Assuming that the prevalence of a CNV is stable in the general population, it is possible to estimate the strength of the selection pressure acting against it. As discussed previously, if a CNV is under selection pressure, then its prevalence will decline in each generation unless new *de novo* CNVs occur at a rate equal to that at which they are removed as a result of reduced fecundity of carriers. The selection pressure or selection coefficient (s) against a CNV approximates to the proportion of CNVs at a locus that are the direct result of *de novo* events in a representative sample of the population: ($s = [N \text{ de novo}]/[N \text{ total}]$). It is also possible to estimate the average number of people that will carry a *de novo* CNV before it is eliminated from the population. This is called pervasiveness and is estimated as $1/s$ (see Rees et al., 2012). In Table 19.2 we present estimates of selection pressure and pervasiveness. All the loci from Table 19.1 are under a strong selection pressure of between 0.11 and 0.81, and are expected each be carried by between 1.2 (for the more pathogenic 17q12 and 22q11.2 deletions) and 9.1 people (for the more common 15q11.2 deletion and 16p13.1 duplication) before they are eliminated from the general population. In other words all these CNVs confer risk to disorders that markedly reduce fecundity or survival and if the frequency in the population is stable, must have high mutation rates. Their mutation rates are indeed high, estimated between 1.7×10^{-5} and 1.4×10^{-4} (Rees et al., 2011). Thus, between 1 in 7,000 newborns (for 15q11.2 deletion) and 1 in 58,000 newborns (for 17q12 deletion) will have a new mutation at each of the loci listed in Table 19.1.

CONCLUSIONS

The recent CNV studies have changed the landscape of SCZ genetics. There are now at least 10 confirmed loci that cause substantial increases in the risk to develop the disorder, and we expect that the list will grow once larger samples are tested, as many CNVs are so rare that tens of thousands of patients need to be genotyped for a confident statistical conclusion to be reached. These studies have shown a rather unexpected overlap with the genetic causes of DD and ASD, with all of the implicated large CNVs conferring increased risk to develop these disorders. For several of the CNVs, the carriers appear even more likely to develop these earlier onset disorders (DD/ASD/intellectual disability), and one could speculate that other genetic or environmental factors protect carriers from developing a disorder during early childhood, but instead they develop SCZ in later life. The penetrance for developing any disorder is incomplete, and it would be fascinating if any protective factors are identified. These large CNVs cause a reduction in fecundity in their carriers, and would be eliminated from the population very quickly, if it were not for their high mutation rates. The main cause for the increased mutation rate at these loci is the abundance of LCRs in the human genome, that causes instability, mostly via NAHR events.

The presence of clearly identified genetic changes that increase risk to develop SCZ raises the question whether

TABLE 19.2. Selection coefficients for associated SCZ CNV loci. Del = deletion, Dup = duplication. Selection coefficients (s) are updated from those estimated by Rees et al. (2011) with data from the recent large paper by Girirajan et al. (2012). The second column presents the numbers of *de novo* mutations in each locus out of the total number (*de novo* + transmitted) reported in studies that systematically ascertained the rates of *de novos* in these loci. Pervasiveness refers to the average number of people who will carry the mutation before it is eliminated from the general population.

CNV LOCUS	N(DE NOVO)/ N(TOTAL)	SELECTION COEFFICIENT S (DE NOVO RATIO)	PERVASIVENESS (1/S)
1q21.1 del	22/76	0.29	3.4
<i>NRXN1</i> exonic del	7/32	0.22	4.5

22q11.2 del	482/601	0.80	1.3

subjects with this disorder should undergo genetic testing and counseling, if requested. This is now routine practice in children with unexplained DD/ASD, and could easily be applied to patients suffering with SCZ. The yield is likely to be much lower than among subjects with DD/ASD/CM, as only about 2–3% of SCZ sufferers are likely to carry a known pathogenic CNV. It will be up to the genetics community and patients to discuss whether such testing will be beneficial and cost-effective for the treatment and counseling of sufferers and their families.

DISCLOSURES

20 | NEUROIMAGING OF PSYCHOTIC DISORDERS

STEPHAN HECKERS, NEIL WOODWARD, AND DOST ÖNGÜR

STUDYING THE BRAIN TO UNDERSTAND PSYCHOSIS

Neuroimaging studies of brain structure and function have significantly advanced our understanding of psychotic disorders. They transformed psychosis research at a very basic level—by capturing the elusive pathology with brain images (Johnstone et al., 1976). At a time when few psychiatrists were neuroscientists, this was crucial for redefining psychotic disorders as brain disorders. Neuroimaging of psychotic disorders began in the 1970s with computed tomography (CT) studies of brain structure, followed by single photon emission computed tomography (SPECT) and positron emission tomography (PET) studies of blood flow, glucose metabolism, and receptor chemistry. It culminated in the application of several magnetic resonance imaging (MRI)–based techniques, including structural MRI, functional MRI (fMRI), MR spectroscopy (MRS), and diffusion tensor imaging (DTI). The widespread use of MR machines in academic medical centers has liberated a new generation of researchers from the constraints of postmortem research and the limitations of inferring brain abnormalities through neurochemical effects in plasma or urine.

Despite tremendous progress, the neuroimaging of psychotic disorders remains heavily influenced by Emil Kraepelin's concept of psychotic disorders. He introduced the dichotomy of nonaffective and affective psychoses at the end of the 19th century and asserted that schizophrenia is caused by a cellular pathology of the cerebral cortex, leading to marked cognitive deficits, whereas bipolar disorder is not. He also began the neuroscientific study of psychotic disorders, using two very different approaches: he conducted psychological experiments in patients and he encouraged the pathological exploration of their brains after death. Encouraged by early successes, anatomists and pathologists dominated the field of schizophrenia research in the first half of the 20th century. They described mainly qualitative abnormalities in the cellular organization of the cerebral cortex and the thalamus. However, by the 1950s, they concluded that the neuropathology was elusive and that they were not able to diagnose schizophrenia in the laboratory. Similarly, the efforts of experimental psychologists did not lead to diagnostic tests that could assist clinicians in the management of psychotic patients.

Two discoveries reinvigorated the neuroscientific study of psychotic disorders. The serendipitous discovery of neuroleptic/antipsychotic drugs raised important questions about their mechanism at the level of cells and circuits. The subsequent

discovery of the neurotransmitter dopamine and its role in mediating the effect of neuroleptic/antipsychotic drugs helped focus the research on a small group of neurons in the midbrain and their diffuse projections to the cortex and subcortical regions. This led to the prominence of neurochemical models for the explanation of schizophrenia, first the dopamine model in the 1960s and then the glutamate model in the 1980s.

Many themes of the neuroimaging research reviewed here overlap with those in postmortem research (see Chapter 23) and cognitive neuroscience research (see Chapter 21). However, the ability to study brain structure and function repeatedly and to correlate it with cognitive and clinical outcomes are unique strengths of neuroimaging studies and will ensure a prominent position of this research methodology in the study of psychotic disorders. Here we provide an overview of the neuroimaging studies of psychotic disorders (mainly schizophrenia and schizoaffective disorder). We will focus on meta-analyses and comprehensive reviews, but will include some seminal studies that have shaped our current understanding of psychotic disorders.

THE GOALS OF NEUROIMAGING IN THE STUDY OF PSYCHOTIC DISORDERS

First and foremost, we look toward neuroimaging to establish illness markers that can distinguish a clinically defined group of patients (e.g., schizophrenia) from healthy controls and from other patient groups (e.g., mood disorder). The ideal outcome is a test that can assist the clinician in the diagnosis and management of the psychotic patient.

Second, we expect that neuroimaging will aid in the understanding of the psychosis phenotype. This includes explanations of abnormal mental states, such as delusions and hallucinations, and of the prominent deficits in the realm of attention, memory, language, and thought.

Third, neuroimaging methods need to improve our neural models of psychotic disorders, including the prominent anatomical models of prefrontal cortex and medial temporal lobe pathology and the neurotransmitter models of dopamine, glutamate, and GABA dysfunction.

Finally, neuroimaging can build a bridge to the genetic mechanisms of the disease. This can be explored by studying monozygotic and dizygotic twins, by studying unaffected relatives of psychotic patients, or by studying the association of risk genes with neuroimaging markers.

Our review is organized according to these four goals of neuroimaging in the study of psychotic disorders. It is important to note that these goals are not necessarily aligned with each other and that relatively specialized communities of researchers have emerged to pursue these studies. Even the same result, for example, abnormal hippocampal structure and function, may be interpreted in largely non-overlapping contexts. For example, one researcher may want to develop it as a diagnostic marker in the early stages of psychosis, whereas another might explore the same finding as an indication of abnormal GABAergic or glutamatergic function in schizophrenia. Yet another setting for the same finding is to study the neural consequences of potential risk alleles such as DISC1 or BDNF. The same scenario holds true for abnormalities of the prefrontal cortex, the thalamus, the cerebellum, or the basal ganglia. The relative merits of these goals are rarely considered, and the neuroimaging community has yet to define shared goals in order to make progress in schizophrenia research.

ESTABLISHING MARKERS OF DISEASE

The vast majority of structural and functional neuroimaging studies compare a group of psychotic patients, at one time point, with a group of healthy control subjects. This cross-sectional approach is modeled after the use of neuroimaging in clinical radiology, where the image of a single patient is contrasted with the standard of a healthy person. Some studies have compared two different groups of patients (e.g., schizophrenia versus bipolar disorder) in order to explore shared or distinct features of psychopathology. So far, few researchers have taken advantage of the unique strength of neuroimaging methods to follow patients over time. This is due in large part to the challenges of a longitudinal study design. In addition, there are several pitfalls when disambiguating illness effects from treatment effects. However, it is likely that the longitudinal study design will ultimately secure a prominent position of neuroimaging in the scientific study and clinical management of psychotic patients.

CROSS-SECTIONAL STUDY OF BRAIN STRUCTURE

There are two main approaches to quantifying brain structure: manual tracing and automated methods. The initial studies of brain structure in schizophrenia used the manual approach to quantify the volume of a specific region-of-interest (ROI). The earliest of these studies employed computed tomography and focused on measuring the size of the ventricles (Johnstone et al., 1976). The subsequent development of MRI afforded substantially better spatial resolution of brain tissue types, that is, gray matter, white matter, and cerebrospinal fluid (CSF), which prompted a large number of volumetric studies. Qualitative and quantitative reviews of structural MRI studies using manual tracing methods confirmed the earlier finding of ventricular enlargement. They also concluded that schizophrenia is associated with reductions in whole brain volume, particularly gray matter volumes of the medial temporal lobe (including hippocampus and amygdala), the superior temporal

gyrus, the frontal and parietal lobes, and several subcortical regions (including the basal ganglia, thalamus, and cerebellum) (Shenton et al., 2001). With better image resolution of more recent studies, this general pattern has not changed substantially (Shenton et al., 2010). While consistent across studies, the magnitude of these changes is subtle, generally falling within the range of 5–10% for specific structures and <5% for whole brain and total gray matter volumes (Wright et al., 2000).

Three regions of interest, the superior temporal gyrus (STG), the thalamus, and the hippocampus, have been studied extensively. Thirty-five out of 46 (76%) studies reported a significant difference in STG volume (mainly reduction) and 18 out of 30 studies reported correlations of STG volume with the severity of auditory hallucinations or thought disorder (Sun et al., 2009). Thirteen studies reported volume reduction of both left and right thalamus in both first-episode patients (six studies) and chronic patients (seven studies), with Cohen's *d* effect sizes ranging from -0.32 to -0.48 (Adriano et al., 2010). Finally, 13 studies of first-episode patients and 22 studies of chronic patients provided compelling evidence for smaller left and right hippocampal volumes in schizophrenia, with Cohen's *d* effect sizes ranging from -0.56 to -0.65 (Adriano et al., 2012). Taken together, there is compelling evidence for localized gray matter volume changes in schizophrenia.

Advances in computing power and computational anatomy spurred the development and application of automated methods for investigating structural brain changes in schizophrenia. In addition to the obvious advantage of being less laborious, compared to manual tracing approaches, automated methods can quantify multiple brain structures, examine changes at higher resolution—for example, down to the voxel-wise level in the case of voxel-based morphometry (VBM), and quantify aspects of cerebral morphology that are difficult to measure, such as cortical thickness.

Three meta-analyses of VBM studies used the activation likelihood estimation (ALE) method to review the current evidence of gray matter (Fornito et al., 2009; Glahn et al., 2008) and white matter (Di et al., 2009) abnormalities in schizophrenia. The ALE method tests for the likelihood that, across the studies under review, spheres around specific brain coordinates differ between groups. A more recent study (Bora et al., 2011) used the signed differential mapping (SDM) method, which includes not only positive changes as in the ALE method, but also negative results for the estimation of group differences. The results of these recent meta-analyses largely confirm the previous ROI-based studies, with two exceptions. First, medial temporal lobe abnormalities are not as prominent in meta-analyses of the VBM studies. This is possibly due to the lower sensitivity of the ALE and SDM methods to the complex anatomy in a relatively circumscribed region (Bora et al., 2011). Second, several brain regions, which had not been implicated by the ROI studies, emerged from the VBM studies. In large part this is due to a more difficult delineation of cortical regions, resulting in fewer studies. This is particularly striking for the insula, for which an ALE-based meta-analysis (Glahn et al., 2008) and an SDM-based meta-analysis (Bora et al., 2011) provided the initial evidence. This has now been confirmed by a third meta-analysis (Shepherd, Matheson, et al., 2012), which localized the changes

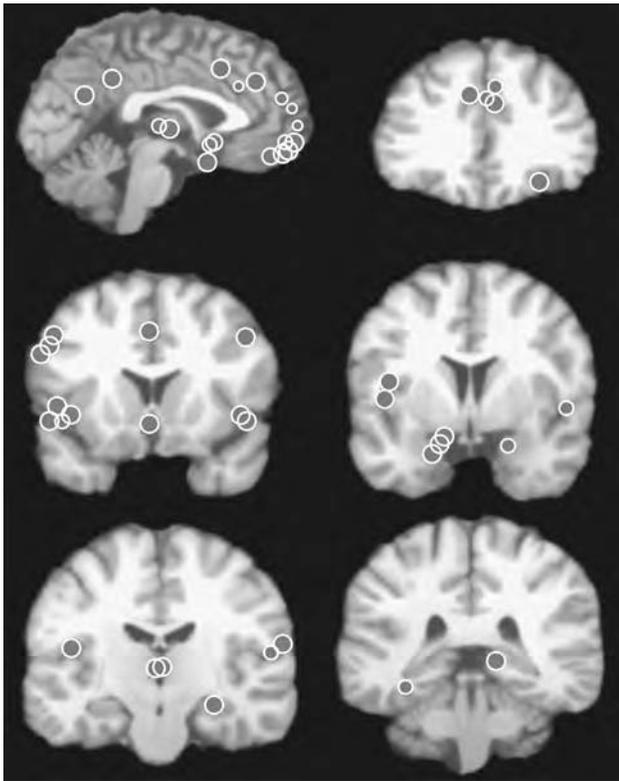

Figure 20.1 Reduced grey matter density in chronic schizophrenia. Dots indicate the spatial proximity of foci identified across multiple voxel-based meta-analyses, with coronal slices progressively posterior from left to right. Reproduced from: Shepherd, A. M., K. R. Laurens, et al. (2012). "Systematic meta-review and quality assessment of the structural brain alterations in schizophrenia." *Neuroscience and Biobehavioral Reviews* with permission from Elsevier.

to the anterior insula (connected to limbic cortex) in both first-episode and chronic patients.

Two recent meta-analyses using the ALE method examined the specificity of the changes observed in schizophrenia compared to bipolar disorder. Both reviews concluded that there is considerable overlap in gray matter volume reduction in schizophrenia and bipolar disorder, with both involving gray matter loss in the anterior cingulate/medial prefrontal cortex, lateral prefrontal cortex, and bilateral insula. However, the extent of gray matter volume loss is greater in schizophrenia and includes additional areas, such as the thalamus and temporal lobe (Ellison-Wright and Bullmore, 2010; Yu et al., 2010).

A comprehensive summary of both ROI and VBM studies of structural brain alterations in schizophrenia concluded that we now have evidence for gray matter reductions of anterior cingulate, frontal (particularly medial and inferior) and temporal lobes, hippocampus/amygdala, thalamus, and insula that may be magnified over time (Shepherd et al., 2012a) (Fig. 20.1).

CROSS-SECTIONAL STUDY OF BRAIN FUNCTION

Cognition is markedly impaired in schizophrenia, with relatively greater deficits in episodic memory, executive cognitive abilities, such as problem solving and working memory,

and processing speed (see Chapter 21). Not surprisingly, the bulk of functional imaging investigations in schizophrenia have focused on elucidating the neural correlates of cognitive impairment, as opposed to clinical symptoms, such as delusions and hallucinations. The advent of functional neuroimaging, beginning with PET in the 1980s then fMRI in the early 1990s, opened new avenues of research into the neural basis of cognitive impairment in schizophrenia. Early PET studies revealed abnormal activity in the prefrontal cortex, often consisting of reduced activation compared to control subjects during performance of executive cognitive tasks (Weinberger et al., 1986a). The non-invasive nature of fMRI coupled with widespread availability, relative to PET imaging, resulted in a rapid increase of functional neuroimaging studies of cognition in schizophrenia. Meta-analyses and qualitative reviews of this literature have revealed several consistent findings (Glahn et al., 2005; Minzenberg et al., 2009; Ragland et al., 2009; Goghari et al., 2010; Niendam et al., 2012; Whalley et al., 2012).

In line with earlier PET studies, schizophrenia patients often demonstrate reduced activation of the dorsolateral PFC during performance of executive cognitive tasks (Glahn et al., 2005; Minzenberg et al., 2009). However, reduced brain activity extends beyond the PFC to include rostral anterior cingulate cortex, thalamus, and inferior/posterior parietal cortex. In addition, increased rather than decreased PFC activity in schizophrenia is observed in several regions, including the midline cortical areas, premotor cortex, and ventrolateral PFC (Glahn et al., 2005; Minzenberg et al., 2009). This more complex pattern of localized increases and decreases of PFC activity during performance of executive cognitive tasks has led to models that go beyond the simple notion of hypofrontality in schizophrenia. On the one hand, the alterations are more consistent with a pattern of dysregulation and decreased efficiency, rather than a simple loss of cortical activity. On the other hand, a distributed network of frontal, subcortical, and posterior brain regions is engaged during the performance of executive cognitive tasks, and the PFC is one of several abnormal nodes in a dysregulated network in schizophrenia.

Reduced activation of the prefrontal cortex, especially the dorsolateral PFC, is also observed during episodic memory (Achim and Lepage, 2005; Ragland et al., 2009). Episodic memory (the ability to encode and retrieve the details of events) and relational memory (the ability to remember not just single items but also their relationships) are significantly impaired in schizophrenia, and it is therefore not surprising that neuroimaging studies have explored the neural basis of this deficit. In addition to the abnormalities of dorsolateral PFC during memory performance, several studies have also reported an abnormal recruitment of the hippocampus and the closely connected parahippocampal cortex. This pattern has been interpreted as an abnormal corticohippocampal network or an abnormal connectivity within the hippocampal formation (Heckers and Konradi, 2010).

PARSING HETEROGENEITY

While neuroimaging studies have supported Kraepelin's assertion that psychotic disorders have a neural basis, they have

also revealed significant heterogeneity. This is apparent in two metrics of the available meta-analyses: the low to medium effect sizes of the group differences and the significant results when measuring the inconsistency between study results. In other words, neuroimaging studies do not have to answer the question “Is the brain abnormal in psychotic disorders?” since the evidence is strongly affirmative. Instead, we now need to turn to the question “Which patient has what abnormality?” in order to parse the still considerable heterogeneity of psychotic disorders. This line of research may proceed along the well-established path of studying diagnostic categories. But neuroimaging methods are very well suited to complement this with an alternative approach. It takes dimensions of psychopathology, cognition, or neural systems as a starting point in order to uncover mechanisms that are not expected to confirm the existing nosology of psychotic disorders. Such cross-cutting dimensions can enrich the diagnostic classification and can provide new avenues to study the mechanism of psychotic disorders, with the hope to develop markers for the development or testing of new treatments.

Neuroimaging findings have not matured yet as validators of the various psychotic disorder diagnoses and will not be included as biological markers in the revision of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5). It is likely that traditional dichotomies such as schizophrenia/healthy control or schizophrenia/bipolar disorder are not sufficient to overcome the low validity and limited clinical utility of neuroimaging methods. However, the ability to correlate brain structure and function with the clinical features of psychotic disorders is one of the strengths of neuroimaging and deserves more attention.

Liddle and colleagues characterized 30 chronic outpatients with schizophrenia, who had a stable pattern of psychotic symptoms, using factor analysis (Liddle et al., 1992). The symptoms were grouped into three syndromes, namely, prominent positive symptoms (reality distortion), prominent negative symptoms (psychomotor poverty), or prominent thought disorder (disorganization). Each of the three patterns was associated with altered perfusion at different loci, including increased medial temporal lobe blood flow in the reality distortion syndrome and decreased prefrontal cortex blood flow in the psychomotor poverty and disorganization syndromes. A similar approach was pursued by VBM studies, which revealed distinct patterns of gray matter density in the three syndromes, with a shared pattern of prefrontal and perisylvian alterations (Nenadic et al., 2012).

Several neuroimaging studies have explored the neural correlates of the negative syndrome or schizophrenia patients with persistent negative symptoms (Hovington and Lepage, 2012). This subgroup constitutes approximately 15–20% of all schizophrenia patients. They show more pronounced reductions of cortical gray matter, more widespread deficits of prefrontal and temporal recruitment during the performance of cognitive tasks, and more significant impairments of several cognitive abilities, especially memory. This group of patients deserves further attention in neuroimaging studies, especially in the early stages of the disease, when treatment effects are less likely to obscure the effects of prominent negative symptoms.

Patients with schizophrenia have also been contrasted with other psychotic patients, for example, schizoaffective disorder and psychotic bipolar disorder patients. A recent review of these studies concluded that medial temporal lobe changes differentiated bipolar patients from patients with schizophrenia, but that alterations in the prefrontal cortex were less discriminating (Whalley et al., 2012). This line of research challenges Kraepelin’s schizophrenia/bipolar dichotomy in two ways. First, it is now clear that bipolar disorder is as much a brain disorder as is schizophrenia, while Kraepelin did not consider bipolar disorder worthy of study in the laboratory or the morgue. More importantly, patients with psychotic bipolar disorder share many of the clinical features of schizophrenia, but may differ with regard to disease onset, progression, and outcome, resulting in different treatments. This allows neuroimaging researchers to disentangle the shared mechanisms of clinical features (e.g., hallucinations, delusions) from the more fundamental mechanisms of the disease. They also allow, to some degree, the study of a major confound in neuroimaging studies of psychotic disorders, namely, pharmacological treatment.

EFFECTS OF ILLNESS AND TREATMENT

Most abnormalities of brain structure and function are described initially in chronic, treated patients, and researchers are then moving to studies of patients in the early stages of the illness, if possible with no or little exposure to current treatments whenever possible.

While many studies of early psychosis confirmed the findings in chronic patients, they typically detect less significant or less widespread changes. For example, a meta-analysis comparing studies of chronic patients to first-episode schizophrenia concluded that many of the structural brain changes observed in chronic patients are present at first episode, including gray matter loss in bilateral insula, left uncus/amygdala, anterior cingulate, and thalamus (Ellison-Wright et al., 2008). For more detail see Chapter 26.

LONGITUDINAL STUDIES

The unique strength of neuroimaging studies is the ability to follow patients over time to study brain abnormalities at all stages of the illness and even predated the illness (high-risk state and prodrome). This puts neuroimaging in the unique position to study the neural mechanisms of course, outcome, and response to treatment. While longitudinal studies are superior to cross-sectional studies, simply by design, they are challenging and are confounded by the effect of treatment and different genetic and environmental backgrounds.

A review of longitudinal studies in chronic schizophrenia (follow-up duration ranging from 1 to 10 years) reported reductions in frontal lobe and thalamus volume and less consistent reductions of whole brain and temporal lobe, particularly STG, volumes. No progressive differences were reported in the hippocampus or cerebellum (Hulshoff Pol and Kahn, 2008). A meta-analysis of ventricular volume change found compelling evidence for increased lateral ventricular volume

over time, in both first-episode and chronic patients (Kempton et al., 2010).

A recent meta-analysis confirmed these earlier findings, reporting a significant change over time for whole brain gray matter, frontal lobe gray matter, and left caudate. No progressive changes were reported in temporal, parietal, or occipital lobe gray matter, hippocampus, amygdala, or cerebellum over a range of 1 to 10 years (Olabi et al., 2011). Interestingly, illness duration before baseline was negatively associated with the effect size in the hippocampus, implying that the magnitude of this volume difference changes as the disease progresses. The consequences of progressive changes in brain structure in schizophrenia remain unclear, but may be associated with poorer outcome, worse negative symptoms, and greater cognitive impairment. It is unclear whether bipolar disorder is associated with similar changes in brain structure over time, as relatively few studies have been carried out (Schneider et al., 2012).

HIGH-RISK STUDIES

Complementing the longitudinal studies of psychotic patients are studies of subjects who are not psychotic, but are at high risk to develop a psychotic disorder. Such cohorts can be defined by a high familial loading for psychotic disorders, that is, at least one or more than one (multiplex) first-degree relative with a psychotic disorder. An alternative recruitment strategy is the detailed characterization of basis symptoms of psychosis or brief, limited, and intermittent psychotic symptoms that do not cross the threshold for a categorical diagnosis. Such studies are time-consuming and require considerable effort in recruitment and follow-up. Recent meta-analyses have reviewed this still young branch of neuroimaging research (Fusar-Poli et al., 2011; Smieskova et al., 2010). They indicate that gray matter volume reductions in temporoparietal, bilateral prefrontal, and limbic cortices are a marker of increased risk for psychosis. In addition, gray matter reductions in superior temporal and inferior frontal areas are associated with later transition to psychosis (Fusar-Poli et al., 2011). These structural studies are complemented by a smaller number of fMRI, PET, and MRS studies, which also point to abnormalities in frontal and temporo limbic brain regions (Smieskova et al., 2010). In contrast to structural imaging studies of the early and chronic stages of schizophrenia, high-risk studies have repeatedly shown an increase in whole brain and gray matter volumes. This somewhat counterintuitive finding has been interpreted as an indication of dynamic brain changes at the time of transition into psychosis and deserves further study.

STATISTICAL CONSIDERATIONS

The vast majority of the neuroimaging studies reviewed here have set out to identify a structural or functional brain abnormality that can separate a group of patients from a healthy control group or a different group of patients. It is important to briefly review several issues of study design and inference testing, including representativeness of the study sample, strength

of the statistical effect, and the sensitivity and specificity of the findings.

Most relevant is the feasibility and clinical utility of the study design. Do the research studies recruit a representative sample of patients from the larger population? While this seems possible for structural imaging studies, it is unlikely for functional studies, which require the active participation of study subjects. It is particularly challenging if the neural function under study (e.g., working memory) is impaired in the patients, but the design of the study asks for matched performance in order to draw stronger inferences about neural mechanisms. This often excludes a large number of patients who cannot perform adequately during the test.

The effect size of most neuroimaging findings in psychotic disorders is less than 0.5, and very few are above 1.0. A recent meta-analysis of structural neuroimaging studies using ROI methods (excluding VBM studies) of several psychiatric disorders concluded that the significance of the group differences has been inflated (Ioannidis, 2011). In short, the number of positive results was too large to be true: the number of positive results was almost double than what would have been expected based on power calculations for the included samples. The excess significance may be due to unpublished negative results or due to selective exploratory analyses (Ioannidis, 2011). The more recent meta-analyses of VBM studies also add a word of caution, as they consistently show a high degree of inconsistency between study results. Taken together, we need to remain cautious about the strength of the statistical inferences.

Finally, even if a difference of brain structure or function is significant, it is not clear whether such a marker is sensitive and specific enough to classify an individual patient accurately. This has been explored in several studies using structural MR datasets. For example, a study of 36 patients with recent-onset psychosis and 36 healthy control subjects showed significantly lower gray matter density in the patients, and a machine learning algorithm was able to correctly classify patients with 86% accuracy (Sun et al., 2009). A similar accuracy was reported in a study of high-risk subjects (Koutsouleris et al., 2009). For now, a skilled clinical interview remains the most efficient and cost-effective diagnostic tool. However, these are encouraging first studies of pattern classification of imaging data in the diagnosis of psychotic disorder patients.

UNDERSTANDING THE PHENOTYPE

So far we have reviewed neuroimaging as a tool to establish disease markers. The non-invasive methods of MR imaging have also attracted the interest of researchers who study the phenomenology of psychosis and are interested in the mechanisms of abnormal mental states, irrespective of categorical diagnoses and their impact on disease management. In essence, they employ neuroimaging to study core questions of psychiatric phenomenology and psychopathology, such as “How does the brain hallucinate?”

Most neuroimaging studies of hallucinations have focused on auditory verbal hallucinations, the most prevalent form of hallucinations in schizophrenia (Allen et al., 2012; Jardri

et al., 2011; Palaniyappan et al., 2012). The initial studies simply compared patients with a history of frequent hallucinations and those who reported a low level of hallucinatory experiences. More recently, ratings for the severity of hallucinations were correlated with brain structure and function (Palaniyappan et al., 2012). These studies have confirmed a hypothesis that can be traced back to postmortem studies 100 years ago: patients with a prominent history of auditory hallucinations have a smaller superior temporal gyrus. In addition to the structural abnormalities of the STG, there is also evidence for structural abnormalities of the insula, anterior and posterior cingulate cortex, inferior frontal gyrus, thalamus, cerebellum, and precuneus. Finally, data are emerging that link auditory hallucinations to abnormalities of brain chemistry, including increased levels of glutamine (Allen et al., 2012).

Few neuroimaging studies have explored patients during the experience of psychotic symptoms (symptom-capture studies). For example, a patient is studied during the experience of

auditory hallucinations, and brain activity is then compared to periods when the hallucinations are not present (Dierks et al., 1999). In addition to the unique challenges of this study design (e.g., infrequent events, reliance on the subject to indicate the experience of the symptom), the studies cannot resolve whether the functional brain abnormalities are primary or secondary to the event of interest. For example, is the activation of the primary auditory cortex the origin of the voices or is the association cortex recruiting the primary auditory cortex during the experience of hearing voices? Despite these caveats, the few symptom-capture studies have provided compelling evidence for an abnormal activation in a bilateral neural network, including Broca's area, anterior insula, precentral gyrus, frontal operculum, middle and superior temporal gyri, inferior parietal lobule, and hippocampus/parahippocampal region (Jardri et al., 2011) (Fig. 20.2). This indicates that the experience of auditory verbal hallucinations involves increased activity in areas involved in speech generation and perception as well as verbal memory.

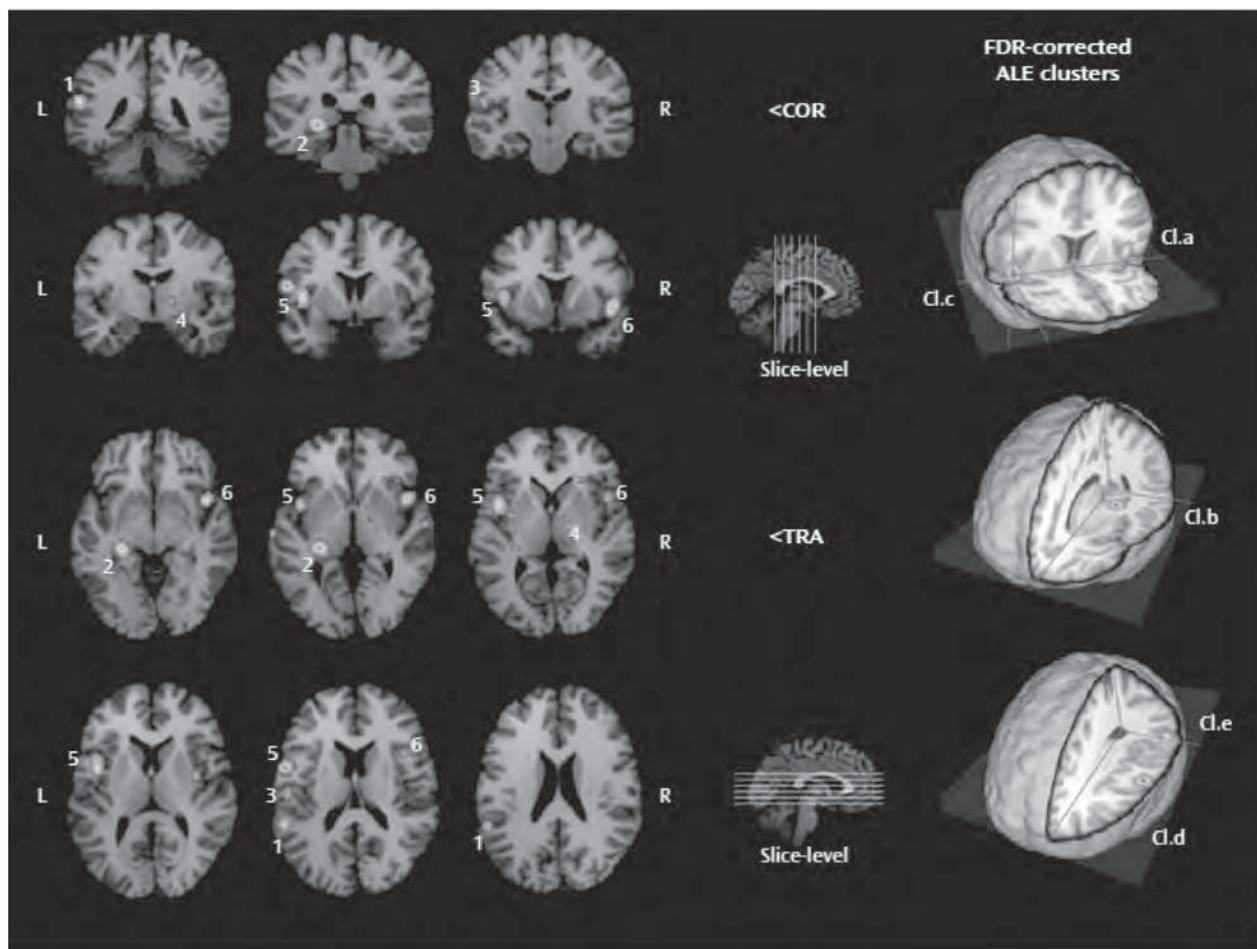

Figure 20.2 Functional brain activity associated with auditory verbal hallucinations in schizophrenia. The first three columns depict the activation likelihood estimation (ALE) results on coronal (COR) views (upper panel) as well as on transverse (TRA) views (lower panel) of the brain anatomy. The fourth column depicts slice levels shown on sagittal views. The fifth column shows clusters (Cl.a to Cl.e) of consistent activity among patients with schizophrenia spectrum disorders experiencing auditory verbal hallucinations. Reproduced from: Jardri, R., A. Pouchet, et al. (2011). "Cortical activations during auditory verbal hallucinations in schizophrenia: a coordinate-based meta-analysis." *The American Journal of Psychiatry* 168(1): 73–81; used with permission. (See color insert).

There are several other phenomena of psychosis that deserve further study using neuroimaging methods: What brain changes characterize catatonia, with its characteristic periods of mutism and stupor? What happens in the brain of a patient who is unable to think and speak coherently? What is at the core of the fractured self? While these questions remain intriguing, developing the proper experimental approaches to capture such phenomena is a challenge.

STUDYING THE NEURAL MECHANISMS

Over the last 100 years, several leitmotifs have captured the attention of neuroscientists who explored the neural basis of psychotic disorders. Here we focus on network models and neurochemistry changes observed in schizophrenia measured using MRS.

NETWORK MODELS OF SCHIZOPHRENIA

The idea that the pathology of schizophrenia involves abnormalities in brain connectivity (i.e., dysconnectivity) can be traced back to the turn of the 20th century (Gage and Hickok, 2005). Dysconnectivity models of schizophrenia received relatively little attention at the time and remained largely ignored for much of the 20th century. The advent of structural neuroimaging, which provided clear evidence that multiple brain regions are affected in schizophrenia, combined with advances in our understanding of the large-scale functional organization

of the human brain, reinvigorated interest in network models of schizophrenia.

Two important advances in functional imaging contributed to the renaissance of dysconnectivity theories of schizophrenia. The first is the development and increased use of network-based approaches to analyzing functional imaging data. In contrast to standard functional imaging methods that focus on detecting differences in brain activity between behavioral conditions (i.e., activations), network-based approaches examine statistical dependencies in activity across brain regions. The most common of these methods, functional connectivity, quantifies correlations between brain regions. Usually this is accomplished by selecting a brain region, called a “seed,” and calculating its correlation with other brain areas. Brain regions that demonstrate correlated activity over time are said to be functionally connected. The second key development is the emergence of resting-state fMRI. As its name implies, no task is performed during the scanning session; subjects are instructed to rest quietly for several minutes. Application of functional connectivity methods to resting-state fMRI data has revealed that activity in several canonical brain networks corresponding to sensory, motor, and cognitive systems remains coherent even during unconstrained mental activity (see Fig. 20.3) (Zhang and Raichle, 2010). The correspondence between resting-state networks and known anatomical connections, along with their striking resemblance to activation patterns observed with task-based fMRI, support the validity of resting-state fMRI (Honey et al., 2009; Smith et al., 2009). Combined, these two developments have

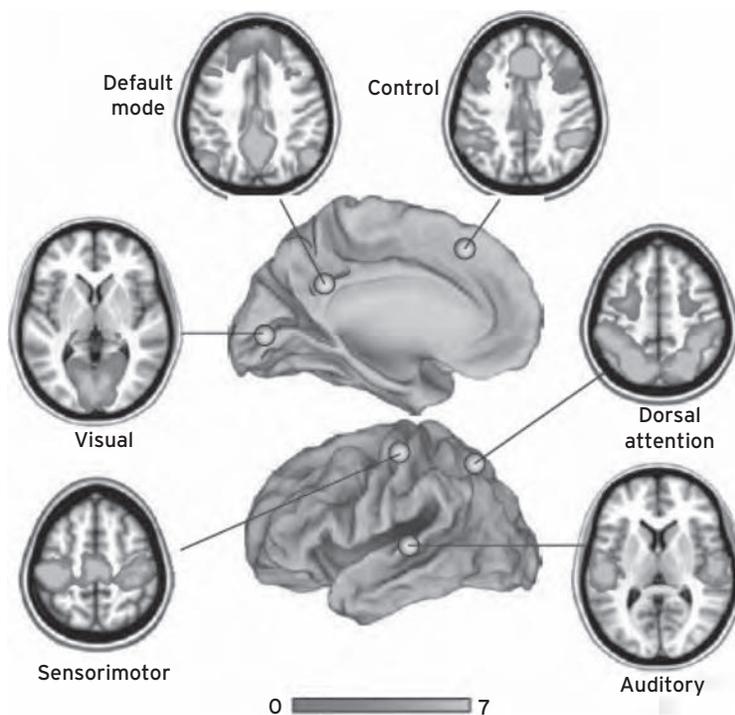

Figure 20.3 Intrinsic neuronal activity of the brain. Correlation of neuronal activity between a seed region (each circle) and the rest of the brain reveals six major networks: visual, sensorimotor, auditory, default mode, dorsal attention, and executive control. The scale numbered 0–7 indicates relative correlation strength. Reproduced from: Zhang, D. and M. E. Raichle (2010). “Disease and the brain’s dark energy.” *Nat.Rev.Neurol.* 6(1): 15–28 with permission from Nature Publications Group. (See color insert).

created novel opportunities to test dysconnectivity theories of schizophrenia.

Several network models of schizophrenia have been proposed. Cortical models integrate the deficits in executive cognitive functioning with frontal cortical gray matter loss and alterations in dorsolateral prefrontal cortex (PFC) microcircuitry. Others link the deficits in episodic memory to hippocampal volume loss and abnormalities of intrinsic or extrinsic hippocampal connectivity. The final set of network models focuses on cortical-subcortical networks. These models are supported by evidence of structural changes in cortex, striatum, thalamus, and cerebellum; alterations in dopamine signaling, and, more recently, animal studies showing that focal disturbances in subcortical structures recapitulates many of the key cognitive and neurotransmitter changes observed in schizophrenia. We review neuroimaging support for each of these network models of schizophrenia. Particular attention is paid to studies that applied network-based analytic approaches to functional imaging data.

ALTERATIONS IN PREFRONTAL CORTEX NETWORKS IN SCHIZOPHRENIA

Executive cognitive functions that rely on the integrity of the PFC, including working memory, initiation, planning, and cognitive flexibility, are impaired in schizophrenia (Heinrichs and Zakzanis, 1998). Not surprisingly, the initial functional imaging investigations of schizophrenia patients attributed executive cognitive impairment to PFC dysfunction (Weinberger, Berman et al., 1986b). Postmortem studies showing reduced dendritic spines, fewer axon terminals, and smaller soma volumes of pyramidal cells, in the context of normal number of neurons, along with a variety of changes in cortical GABA interneurons provides a possible mechanistic explanation for the structural and functional changes in the PFC (Lewis, 2012).

The PFC, however, is densely connected to other cortical areas, particularly the posterior parietal cortex, temporal lobe, and subcortical brain structures, and damage to or dysfunction of these regions can also produce impairments in executive cognitive functions (Fuster, 2008). Functional neuroimaging has confirmed that, in addition to the PFC, the posterior parietal cortex, and rostral/dorsal anterior cingulate cortex are consistently activated by a variety of executive cognitive tasks (Niendam et al., 2012). The combination of traditional lesion studies and functional neuroimaging has led to the idea that a “superordinate” fronto-cingulo-parietal network (FCPN) underlies executive cognitive functioning (Niendam et al., 2012).

There is considerable evidence of activation differences during performance of executive cognitive tasks in schizophrenia. A recent meta-analysis of 41 imaging studies concluded that reduced neural activity in schizophrenia extends beyond the PFC to include additional regions of the FCPN, including the rostral/dorsal anterior cingulate and inferior/posterior parietal cortex (Minzenberg et al., 2009). Dysconnectivity within the FCPN, and PFC more generally, during task performance has been confirmed by functional connectivity analyses. The general picture to emerge from these investigations is that connectivity

of the PFC is reduced in schizophrenia, and that PFC connectivity with parietal and temporal lobe regions is especially affected (Pettersson-Yeo et al., 2011). PFC dysconnectivity has also been consistently observed in resting-state studies. As with task-based imaging, these studies have shown reduced connectivity within the PFC and between dorsolateral PFC and parietal cortex (Cole et al., 2011; Woodward et al., 2011; Zhou et al., 2007). Importantly, PFC dysconnectivity is present in both first-episode and chronic patients, unaffected relatives of patients, and even individuals at high risk for developing schizophrenia (Pettersson-Yeo et al., 2011). Combined, the evidence strongly suggests that functional connectivity of the PFC, particularly the dorsolateral PFC, is altered in schizophrenia and that the abnormality is a fundamental component of the illness that transcends cognitive state and illness stage.

HIPPOCAMPAL NETWORK DYSFUNCTION

Smaller hippocampal volume was the initial evidence for an involvement of the hippocampus in schizophrenia. This finding is now firmly established, and postmortem as well as animal studies have supported several models of hippocampal dysfunction in schizophrenia (Heckers and Konradi, 2010).

For example, one model proposes that the reciprocal connections of the hippocampus and the multimodal association cortex are perturbed in schizophrenia and that this leads to the well-known deficits of abnormal episodic and relational memory. Functional neuroimaging studies have supported this hypothesis with evidence for an impaired recruitment during memory encoding and retrieval (Heckers and Konradi, 2010). But it remains unclear whether hippocampal or cortical nodes in this network drive the memory dysfunction. It is also not clear when these changes occur, since first episode and at-risk subjects already show hippocampal alterations, and whether the changes are amenable to treatment.

Several competing models propose that only some aspects of the hippocampus are abnormal in schizophrenia, leading to a specific rather than general pathology. This includes proposed changes of anterior but not posterior hippocampal regions, of the CA 2/3 but not the CA1 sector and of interneurons but not glutamatergic cells (Lisman et al., 2008; Heckers and Konradi, 2010). Some of these hypotheses are supported by postmortem and animal studies and can now be studied with neuroimaging studies. For example, high-resolution (7T) imaging can resolve the regions and sectors of the human hippocampus. Similarly, studies of cerebral blood flow and blood volume can provide an index of tonic activity of the hippocampus and can test for GABAergic and glutamatergic dysfunction in schizophrenia (Small et al., 2011).

CORTICAL-SUBCORTICAL NETWORK DYSFUNCTION

Cortical projections to striatum and cortex are arranged topographically in several segregated networks, linking different cortical areas to specific subregions of the striatum and thalamus. This arrangement raises the possibility that schizophrenia may involve selective dysfunction

of cortical-subcortical circuits or, alternatively, widespread disruption by a focal abnormality within a zone of convergence, such as the thalamus. Indeed, reduced thalamic volume loss is a consistent structural neuroimaging finding (Adriano et al., 2010), and a variety of striatal and thalamic abnormalities have been reported in postmortem studies, although postmortem findings tend to be less consistent than volumetric changes observed on MRI (Dorph-Petersen and Lewis, 2011).

The “cognitive dysmetria” hypothesis posits that the diverse array of symptoms associated with schizophrenia are the consequence of a core defect in coordinated information processing related to disruption of networks linking cortex, thalamus, and cerebellum (Andreasen et al., 1999). This hypothesis was prompted by a series of PET functional imaging investigations that repeatedly found reduced activity in the cortex, thalamus, and cerebellum during performance of cognitive tasks (Andreasen et al., 1999). Reduced activity in the frontal cortex and thalamus, especially mediodorsal nucleus, continues to be a robust finding in fMRI investigations (Minzenberg et al., 2009). Alterations in thalamocortical connectivity, especially between the PFC and mediodorsal thalamus, and in cortico-cerebellar connectivity have also been observed in several resting-state studies (Collin et al., 2011; Skudlarski et al., 2010; Welsh et al., 2010; Woodward et al., 2012).

Cortico-striatal models of schizophrenia emerged from PET investigations of glucose metabolism and dopamine receptor function (Buchsbaum and Hazlett, 1998; Honey et al., 2009; Meyer-Lindenberg et al., 2002). In addition, reduced activation of the striatum is commonly observed in fMRI studies of executive function (Minzenberg et al., 2009). However, the effects of antipsychotic medications on the function and structure of the striatum poses interpretational challenges (Buchsbaum and Hazlett, 1998; Brandt and Bonelli, 2008). It is noteworthy in this regard that unaffected relatives of schizophrenia patients show altered striatal activity, which suggests that at least some of the functional abnormalities detected in patients are not a consequence of antipsychotic treatment (Vink et al., 2006). As with other network models tested using functional imaging, it is unclear where the primary point of pathology resides, as dysfunction in any node could lead to pathological changes in the network. Interestingly, multimodal imaging investigations in both schizophrenia patients and prodromal subjects have found that abnormal functional activation of the prefrontal cortex is associated with elevated striatal dopamine signaling (Fusar-Poli et al., 2010; Meyer-Lindenberg et al., 2002).

NEUROCHEMICAL SYSTEMS

In addition to brain structure and activity, neuroimaging methods can also be used to study brain chemistry. One such method is magnetic resonance spectroscopy (MRS), a non-invasive MRI approach that can easily be implemented on routine scanners. Signal from several nuclei can be detected using MRS, but the ones most useful for brain research are proton (^1H)MRS and phosphorus (^{31}P)MRS. These approaches provide information on brain chemicals relevant to various

aspects of neurotransmission and brain metabolism. The utility of MRS has historically been limited by poor spatial and temporal resolution and by technical non-uniformity across research centers. The typical MRS dataset is acquired over several minutes from voxels that are several centimeters in each dimension. Nevertheless, recent advances in MRS data acquisition and analysis techniques coupled with the greater availability of higher field strength magnets has generated new opportunities for obtaining insight into neurochemical abnormalities in psychotic disorders from smaller brain regions with shorter duration scans.

Many current theories regarding the pathophysiology of psychotic disorders in general and schizophrenia in particular implicate abnormalities in glutamatergic and GABAergic neurotransmission (Lisman et al., 2008). Since glutamate (Glu) and GABA are the principal excitatory and inhibitory neurotransmitters in the brain, these abnormalities have major implications for brain function in schizophrenia. ^1H MRS provides the ability to assess concentrations of Glu, GABA, and other related brain metabolites such as glutamine (Gln), the principal metabolite of Glu at the synapse. Due to technical limitations, most publications on glutamate-related metabolites in schizophrenia have reported a composite measure termed Glx. Glx contains contributions from Glu, Gln, GABA, and aspartate. As a result, Glx is best considered a general index of multiple glutamate-related metabolites but provides no information on individual ones. Recent advances have allowed the resolution of signals coming from Glu, Gln, and GABA. Glu and Gln play roles in intermediary metabolism in addition to their functions in neurotransmission. Therefore, brain levels of these metabolites cannot be interpreted solely in the context of synaptic activity. However, since Glu released into the synapse is converted to Gln in glial cells, the relative concentrations of Gln and Glu may provide information more closely related to neurotransmission than the concentration of either molecule alone (Yuksel and Ongur, 2010) (Fig. 20.4). GABA levels in the brain parenchyma are thought to be more closely related to neurotransmission since GABA does not play a prominent role in intermediary metabolism.

A recent meta-analysis of 28 published ^1H MRS studies concluded that medial PFC Glu levels were reduced and Gln levels elevated in schizophrenia (Marsman et al., 2013). In addition, age-by-group analyses revealed that Glu and Gln concentrations decreased at a faster rate with age in patients with schizophrenia than in healthy controls. With the caveat that brain concentrations of Glu and Gln can be affected by metabolic processes unrelated to neurotransmission, this pattern of findings has been tentatively interpreted as evidence for a two-step abnormality in schizophrenia: during the first episode of psychosis there may be elevations in Glu neurotransmission leading to depletion of Glu and buildup of its metabolite Gln; with chronic disease there is an impoverishment of the entire Glu neurotransmission machinery, leading to lower than normal levels of both Glu and Gln. In addition to emerging from a meta-analysis, this pattern has also been found in an elegant longitudinal study in a single patient cohort (Theberge et al., 2007). In addition to dynamic Glu and Gln changes in the PFC and thalamus, Theberge and colleagues also reported that the

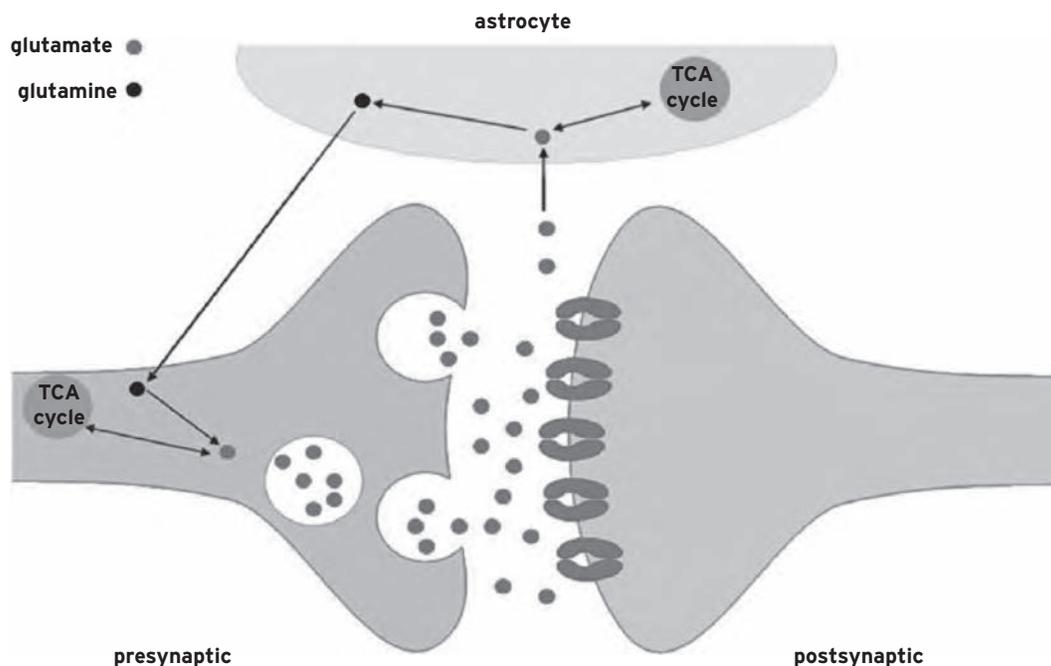

Figure 20.4 Schematic representation of glutamate-glutamine (Glu-Gln) cycling at the synapse. Glu is synthesized from TCA cycle metabolites or from Gln, packaged into synaptic vesicles and released into the synaptic cleft. After interacting with postsynaptic receptors, the actions of Glu are terminated by uptake into adjacent glial cells (red profiles), where it is converted to Gln. Gln then diffuses back to neurons to complete the cycle.

change in Gln seen during the transition from first episode to chronic illness correlated with gray matter losses in temporal and parietal cortices in the same patients during the same period.

Although the relationship of GABA level abnormalities to neurotransmission would be more straightforward to interpret than those of Glu and Gln, ^1H MRS studies of GABA have reported conflicting findings in schizophrenia. Using similar GABA-dedicated MRS acquisition techniques, some studies (including one with first-episode patients) have reported GABA reductions in this condition (Goto et al., 2009; Yoon et al., 2010), while others (including one with unmedicated patients) have reported elevations (Ongur et al., 2010; Kegeles et al., 2012). Demographic and clinical patient differences or other variables may explain the discrepancy. But it appears unlikely that there is a substantial and sustained abnormality in parenchymal GABA levels in schizophrenia, since that would already be detected across all studies. Instead, there seems to be a decoupling between brain GABA levels and the well-documented abnormalities in GABAergic neurotransmission in schizophrenia.

NEURONAL HEALTH AND BIOENERGETICS

In addition to neurochemical systems, MRS studies also provide information on a range of metabolites related to neuronal health as well as energy production and utilization in the brain *in vivo*. The three most prominent and most easily quantifiable metabolites in the ^1H spectrum from the human brain are *N*-acetylaspartate (NAA), creatine (Cr), and choline (Cho). NAA is an amino acid found almost exclusively and in high concentrations (around 10 mM) in neurons. Its precise functions are not well understood

but a large experimental and clinical literature has identified NAA concentrations as a marker for neuronal integrity and health (Lyoo and Renshaw, 2002). The Cr signal arises from Cr as well as its phosphorylated counterpart phosphocreatine (PCr), which functions as a high-energy phosphate store for cellular energy needs. Similarly, the Cho signal arises from several choline-including metabolites mostly related to cell membrane metabolism (with a minor contribution from acetylcholine).

The literature contains multiple well-done ^1H MRS studies quantifying NAA, Cr, and Cho in the neocortex, hippocampus, and white matter in schizophrenia. The most consistent finding across these studies, confirmed in a meta-analysis, is a reduction in NAA in all brain regions (Steen et al., 2005). This pattern is widely interpreted as reflecting abnormalities in neuronal integrity and health in schizophrenia, although NAA measures per se cannot determine whether there are reductions in neuron number. Some, but not all, of these studies have also reported reductions in Cr, which may indicate a bioenergetic abnormality in schizophrenia.

^{31}P MRS is a related technique that provides information on phosphate-containing metabolites in the brain. Some studies have reported abnormalities in phosphomonoesters (PME) and phosphodiesteres (PDE) in schizophrenia using this approach (Keshavan et al., 1993). Due to the role PMEs and PDEs play in cell membrane turnover, these findings were often interpreted as suggesting an impoverishment of dendritic remodeling and synaptic pruning. More recently, new ^{31}P MRS techniques are making it possible to obtain dynamic measures of brain bioenergetics *in vivo*. These approaches rely on the principle of magnetization transfer to calculate reaction rate constants for the creatine kinase (CK) and ATP synthase reactions noninvasively in the human brain (Du et al., 2012). Although in early stages of

application to psychiatric conditions, the magnetization transfer ³¹P MRS approach holds great promise for examining bioenergetic and mitochondrial abnormalities in schizophrenia and bipolar disorder.

So far, the MRS literature on bipolar disorder is small. Reductions in NAA are a consistent finding (Bertolino et al., 2003). A recent review of ¹H MRS studies of glutamatergic metabolites revealed distinctive elevations in Glx in people with bipolar disorder when compared with healthy individuals and in contrast to the reductions seen in major depressive disorder (Yuksel and Ongur, 2010). This would suggest an increase in the overall pool of glutamate-related metabolites in bipolar disorder. In addition, there may be systematic variation in the Gln/Glu ratio across the depressive/euthymic/manic phases of the illness (Yuksel and Ongur, 2010).

What can we learn about the neurobiology of psychosis from MRS studies? Although this modality is less well-developed compared to other MRI approaches due to its inherently low resolution, it has nonetheless contributed to our understanding of psychotic disorders. The widely replicated finding from ¹H MRS studies of elevated Gln/Glu ratio in first-episode schizophrenia followed by a reduction in Glx in chronic illness is a good example. This pattern of findings suggests a dynamic process of inappropriately elevated glutamatergic neurotransmission followed by an impoverishment in this process.

It is intriguing to consider the future of MRS in the study of psychotic disorders. The advent of higher magnetic field MRI scanners aids MRS through increased signal to noise ratio and better spectral dispersion, which allows separation of metabolite signals. In fact, higher field strengths benefit MRS more so than other MRI approaches. Thus, widespread availability of ultra-high field (4 Tesla and higher) magnets will help MRS at least partially overcome its key shortcoming of poor temporal and spatial resolution. MRS data collection from millimeter voxels using shorter acquisition times is leading to whole-brain data collection—a technique termed chemical shift imaging. Collection of MRS data in parallel with fMRI and DTI will provide converging evidence of abnormalities in glutamatergic or GABAergic neurotransmission or neuronal metabolism and allow investigators to gain deeper insights into pathophysiology (for some early examples, see Falkenberg et al., 2012; Northoff et al., 2007). In addition, better MRS data acquisition hardware and software have improved our ability to non-invasively measure brain processes of great interest to psychiatric neuroscience (such as neurotransmission and bioenergetics) in the past decade. Some possible directions include improved quantification of lactate (related to energetic abnormalities), glutathione (the brain's principal antioxidant), and *N*-acetylaspartylglutamate (NAAG—a neuromodulator); the promise of quantifying markers of neural stem cells in the human brain *in vivo* (Mangano et al., 2007); and the use of diffusion MRS and T1 and T2 relaxation characteristics to quantify the brain's microenvironment.

It has been said that “MRS is a technique of the future and always will be.” The inherent poor sensitivity of the MRS signal has hampered the development of this field in psychiatric research, but the technique holds promise for studies of neurochemical processes in psychotic disorder patients.

DISCOVERING GENETIC MECHANISMS

Neuroimaging methods have aided in the discovery of genetic risk factors for psychotic disorders. Here we briefly review three complementary approaches: studies of non-psychotic first-degree relatives of probands, studies of monozygotic and dizygotic twins affected by schizophrenia, and neural correlates of psychosis risk genes.

Family members of patients with schizophrenia show several brain abnormalities, including decreases in whole brain and (primarily left) hippocampus volumes (Boos et al., 2007). These changes are similar to those seen in patients with schizophrenia and parallel the findings of memory impairments in patients and relatives. However, it is not possible to disentangle the effects of risk genes (such as DISC 1 or BDNF) and environmental stressors from these studies. A recent study of 158 twin pairs who were concordant or discordant for schizophrenia or bipolar disorder revealed that increased genetic risk for schizophrenia and bipolar disorder is reflected in loss of white matter volume and in abnormalities of the cortical thickness, especially in the frontal and temporal lobes (Hulshoff Pol et al., 2012). In addition, a direct comparison of monozygotic twins discordant for schizophrenia revealed that, above and beyond the shared genetic risk, the affected twin showed reduced gray matter volume in prefrontal, cingulate, and superior temporal cortex (Borgwardt et al., 2010).

More recently, neuroimaging studies have revealed some of the neural mechanisms of putative schizophrenia risk genes from early candidate gene association studies (Meyer-Lindenberg, 2010). For example, allelic variants in the gene *neuregulin 1* have been associated with smaller hippocampal volume and larger ventricular volumes. Similarly, the gene *DISC1*, originally identified in a large Scottish pedigree with multiple individuals affected by schizophrenia and bipolar disorder, has been associated with reduced hippocampal gray matter and increased hippocampal-PFC connectivity (Meyer-Lindenberg, 2010). These are two examples for the role of neuroimaging in the exploration of the allelic effects of schizophrenia risk genes.

SUMMARY

Neuroimaging studies have restored Kraepelin's optimism that we will find the neural mechanisms of psychotic disorders. What is needed now is a dimensional assessment of psychopathology that allows neuroimaging researchers to go beyond the classic categories of psychotic disorders and reveal the mechanisms of genes and environmental risk factors leading to psychosis. The unique strengths of neuroimaging, namely, the repeated assessment of patients (especially in the early stages of the illness) and the ability to correlate brain imaging data with clinical and treatment variables, will ensure a prominent position for this research domain in the study of psychotic disorders.

DISCLOSURES

Dr. Heckers is a member of the DSM-5 work group on Psychotic Disorders. He has no other conflicts to disclose.

Dr. Woodward has no conflicts of interest to disclose. He has received support from NIMH and NARSAD. Grant Support: NIMH (1R21MH096177-01A1) and National Alliance for Research on Schizophrenia and Depression (NARSAD) Young Investigator Award.

Dr. Ongur's research is funded by NIMH and Shervert Frazier Research Institute at McLean Hospital, and he is PI on a research contract with Rules Based Medicine Inc. (a for-profit entity), he teaches a CME course for New England Educational Institute (not-for-profit), and he draws income as Associate Editor for the journal *Archives of General Psychiatry*.

21 | COGNITIVE AND MOTIVATIONAL NEUROSCIENCE OF PSYCHOTIC DISORDERS

ALAN ANTICEVIC, ERIN C. DOWD, AND DEANNA M. BARCH

OVERVIEW

Typically, when we think of the core symptoms of psychotic disorders such as schizophrenia, we think of people who hear voices, see visions, and have false beliefs about reality (i.e., delusions). However, clinicians have long recognized that abnormalities in cognitive function and motivated behavior are a key component of psychosis, and of schizophrenia in particular. As such, the last three decades have witnessed a relative explosion of research on cognition in schizophrenia, much of it couched within the framework of understanding the cognitive neuroscience of schizophrenia and the neural correlates of cognitive deficits. This emphasis on cognition in schizophrenia is in part due to the growing body of research suggesting that cognitive dysfunction in this illness is a substantial source of disability and loss of functional capacity for patients (Nuechterlein et al., 2011). This work is complemented by an additional recent focus on understanding the psychological and neurobiological impairments leading to deficits in motivation and goal-directed behavior in schizophrenia (Barch and Dowd, 2010; Gold et al., 2008; Kring and Moran, 2008), raising critical and important questions about the potential interactions between motivational and cognitive impairments in schizophrenia, and their influence on function, course, and outcome in this illness.

The challenge we face in understanding the cognitive and motivational neuroscience of schizophrenia is that individuals with this illness appear to exhibit deficits in a diverse array of domains (Mesholam-Gately et al., 2009). It is of course possible that this seemingly diverse array of impairments reflects dissociable deficits, each with its own psychological and neural pathophysiology. However, such an explanation does little to help us move forward in our conceptualization of the final common pathway leading to cognitive or motivational dysfunction in this illness, or in other psychotic disorders. Instead, we and others have argued that a common mechanism contributing to cognitive impairments across a range of domains in schizophrenia may arise due to an inability to actively represent goal information in working memory (WM) as needed to guide behavior, and that this deficit reflects profound impairments in the function of the dorsolateral prefrontal cortex (DLPFC) and its interactions with other brain regions such as parietal cortex, thalamus, and striatum, as well as altered function of neurotransmitter systems such as dopamine (DA), γ -aminobutyric acid (GABA), and glutamate. Importantly, in recent years,

this hypothesis postulating a “core” deficit in goal representation has been expanded to integrate work on emotion, reward processing, and motivational impairments in schizophrenia. Specifically, we postulate that these deficits may reflect, at least in part, impairments in the ability to actively maintain and utilize internal representations of emotional experiences, previous rewards, and motivational goals in order to drive current and future behavior in a way that would normally allow individuals to obtain desired outcomes. In the sections that follow, we provide a discussion of the evidence for such impairment in schizophrenia, how it manifests in domains typically referred to as executive control, WM, and episodic memory, and how it may help us understand impairments in reward processing and motivation in schizophrenia. We conclude with a brief discussion of emerging evidence of cortical microcircuit pathophysiology in schizophrenia and how it may relate to cognitive and motivational deficits in this population.

CONTEXT PROCESSING AND PROACTIVE CONTROL IN SCHIZOPHRENIA

CONTEXT PROCESSING

In previous work based in part on computational modeling, Cohen and colleagues put forth the hypothesis that DA activity in DLPFC was responsible for the processing of context, and that a disturbance in this mechanism could be responsible for a range of cognitive deficits in schizophrenia (Braver et al., 1999; Cohen and Servan-Schreiber, 1992). Here, context refers to prior task-relevant information that is represented in such a form that it can bias selection of the appropriate behavioral response. Because context representations are maintained on-line, in an active state, they are continually accessible and available to influence processing in the service of ongoing goals. Consequently, context can be viewed as the subset of representations within WM that govern how other representations are used. One important insight that emerged from this work was that a single deficit in one aspect of executive control could contribute to deficits in cognitive domains often treated as independent. As such, this theory argued that deficits in WM, attention, and inhibition in schizophrenia can all be understood in terms of a broader deficit in context-processing (Braver et al., 1999; Cohen et al., 1999; Cohen and Servan-Schreiber, 1992). When a task involves competing, task-irrelevant processes (as in the Stroop task), context representations serve to inhibit such

task-irrelevant processes by providing top-down support for task-relevant processes. When a task involves a delay between a cue and a later contingent response, context representation involves maintaining task-relevant information against the interfering and cumulative effects of noise over time. Further, in both inhibition and WM conditions, context representations serve an attentional function by selecting task-relevant information for processing over other potentially competing sources of information (Miller and Cohen, 2001). Thus, the context hypothesis was used to explain why patients with schizophrenia demonstrate deficits on several tasks thought to tap WM, as well as deficits on other executive control tasks that may not involve a high WM load (e.g., Stroop); in other words, patients show deficits on tasks in which context information needs to be determined and maintained, even if this context information constitutes a low WM load (Barch et al., 2003; Cohen et al., 1999). Numerous studies have provided support for these hypotheses concerning context-processing deficits in schizophrenia (for a review, see Barch and Braver, 2007), as well as evidence for impairments in individuals at risk for schizophrenia (e.g., MacDonald et al., 2005; Snitz et al., 2006), suggesting that such deficits may be associated with liability to schizophrenia as well as manifest illness.

PROACTIVE AND REACTIVE CONTROL IN SCHIZOPHRENIA

In more recent years, context processing in cognition has been reconceptualized more broadly as the function of proactive cognitive control (Braver, 2012; Edwards et al., 2010). This conceptualization builds on earlier ideas of context processing to argue for flexible mechanisms of cognitive control that allow humans to deal with the diversity of challenges that we face in everyday life. In this theory, termed dual mechanisms of control (Braver, 2012; Edwards et al., 2010), a distinction is made between proactive and reactive modes of cognitive control. The proactive control model can be thought of as a form of “early selection,” in which goal-relevant information is actively maintained in a sustained or anticipatory manner, before the occurrence of cognitively demanding events. This allows for optimal biasing of attention, perception, and action systems in a goal-driven manner. In this case, goals refer to the information one needs to accomplish a particular task or the intended outcome of a series of actions or mental operations. In real life, such goal information may include the main points one wishes to communicate in a conversation, or the need to organize a shopping trip so that one can make sure to get everything that is needed. In contrast, in the reactive mode, attentional control is recruited as a “late correction” mechanism that is mobilized only when needed, such as after a high-interference event is detected (e.g., an unexpected distracting stimulus is encountered and there is a need to retrieve the topic of conversation). Thus, proactive control relies on the *anticipation* and prevention of interference before it occurs, whereas reactive control relies on the *detection* and resolution of interference after its onset.

This theory postulates that proactive control depends on actively representing information in lateral prefrontal cortex

(PFC), and that the updating and maintenance of such information relies on precise inputs from neurotransmitter systems such as DA into PFC. However, as discussed in the following, it is clear that other neurotransmitter mechanisms such as GABA and glutamate are critical for active maintenance of information in PFC, and that deficits in *N*-methyl-*D*-aspartate (NMDA) receptor function may underlie impaired delay-related activity during WM in schizophrenia (e.g., Krystal et al., 2003; Wang et al., 2008). As outlined in detail in Braver (2012), proactive and reactive control functions are not mutually exclusive, and some balance between the two modes is necessary to successfully meet most ongoing cognitive demands. However, Braver (2012) has argued that the two control modes can be distinguished based on their temporal characteristics (e.g., *when* they are engaged in the course of cognitive processing) and the requirement to actively maintain control representations over time for proactive control. Further, Braver has suggested that there may be biases to favor one processing mode over the other, which may be dependent on task demands (e.g., high conflict situations may push toward a proactive control mode), as well as on individual differences in factors such as WM capacity, fluid intelligence, and even personality traits such as reward sensitivity. Proactive control may also be particularly vulnerable to disruption, given that it is resource demanding and dependent on temporally precise active maintenance mechanisms. Thus, populations characterized by disordered PFC function (such as schizophrenia) may rely more heavily on reactive control, as it may be more robust in the face of such dysfunction (Edwards et al., 2010). Consistent with this hypothesis, there is ample evidence for an association between impairments in DLPFC activity and deficits of proactive control in schizophrenia (e.g., Minzenberg et al., 2009) as well as those at risk for the development of schizophrenia (e.g., MacDonald et al., 2009). Further, there is growing evidence for a critical role of impaired connectivity between the DLPFC and other cognitive control related brain regions (e.g., Anticevic et al., 2013, Repovs et al., 2011; Yoon et al., 2008), positive impacts of DA enhancement on cognitive control in psychosis (e.g., Barch, 2005), and intriguing evidence for GABAergically mediated (Lewis and González-Burgos, 2008) impairment in neural oscillations that may support representations in DLPFC (e.g., Cho et al., 2006).

WORKING MEMORY IN SCHIZOPHRENIA

COGNITIVE NEUROSCIENCE MODELS OF WORKING MEMORY

Although a good deal of work has been devoted to understanding cognitive control deficits in schizophrenia, perhaps the greatest amount of cognitive neuroscience research in schizophrenia has been focused on WM since the seminal writings of Patricia Goldman-Rakic (Goldman-Rakic, 1995). There is a huge body of evidence to suggest that individuals with schizophrenia show deficits in WM (e.g., Forbes et al., 2009; Lee and Park, 2005). However, WM is a complex construct with many subprocesses. As such, we need to move beyond simply saying that individuals with schizophrenia

experience WM deficits, toward understanding what specific aspects of WM are impaired in this illness and how they may relate to shared deficits in context processing. To do so, it is important to discuss some of the leading cognitive neuroscience models of WM as they provide conceptual leverage on findings in schizophrenia by anchoring our understanding in findings in healthy adults. WM traditionally refers to temporary storage and manipulating information “on-line,” typically in the service of some goal (Baddeley, 2000). According to one prominent cognitive model, WM is thought to be comprised of a central executive resource system, and two slave subsidiary systems: the phonological loop and the visuospatial sketchpad—i.e., WM is conceptualized as a multistore process relying on distinct subcomponents. This cognitive model was later updated to include a fourth component: the episodic buffer (Baddeley, 2000). Alternatively, rather than dividing the WM process into “cognitive” modules, one can consider WM to consist of distinct stages in time. In that sense, the WM process can be roughly subdivided into three distinct temporal components (Jonides et al., 2008): (1) encoding of novel information and forming an internal representation, (2) active maintenance of this information over some period (i.e., refreshing the memory trace, which is aligned with the function of two slave subsystems), and (3) manipulation of maintained information in the service of some goal (i.e., the central executive).

BEHAVIORAL FINDINGS ON WORKING MEMORY IN SCHIZOPHRENIA

There is robust evidence suggesting that individuals with schizophrenia display deficits in WM (e.g., Forbes et al., 2009; Lee and Park, 2005). These deficits are present in both medicated and unmedicated patients, the first-degree relatives of individuals with schizophrenia, and individuals with schizotypal personality, suggesting that WM is a critical abnormality manifesting across the schizophrenia spectrum. There is relatively little evidence that such WM deficits can be unambiguously attributed to dysfunction in either the verbal or visual-spatial buffer systems, as individuals with schizophrenia exhibit abnormalities on WM tasks with many different material types, with relatively little evidence for selective deficits for one material type over another (Lee and Park, 2005; Forbes et al., 2009). This has led to the suggestion that WM deficits in schizophrenia might primarily reflect deficits in the central executive, or the active maintenance and manipulation of information over time, an interpretation consistent with a central role for deficits in the proactive control of behavior. Such a modality non-specific deficit in the ability to maintain and manipulate information over time would also be consistent with emerging hypotheses detailing synaptic-level pathophysiology in schizophrenia (Marin, 2012), which is not likely to selectively disrupt verbal vs. non-verbal cortical circuits (discussed in what follows).

However, it is also important to consider the temporal aspects of WM function, and the distinction between encoding and maintenance, which rely on distinct neural dynamics. An influential meta-analysis suggested that the degree of WM impairment in schizophrenia is fairly constant even

when extending the maintenance period (Lee and Park, 2005), such that the effect sizes of WM impairment across studies did not change as a function of the delay period used. This may imply that breakdowns in WM may be occurring as early as the encoding stage—i.e., when internal representations are still forming. In turn, such deficits in the initial generation of representations could impact the stability of such representations and the ability to accurately maintain them over time. Consistent with this hypothesis, studies examining encoding deficits have demonstrated that patients with schizophrenia exhibit short-term memory deficits even in the absence of a delay (e.g., Tek et al., 2002) and when allowed only a fixed duration to encode. However, such “encoding” deficits can be minimized if individuals with schizophrenia are given a longer period of time to process the information, suggesting that such deficits may reflect “speed of processing” rather than fundamental deficits in the ability to encode information into WM (e.g., Badcock et al., 2008). Nevertheless, speed-of-processing reductions at encoding may still be interpreted as an “encoding” deficit in that a reduction in the speed with which the information can be robustly encoded will degrade the quality of internal representations. At the same time, a number of studies have provided evidence for deficits in the ability to maintain information across time in schizophrenia, even after controlling for encoding differences (e.g., Badcock et al., 2008; Tek et al., 2002). One issue that still needs to be fully resolved in the context of WM tasks, especially those involving a match versus non-match decision, is to what extent group differences are exacerbated by tasks involving more complex “probe” decisions, which are difficult for patients given their slow processing speed and/or decision-making difficulties and may contribute to poor performance without reflecting deficits in working memory per se. In that sense, simple continuous report WM tasks (Badcock et al., 2008), similar to those used in non-human primate work (Funahashi et al., 1989), may prove better equipped for careful characterization of encoding versus delay deficits (as they circumvent match/non-match decisions).

Taken together, the existing evidence base suggests that there are abnormalities evident across both encoding and maintenance phases of WM in schizophrenia. The encoding deficits may be due to increases in time necessary to rapidly form an accurate internal representation (e.g., Badcock et al., 2008), while the deficits in the maintenance of information are consistent impairments in the central executive aspects of WM and impairments in the ability to proactively represent information necessary to guide behavior. Further, behavioral WM studies in schizophrenia argue that deficits exist not only in the maintenance mechanisms but also in the ability to resist external sources of interference and that these abnormalities are present in both visuospatial and verbal domains. Such impairments are consistent with a role for a fundamental impairment in the ability to represent and maintain representation in WM that can be used to guide goal directed behavior, and with an impairment in the ability to use proactive cognitive control mechanisms in order to regulate behavior.

PREFRONTAL RECRUITMENT DURING WORKING MEMORY IN SCHIZOPHRENIA

Building on the behavioral evidence of WM deficits, there is a growing functional neuroimaging literature demonstrating the presence of brain abnormalities associated with WM dysfunction in schizophrenia. The majority of findings suggest that regions comprising the dorsal frontal-parietal network are affected in patients and may be contributing to WM abnormalities. Specifically, reductions in DLPFC (Brodmann's Area 9/46) activations have been documented while patients perform WM tasks, suggesting that patients exhibit task-related "hypofrontality" (Barch et al., 2001; Callicott et al., 1998). These findings have also been confirmed through quantitative meta-analytic studies (Glahn et al., 2005; Van Snellenberg et al., 2006). Such DLPFC deficits are present even in medication naïve individuals (Barch et al., 2001), and are also present, albeit to a lesser extent, in the first-degree relatives of individuals with schizophrenia (e.g., MacDonald et al., 2009), suggesting a potential role as an endophenotypic marker.

However, there have been discrepant findings with regard to over- or underrecruitment of DLPFC regions during WM (Callicott et al., 2003). A number of findings have suggested that WM capacity in healthy subjects may be dependent on level of recruitment of DLPFC, which is thought to operate according to an inverted "U" model of WM capacity (Goldman-Rakic et al., 2000). In other words, the model suggests that with increasing WM demands there is a concomitant parametric DLPFC signal increase. However, as WM load demands reach and exceed capacity limitations, DLPFC signals begin to drop, presumably due to information load exceeding available computational resources (Goldman-Rakic et al., 2000). In line with this hypothesis, recent evidence suggests that patients with schizophrenia may exhibit a shifted inverted U function, such that capacity limitations are reached faster (i.e., with lower WM load levels), which may result in over- or underrecruitment when compared to healthy controls depending on level of WM load at which the groups are compared (Johnson et al., 2006). In other words, at low difficulty levels patients may find performance more effortful and may have to recruit more PFC resources than healthy controls to accomplish the same task, leading to findings of "hyperactivity" in PFC cortex. Consistent with this model, a meta-analysis by Van Snellenberg and colleagues demonstrated that the magnitude of WM performance differences between patients and healthy controls was positively correlated with the magnitude of activation differences in dorsal-lateral prefrontal regions (Van Snellenberg et al., 2006).

THE TEMPORAL DYNAMICS OF PREFRONTAL ACTIVATION DURING WORKING MEMORY IN SCHIZOPHRENIA

The previous discussion focused on the general involvement of PFC, specifically the DLPFC, in WM. However, one can also consider the ways in which cognitive mechanisms involved in proactive control and the active representation of information

may influence the magnitude and timing of brain activation in WM. A failure to use proactive control would suggest that patients might show reduced activity during encoding and/or maintenance in lateral PFC regions if they fail to effectively encode or maintain information over the delay in preparation for responding. There are several studies showing evidence consistent with such an alteration in activity in DLPFC during encoding (e.g., Anticevic et al., 2013; Edwards et al., 2010; Johnson et al., 2006) and/or maintenance (Anticevic et al., 2013; Driesen et al., 2008; Edwards et al., 2010). This impairment in encoding and maintenance of information may shift individuals with schizophrenia into a greater reliance on more *reactive* modes of processing. In other words, when a response is needed, patients may need to engage additional computational mechanisms to retrieve the memoranda, potentially resulting in *increased* activation in brain regions associated with memory retrieval or response selection. Consistent with this hypothesis, studies that have specifically examined retrieval-related activity have found evidence for *increased* activation among individuals with schizophrenia in either the same or different regions that showed reduced encoding/maintenance related activation (Johnson et al., 2006; Edwards et al., 2010). Future work may determine whether such increased retrieval signals are accompanied by increases in functional connectivity in a distributed retrieval-associated network, and importantly, whether such "compensatory" signal increases and/or connectivity changes are predictive of better performance in patients.

ALTERED DEFAULT MODE PROCESSING DURING WORKING MEMORY IN SCHIZOPHRENIA

The preceding discussion focused on the role of the DLPFC in WM and the importance of impaired DLPFC function to understanding impairments in WM and proactive control in schizophrenia. However, there is also a growing literature suggesting that WM deficits in schizophrenia may be associated with failures to "deactivate" regions overlapping with what is termed the default mode network (DMN) (e.g., Anticevic et al., 2013; Metzak et al., 2012; Whitfield-Gabrieli et al., 2009; although see Mannell Franco et al., 2010, for how cognitive load may modulate this effect). The DMN is a network of brain regions including the medial anterior PFC and the posterior cingulate that normally show reduced activity during cognitively demanding externally oriented mental processing in healthy individuals. DMN activation has been hypothesized to be associated with self-referential and spontaneous cognition (Raichle and Snyder, 2007). It is now widely accepted, based on evidence from both task-based and connectivity findings, that in healthy adults there exists an inverse/anticorrelated relationship between these distributed neural systems purportedly supporting these different aspects of cognition (Fox et al., 2005). In fact, our previous work in healthy adults has demonstrated that the degree of DMN suppression is directly related to accurate WM performance (e.g., Anticevic et al., 2010). The combination of altered DLPFC activity (frequently reduced) and a failure to suppress DMN regions in schizophrenia suggests that there

may be a malfunction in reciprocal communication between brain networks involved in active task engagement and passive mental states or attention to internal representations. Related to this point, the preceding sections discussed interference resolution as a critical component of WM function and that there is clear evidence for breakdowns in filtering of interfering signals during WM maintenance in schizophrenia. In that sense, one can conceptualize the lack of DMN suppression in individuals with schizophrenia as possibly contributing additional sources of unwanted signals during WM. In other words, if there is a breakdown of such distributed regional suppression during WM in patients, superfluous activation of regions involved in passive mentation may contribute an additional source of “noise” during WM and render the ongoing task representations more susceptible to interference. Therefore, these findings raise the possibility that DMN suppression deficits may compromise signal processing in cortical networks by rendering network function “noisy” or inefficient, given that a lowered DMN signal is thought to reflect the suppression of cognitive operations carried out by the DMN (e.g., Raichle and Snyder, 2007). However, as of yet, the direction and causality of the relationship between altered DMN activity and impaired DLPC function during WM in schizophrenia have not been established. Put differently, we do not yet know whether a failure to suppress DMN activity is simply a by-product of a failure to engage frontoparietal control nodes to an appropriate extent to support WM and proactive cognitive control, or whether there is an independent deficit in DMN processing or connectivity with the DLPFC such that an inability to suppress DMN interferes with DLPFC function and processing. Additional research is needed to arbitrate between these differing possibilities and to better understand the complex causal dynamics as well as synergistic contributions of the DMN to cognitive impairment in schizophrenia.

SUMMARY OF WORKING MEMORY FINDINGS IN SCHIZOPHRENIA

In summary, both behavioral and functional neuroimaging evidence points to WM abnormalities in schizophrenia, which extend across both the encoding and maintenance phases and which are consistent with deficits in the ability to generate and maintain internal representations that can be used to guide behavior in a proactive fashion. These deficits are also associated with abnormalities in the function of brain regions such as the DLPFC and the DMN, as well as with connectivity in a distributed cortical circuit that includes frontoparietal, striatal, and thalamic interactions. Such deficits may involve not only abnormalities in sustaining activation across a delay, but also breakdowns in interference resolution from incoming distraction.

EPISODIC MEMORY

COGNITIVE NEUROSCIENCE MODELS OF EPISODIC MEMORY

As with efforts to understand the nature of WM deficits in schizophrenia, it is useful to briefly review the cognitive neuroscience literature on the processing and brain regions involved

in episodic memory (EM) as a means to organize the research pertaining to EM deficits in schizophrenia. A key place to start is work on the specific role that the hippocampal formation plays in EM. A common theme in theories regarding the role of the hippocampal formation in EM is the idea that it is critical for the rapid binding of novel configurations of information (e.g., Cohen and Eichenbaum, 2001; Squire, 1987). Consistent with this hypothesis, a number of human neuroimaging studies have shown activation of the hippocampus during the encoding or retrieval of novel relational information (e.g., Wendelken and Bunge, 2010), and work in amnesic patients emphasizes the importance of hippocampal structures in relational processing (e.g., Bowles et al., 2010). Moreover, a number of functional neuroimaging studies in healthy humans have demonstrated that enhanced hippocampal/parahippocampal activity at the time of encoding predicts subsequent successful retrieval of that information (e.g., Brewer et al., 1998; Wagner et al., 1998). In addition, work with depth electrodes implanted in humans undergoing epilepsy surgery has also demonstrated that hippocampal activity at the time of encoding predicted subsequent memory for verbal stimuli (Cameron et al., 2001). Although more recent models of EM also suggest differential roles for hippocampal versus perirhinal regions of the medial temporal lobes in encoding of item versus relational memory (Davachi, 2006), there is still a strong consensus on the importance of the hippocampus for relational encoding of a range of information types.

The field has also garnered information about the important contribution made by PFC structures to EM. Damage to the prefrontal cortex can lead to EM deficits, among other cognitive impairments (e.g., Janowsky et al., 1989). Such findings have contributed to the hypothesis that PFC damage alters EM by impairing strategic contributions to memory formation and retrieval (e.g., Janowsky et al., 1989). For example, studies have shown activation of ventral PFC regions such as Brodmann’s areas 45 and 47 when participants are asked to process verbal information using semantic elaboration strategies (e.g., Wagner et al., 1998) that promote subsequent memory. For a recent meta-analysis, see (Spaniol et al., 2009). Further, there is recent work suggesting that DLPFC may contribute specifically to successful relational memory formation and retrieval (e.g., Blumenfeld et al., 2011).

EPISODIC MEMORY IMPAIRMENTS IN SCHIZOPHRENIA

As described in the preceding, most theories of hippocampal function posit a key role in binding together novel configurations of information. One way to examine whether individuals with schizophrenia have binding deficits is to determine if they are more impaired on memory for associative information (e.g., the association of previously unrelated words or items) as compared to memory for individual items. To address this question, Achim and Lepage conducted a meta-analysis comparing performance on associative and item memory tests in individuals with schizophrenia, and concluded that there was evidence for a 20% greater impairment in associative as compared to item memory in individuals with schizophrenia

(Achim and Lepage, 2003). However, a number of the associative memory studies included in this meta-analysis were tests of source memory rather than associations of novel pairs of items, and the human neuropsychological and imaging literatures suggest that PFC function may make an important contribution to source memory (Mitchell and Johnson, 2009). In addition, few of the studies that have compared item and associative memory have dealt with the ubiquitous problems of discriminating power. Associative memory tests are often more difficult than item memory tests. Greater task difficulty by itself does not necessarily indicate higher discriminating power, but it does raise the question of whether a pattern of greater impairment on associative versus item memory is truly indicative of a selective deficit in binding of novel information. More recently, clinical researchers have begun to use tasks derived from the animal literature on hippocampal function, such as the transitive interference test, which measures the ability to learn the relationships among hierarchically arranged stimulus pairs, as well as the transitive patterning test, in which individuals have to learn about relationships between items for correct selection. Individuals with schizophrenia are impaired on critical conditions of these tasks requiring relational processing, but not on conditions that require simpler associative reinforcement mappings (e.g., Heckers et al., 2004). Other work has used eye-movement measures of relational memory, shown to be impaired in patients with hippocampal lesions (e.g., Hannula and Ranganath, 2009), to identify relational memory impairments in schizophrenia (e.g., Hannula et al., 2010). There is also work indicating impairments in both item and relational retrieval for information that was relationally encoded in schizophrenia (Ragland et al., 2012b). Still other work has provided evidence for greater deficits in recollection than familiarity in schizophrenia, which have also been interpreted as reflecting relational memory impairments (e.g., van Erp et al., 2008).

Many researchers have taken this body of work to suggest that EM impairments in schizophrenia reflect medial temporal lobe deficits, with a specific focus on the hippocampus (e.g., Heckers and Konradi, 2010). However, the findings in healthy individuals about the role of the PFC cortex in EM raise the possibility that at least some EM impairments among individuals with schizophrenia also reflect deficits in PFC mediated cognitive functions that contribute to successful memory encoding and retrieval, including strategic mechanisms that may facilitate memory formation. Consistent with this hypothesis, a number of studies suggest that individuals with schizophrenia are impaired in their ability to generate effective mnemonic strategies. However, when provided with strategies that promote successful episodic encoding, individuals with schizophrenia are typically able to benefit as much as controls from these strategies and can even show intact item recognition when provided with support for effective encoding (for review, see Barch, 2005). Further, a meta-analysis of brain activity alterations during EM performance in schizophrenia showed consistent evidence for reduced activation in both ventrolateral and DLPFC, but did not find consistent evidence for altered hippocampal activity (Ragland et al., 2009). Recent work on relational memory encoding

and retrieval has shown evidence for impaired DLPFC function associated with impaired relational memory function in schizophrenia (Ragland et al., 2012a), though other recent work has also implicated hippocampal function (e.g., Hanlon et al., 2011). These findings do suggest a need to also take into account a role for PFC mediated cognitive functions as well as hippocampally mediated processes in understanding the source and nature of EM deficits in schizophrenia. Further, the findings on strategic changes in schizophrenia and the role of DLPFC in EM suggests that examining the role of executive control deficits and effective encoding manipulations may be a fruitful avenue for future research on enhancing EM in schizophrenia.

Prior to transitioning to motivational deficits in schizophrenia an important final point relates to heterogeneity of cognitive deficits and the possibility of their occurrence across diagnostic categories. The chapter's focus is on schizophrenia, but cognitive deficits are also observed in other neuropsychiatric conditions that may share behavioral and genetic features with schizophrenia. One example is bipolar illness. Evidence suggests that psychotic symptoms occur in 50–70% of individuals with bipolar disorder (Dunayevich and Keck, 2000; Goodwin and Jamison, 1990) and psychosis aggregates within families of bipolar patients (Potash et al., 2001). One possibility is that comorbid psychosis symptoms in bipolar illness represent a more severe form of the illness associated with worse prognosis (Bellivier et al., 2001; Coryell et al., 2001; but see Keck et al., 2003) and poorer cognitive performance (Glahn et al., 2007) as well as abnormalities in brain structure (Strasser et al., 2005) and function (Pearlson et al., 1995) that may be observed in schizophrenia and associated with cognitive deficits. Therefore, it will be vital to carefully establish to what extent observed cognitive and associated neural disturbances scale, not only as a function of schizophrenia heterogeneity, but also whether cognitive deficits manifest across diagnoses with shared risk. In the concluding section we highlight such need for future studies to investigate endophenotypic markers that may underlie shared versus dissociable disturbances along the psychosis spectrum. Perhaps one way to investigate neural correlates of cognitive (or emotional) disturbances that may scale along the schizophrenia spectrum or co-occur in bipolar illness is to capitalize on the dimensional approach articulated by NIMH Research Domain Criteria (RDoC) initiative (Cuthbert and Insel, 2010; Keshavan et al., 2011; Potash, 2006). One hypothesis suggests that these seemingly separate illnesses represent different endpoint phenomenological expressions of a similar underlying problem at a neural circuit level (Keshavan et al., 2011; Potash, 2006). Emerging reports using novel connectivity approaches in schizophrenia (Cole et al., 2011) and bipolar illness with psychosis history (Anticevic et al., 2012a) indeed raise the intriguing possibility that there may be shared neural (and consequently behavioral) disturbances across the two conditions, which may extend to cognitive deficits. Thus, future work should quantify prefrontal function that may relate to illness severity and comorbidity of psychosis across diagnoses. We return to these issues in the concluding remarks.

Next, we turn to additional disturbances in schizophrenia that extend beyond cognitive deficits.

GOAL REPRESENTATIONS AND MOTIVATIONAL DEFICITS IN SCHIZOPHRENIA

The preceding discussion focused on “cold” cognitive impairments in proactive control, WM, and EM in schizophrenia. These domains have received massive research attention in the schizophrenia literature, which is quite logical given the evidence for their importance in understanding function and outcome, their presence across the spectrum of psychosis, and their links to genetic risk for the development of psychosis. However, a variety of emotional and motivational impairments have also long been clinically documented in patients (Barch and Smith, 2008; Gold et al., 2008; Meehl, 1962), and there has been resurgence of interest in understanding the psychological and neural bases of what are often referred to as “negative symptoms” in schizophrenia. These aspects of schizophrenia pathology include constructs such as asociality (disengagement from others), avolition (a reduction in the motivation to initiate or persist in goal-directed behavior), and anhedonia (a reduction in the ability to experience pleasure). This resurgence of interest in negative symptoms in schizophrenia has been driven by at least two factors. The first factor is the realization that addressing the pervasive cognitive impairment present in schizophrenia may not be enough to fully understand and remediate the functional impairments that can make life so difficult for individuals with this disorder. In other words, we may also need to understand how cognitive impairments interact with reward and emotional processing systems in a way that leads to profound abnormalities in goal-driven behaviors. A second factor, paralleling the aforementioned developments in cognitive neuroscience, is that major advances have occurred in the field of affective neuroscience that provide a theoretical and empirical foundation on which to draw in order to identify candidate psychological and neural mechanisms that drive interactions between cognitive function, reward, and motivation (e.g., Wallis 2007). Here we would like to propose that there may be some common mechanisms that drive impairments in cognition and motivated behavior (e.g., anhedonia/amotivation) in schizophrenia—specifically the ability to use representations about motivational salient incentives or rewards to generate and represent goal-directed action plans necessary to achieve those incentives or rewards. This perspective builds on our previously articulated goal and the hope for the field; namely, to understand several complex and seemingly distinct behavioral manifestations in schizophrenia via parsimonious final common mechanistic pathways (Yizhar et al., 2011).

In order to understand the basis for this argument, it is important to overview the psychological processes and neural systems thought to support linking experienced or anticipated rewards and/or incentives with the action plans that need to be generated and maintained in order to obtain these rewards. The literature on the neural bases of reward and

motivation is large and complex. However, one can organize this literature by focusing on four major components to the translation of appetitive or reward information into behavioral responses (Berridge et al., 2009; Schultz, 2007; Wallis, 2007) (see Fig. 21.1). While this conceptualization is clearly an oversimplification, it provides a useful set of organizing principles in approaching the study of which contributors to goal-directed behavior are impaired in schizophrenia. The first component *hedonics or liking* (Fig. 21.1a) reflects the ability to “enjoy” the stimulus or event that may provide pleasure or reward. It had traditionally been thought that the neurotransmitter dopamine (DA) was the primary substrate of liking (Berridge, 2004), but more recent research has shown that experimental depletion of DA does not reduce liking when it can be measured by facial expression and/or subjective reports (Berridge et al., 2009). Instead, hedonic responses (at least to primary sensory stimuli) seem to be mediated by activation of the opioid and GABAergic systems in the nucleus accumbens shell and its projections to the ventral pallidum, as well as in the orbital frontal cortex (OFC) (e.g., Berridge et al., 2009).

A second component *reward prediction and wanting* (Fig. 21.1b) is mediated by the midbrain DA system, particularly the projections to ventral and dorsal striatum (Schultz, 2007; Berridge et al., 2009). Many DA neurons in the substantia nigra and ventral tegmental area respond to stimuli that *predict* reward, as well as to the rewarding stimuli themselves, with the degree of response depending on reward predictability. These types of DA/striatal responses have been captured by temporal difference models that simulate learning about stimuli that predict rewards (e.g., Montague et al., 1996). These mechanisms are also thought to underlie basic aspects of reinforcement learning that may occur without conscious awareness (e.g., Frank et al., 2004). A prominent, though slightly different theory, emphasizes the role of the DA-learning process in transferring incentive salience from the reward itself to reward-predicting cues, thus imbuing these cues with motivational properties themselves (e.g., a “wanting” response; Berridge et al., 2009).

A third component is *cost-benefit analysis*, or the ability to integrate information from different sources to derive and update the value of potentially rewarding outcomes. One aspect, thought to be mediated in part by orbitofrontal cortex (OFC) (e.g., Padoa-Schioppa and Cai, 2011), is the ability to represent value information (Fig. 21.1c), which takes into account not only the hedonic properties of a stimulus, but also the internal state of the organism (e.g., value of juice when thirsty versus not), the delay before the reward occurs, the available reward options (e.g., juice versus wine after a hard day), and the changing contingencies associated with a stimulus (a previously rewarded response is now punished) (e.g., Dias et al., 1996). Some researchers have described the OFC as being involved in “working memory for value,” or the ability to maintain, update, and integrate different sources of information about value over a short period of time (e.g., Frank and Claus, 2006). Human functional neuroimaging studies also highlight activation of OFC under conditions requiring value representations (e.g., O’Doherty, 2007), particularly those in which response contingencies need to be updated, such as

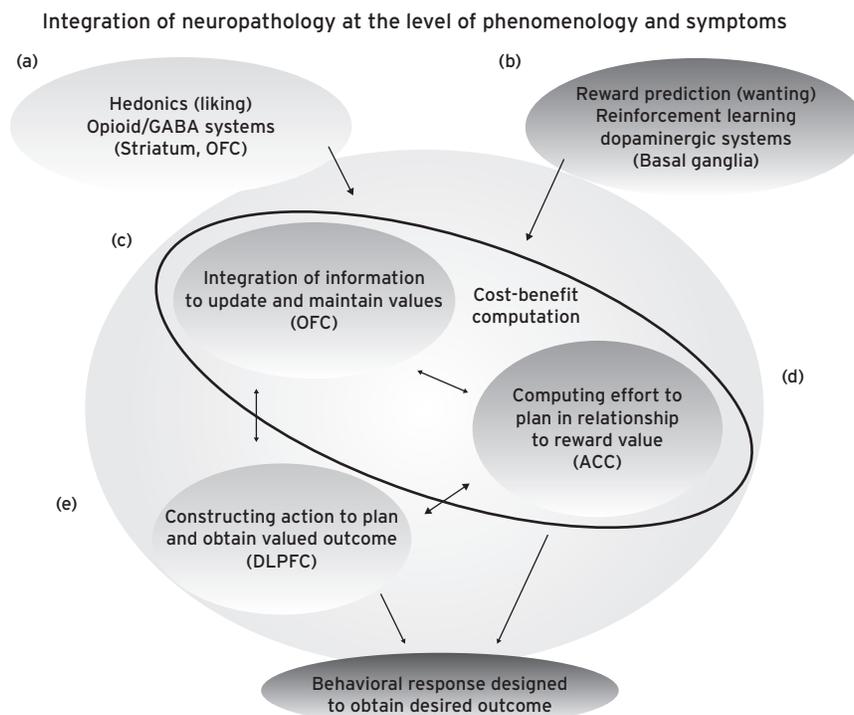

Figure 21.1 Integration of neuropathology at the level of phenomenology and symptoms—goal representations and motivational deficits in schizophrenia. (Figure adapted from Barch and Dowd, 2010.) This figure outlines a conceptual overview of several processes thought to be involved in translating reward information into goal-directed behaviors, which may be compromised in schizophrenia.

reversal learning (e.g., Cools et al., 2007). In addition, humans with OFC lesions can show reversal learning impairments (e.g., Fellows and Farah, 2005).

Another aspect of representing value information is *effort computation* (Fig. 21.1d), that is, determining the cost of engaging in whatever actions it will take to obtain that outcome. For example, you may really want to eat some ice cream, and may perceive eating ice cream as rewarding, but you may not want to extend the effort to go to the store to get the ice cream. Some research suggests that the dorsal anterior cingulate cortex (ACC) may be important for evaluating the effort associated with different action plans, with contributions from DA input from nucleus accumbens and related forebrain circuitry (e.g., Salamone et al., 2007). For example, research has shown that ACC lesions, as well as depletions of accumbens DA, lead animals to choose low effort but low reward options over higher reward, but higher effort options (e.g., Rushworth et al., 2007; Salamone et al., 2007).

A fourth component is the ability to *generate and execute goal-directed action plans necessary to achieve the valued outcome* (Fig. 21.1e), a function closely aligned with the concept of proactive control. A number of researchers have discussed the role of the lateral PFC in relation to this component in the context of reward and motivation (in particular DLPFC) (Braver et al., 1999; Miller and Cohen, 2001; Wallis, 2007), a function that is consistent with a number of other lines of research and theory, including: (1) the role of the DLPFC in top-down control of cognitive processing; (2) models suggesting that the DLPFC provides a bias signal that helps to facilitate goal-directed behavior (Miller and Cohen, 2001); (3) evidence

for impaired action planning following lateral PFC lesions (e.g., Zalla et al., 2001); and (4) evidence that increases in DLPFC activity mediate “motivated” cognitive control enhancements that occur with the provision of incentives in both animals (e.g., Sakagami and Watanabe, 2007) and humans (e.g., Jimura et al., 2010). In other words, intact DLPFC function may be necessary to translate information about value into goal representations and to maintain such information so that it can be implemented as action plans to achieve the desired outcome.

HEDONICS AND LIKING IN SCHIZOPHRENIA

Numerous studies have emphasized that individuals with schizophrenia and controls show similar patterns of valence and arousal (e.g., liking) in their self-reported emotional responses to affect-eliciting stimuli (for reviews, see Krings and Moran, 2008; Cohen and Minor, 2010). The neuroimaging studies examining striatal responses to the receipt of monetary rewards in schizophrenia have also shown a consistent pattern of intact responses. Specifically, these studies have found robust ventral striatal responses to the receipt of money (e.g., Simon et al., 2009; Dowd and Barch, 2012). Interestingly, Simon and colleagues found that the magnitude of the reward receipt response in the ventral striatum was inversely associated with severity of depression, but not with anhedonia (Simon et al., 2009). Schlagenhauf and colleagues did not find group differences in the response to rewards in the ventral striatum, though they did not clearly see intact responses in patients, and there were reduced striatal responses to loss-avoidance among the individuals with schizophrenia (Schlagenhauf et al., 2009).

However, while striatal responses to reward receipt seem to be largely intact in schizophrenia, some of these studies did report abnormal cortical responses to reward receipt (Schlagenhauf et al., 2009; Walter et al., 2010; Waltz et al., 2010). A more mixed picture has arisen from functional neuroimaging studies that have examined brain responses to other types of pleasurable stimuli in schizophrenia (e.g., Crespo-Facorro et al., 2001; Dowd and Barch, 2010; Grimm et al., 2012; Paradiso et al., 2003; Plailly et al., 2006; Waltz et al., 2009).

In sum, the self-report literature provides relatively consistent evidence for intact self-reports of “liking” in schizophrenia, though there is evidence that greater self-reports of anhedonia or negative symptom ratings are associated with less “liking” (e.g., Dowd and Barch, 2010). In addition, the functional neuroimaging literature on the receipt of monetary rewards shows consistent evidence for intact receipt responses. However, the functional neuroimaging literature on responses to other types of rewarding stimuli provides a more confusing picture, with some evidence for reduced insular responses, and mixed evidence for altered striatal responses. Further, those studies that have examined individual differences in negative symptoms do suggest an important relationship between the magnitude of striatal responses to rewarding or pleasurable stimuli and anhedonia among individuals with schizophrenia (Waltz et al., 2009; Dowd and Barch, 2010).

REWARD PREDICTION AND WANTING IN SCHIZOPHRENIA

In schizophrenia, there is robust evidence for altered DA and basal ganglia function (e.g., Fusar-Poli and Meyer-Lindenberg, 2013; Howes et al., 2012). As such, it is surprising that a relatively large number of studies have suggested intact reinforcement learning in schizophrenia using a range of tasks in which learning is either relatively easy or relatively implicit (e.g., Heerey et al., 2008; Waltz et al., 2007), though with some exceptions (e.g., Pantelis et al., 1999). However, when the paradigms become more difficult and require the explicit use of representations about stimulus-reward contingencies, individuals with schizophrenia show more consistent evidence of impaired reinforcement learning (e.g., Gold et al., 2012; Waltz et al., 2007; Yilmaz et al., 2012). Interestingly, there are hints that these impairments may be greater when individuals with schizophrenia must learn from reward versus from punishment (Cheng et al., 2012; Gold et al., 2012; Waltz et al., 2007). Although such deficits could reflect impaired basal ganglia-mediated reinforcement learning mechanisms, they may also reflect impairments in more explicit and rapid on-line learning mechanisms that may be mediated by OFC and/or DLPFC, as hypothesized by Gold and colleagues (Gold et al., 2008) and discussed in what follows.

In the neuroimaging literature, studies of reward prediction (wanting) have primarily used paradigms that directly examine neural responses to reward-predicting cues, sometimes following conditioning trials and sometimes through explicit instruction, such as in the monetary incentive delay (MID) task. A number of studies have reported reduced ventral striatum activity to cues predicting reward in schizophrenia in the

MID. These results have been found in unmedicated individuals with schizophrenia (e.g., Nielsen et al., 2012a), as well as in individuals taking typical antipsychotics, but not in individuals treated with atypicals (e.g., Simon et al., 2009), nor in prodromal individuals (Juckel et al., 2012). Kirsch also found reduced ventral striatal responses to reward cues in individuals with schizophrenia taking typicals compared to atypicals (Kirsch et al., 2007), and Nielsen et al. (2012b) found reduced ventral striatal responses to anticipation cues in antipsychotic-naïve patients with schizophrenia, which improved following treatment with amisulpride. Importantly, a number of these studies also showed a relationship between negative symptom severity and deficits in anticipatory ventral striatal activity. Juckel and colleagues showed that the severity of negative symptoms predicted the reduction in ventral striatal responses in unmedicated and typically medicated patients. In addition, Simon and colleagues showed that the magnitude of this response was inversely correlated with apathy ratings, and Waltz showed a relationship between negative symptom severity and ventral striatal activation during anticipated gains (Waltz et al., 2010). We have also studied reward prediction using a Pavlovian task, and found a relationship between reduced striatal response to reward-predictive cues and greater anhedonia among individuals with schizophrenia (Dowd and Barch, 2012).

A number of studies have also examined prediction error responses—an increase in striatal (presumably dopaminergic) responses to unexpected rewards and a decrease in striatal responses when predicted rewards do not occur. Murray found evidence for reduced prediction error responses to rewards among schizophrenia spectrum patients in bilateral midbrain and right ventral striatum, coupled with enhanced prediction error responses to neutral stimuli (Murray et al., 2008). Somewhat consistent with this finding, Morris found reduced prediction error responses in the striatum in schizophrenia, as well as enhanced responses for unsurprising reward stimuli that were not expected to elicit prediction errors (Morris et al., 2012). Gradin found reduced prediction error responses in the caudate, but increased activation associated with expected reward value in the ventral striatum (Gradin et al., 2011). Waltz and colleagues examined positive and negative prediction error responses in a passive paradigm that required participants to learn about the timing of a potential reward (Waltz et al., 2009). These researchers found evidence for reduced positive prediction error responses in a range of regions that included the striatum (dorsal and ventral) as well as insula, but relatively intact negative prediction errors in these same regions. Interestingly, Waltz et al. did find that the magnitude of prediction errors in basal ganglia among patients was negatively correlated with avolition scores. In more recent work, Walter et al. (2010) found intact prediction error responses in the striatum for both positive and negative prediction errors, though this was a relatively low negative symptom sample.

To summarize, the literature on reinforcement learning and reward prediction in schizophrenia suggests relatively intact learning on simple reinforcement learning paradigms, though this may reflect a ceiling. On more difficult tasks, there is more consistent evidence for impaired performance,

though in terms of absolute levels of performance rather than in learning rates. The open question in regard to this literature is the degree to which these impairments reflect differences in striatum-influenced learning mechanisms that may be more implicit, versus explicit learning mechanisms that may be more cortically mediated. Consistent with the hypothesis that some of these reinforcement learning impairments may reflect striatal mechanisms, a growing number of studies in the imaging literature suggest reduced ventral striatal reward prediction/“wanting” responses in unmedicated and typically medicated individuals with schizophrenia (though not in those taking atypical antipsychotics) and evidence for reduced positive prediction errors. However, not all studies have found impaired striatal responses to reward prediction cues or to prediction error, and there is also evidence that the magnitude of these striatal impairments may be related to the severity of negative symptoms, again pointing to the importance of examining individual difference relationships among individuals with schizophrenia. Further, a number of studies have also found altered activation in frontal regions during reward prediction or reinforcement learning, suggesting a potentially important role for cortically mediated mechanisms.

VALUE COMPUTATIONS AND OFC FUNCTION IN SCHIZOPHRENIA

There are two experimental paradigms that have been frequently used as probes of lateral and medial OFC function: probabilistic reversal learning and the Iowa gambling task. Both tasks require individuals to integrate information about rewards and punishments across trials, and to use such information to update value representations appropriately. Several studies suggest impaired reversal learning in schizophrenia (e.g., Waltz and Gold, 2007), though a few studies using the ID-ED task did not find simple reversal learning deficits in schizophrenia (e.g., Jazbec et al., 2007). These reversal-learning impairments are present even when individuals with schizophrenia and controls are matched on initial acquisition performance (Weiler et al., 2009). The literature on the Iowa gambling task in schizophrenia also provides evidence for impairment (e.g., Kim et al., 2009), again with some exceptions (e.g., Turnbull et al., 2006). There is also evidence for structural and functional changes in OFC in schizophrenia (e.g., Pantelis et al., 2003; Plailly et al., 2006), though such changes have not been directly related to reversal learning or Iowa gambling task performance. There is also reasonable evidence for olfactory functioning deficits in schizophrenia (e.g., Kamath et al., 2013), which could be related to OFC function (given that olfactory cortex is located in OFC) (Moberg and Turetsky, 2003), although it is not clear whether olfactory functions rely on the same OFC regions that support value computations. In sum, there is good evidence from the behavioral literature for deficits in tasks thought to reflect OFC function in schizophrenia, but no direct evidence of impaired OFC function in relationship to deficits in value computation, as one might find in imaging studies of probabilistic reversal learning (Cools et al., 2002).

EFFORT COMPUTATIONS AND ACC FUNCTION IN SCHIZOPHRENIA

To our knowledge, there is no work directly addressing effort computations in schizophrenia. Several studies suggest that individuals with schizophrenia show reduced error-related ACC responses (e.g., Polli et al., 2008), as well as reduced post-error slowing (e.g., Kerns et al., 2005). However, there is also evidence that patients with schizophrenia can show normal error correction performance even in the context of reduced ACC responses to errors (e.g., Polli et al., 2006) and that the relationship between the magnitude of the error-related negativity (ERN) and error-related behaviors is intact in schizophrenia (Morris et al., 2006). Thus, there is some reason to believe that conflict monitoring, error processing, and ACC function may be altered in individuals with schizophrenia, though more work is needed to address whether these reflect the same mechanisms supporting effort computations.

GOAL-DIRECTED ACTION AND DLPFC FUNCTION IN SCHIZOPHRENIA

As previously reviewed, there is strong evidence from a variety of sources for impairments in goal representation, proactive control, and DLPFC function in schizophrenia. Thus, an important question is whether some of the motivational impairments observed in schizophrenia reflect, at least in part, problems in translating reward information into goal representations that can be used and maintained in DLPFC to guide goal-directed behavior. One means of examining this issue is to determine how motivational incentives impact cognitive performance, potentially via modulation of DLPFC activity. Several studies suggest that individuals with schizophrenia are not able to improve their performance on cognitive tasks when offered monetary incentives (e.g., Hellman et al., 1998); while an equal number suggest at least some evidence for improvement with reward (e.g., Rassovsky et al., 2005), though the studies showing improvements have not used executive control tasks. There is also work on the use of token economies in schizophrenia that suggests functioning can be improved through an explicit reward system, though token economies provide a number of “external” supports for maintaining reward-related information that could compensate for deficits in the ability to translate reward information into action plans. However, to date, there are no fMRI studies examining whether or not incentives modulate DLPFC activity during cognitive control or WM tasks in schizophrenia.

Recent elegant work by Ursu and colleagues provides some data at least indirectly consistent with the presence of deficits in the ability to maintain emotionally relevant information in schizophrenia (Ursu et al., 2011). In the scanner, Ursu and colleagues presented participants with affective or neutral pictures for a brief period followed by a delay interval during which subjects “maintained” the affective state. Following the delay, all participants provided ratings of their emotional experience of the previously presented stimulus. Interestingly, during the initial stimulus presentation phase (i.e., while the physical stimulus was presented on screen), patients and healthy

comparison subjects showed little difference in neural activity, as revealed by a direct contrast. In fact, both groups activated a distributed network of regions previously associated with processing affective stimuli, including the visual cortex, insula, thalamus, midbrain structures, and other regions. However, when required to “maintain” the affective content over the delay, individuals with schizophrenia exhibited marked reductions in signal across regions previously linked to cognitive control (e.g., DLPFC). The lack of maintenance signals correlated with negative symptom severity in their sample. It is important to note that Ursu and colleagues found an association with negative and not positive stimuli, which somewhat limits the generalizability of their findings to discussion of reward and motivation. Nevertheless, this general pattern of reduced PFC signal in the context of maintaining affective information is in correspondence with a body of evidence showing that schizophrenia is associated with reduced DLPFC signals during cognitive control and WM tasks described in the preceding, and is consistent with the hypothesis that individuals with schizophrenia may have difficulty representing information about rewards and incentives that can be used to drive goal directed behavior (Heerey and Gold, 2007).

SUMMARY OF REWARD AND MOTIVATIONAL NEUROSCIENCE IN SCHIZOPHRENIA

Taken together, the results of the current literature review are generally consistent with the interpretation that hedonics are relatively intact in schizophrenia. In contrast, the literature increasingly suggests that there may be a deficit in putatively DA mediated reward learning and/or reward prediction functions. Such findings suggest that impairment in striatal reward prediction mechanisms may influence “wanting” in schizophrenia in a way that reduces the ability of individuals with schizophrenia to use anticipated rewards to drive motivated behavior. Although there is ample evidence for impaired DLPFC function and action planning in schizophrenia, there is little work directly examining the influence of rewards on the ability to modulate these mechanisms in schizophrenia. However, the literature on DLPFC mediated cognitive impairments in schizophrenia, and the recent work by Ursu (Ursu et al., 2011) suggests some potentially intriguing interactions between reward predictions and proactive control in contributing to motivational impairments in schizophrenia. To illustrate, consider the following scenario: An individual with schizophrenia may report that they enjoy chocolate chip cookies, but may not be able to engage in the behaviors necessary to obtain or make more chocolate chip cookies (Barch and Dowd, 2010; Kring and Moran, 2008). Planning, purchasing, preparing, or baking the cookies requires ongoing maintenance of contextual or cue information that should trigger associations about the food’s rewarding properties, which will ultimately guide the volitional pursuits over time that may lead to such a reward (in this case intake of appetitive food). An intact reward valuation and prediction system is necessary for this set of behaviors to take place, and deficits in these functions in schizophrenia may reduce the ability of appetitive food cues to drive behavior. However, these functions also depend on

the intact ability to maintain appetitive cues or context over time—a process that may be reliant on WM and proactive cognitive control, which are compromised in schizophrenia (Barch and Dowd, 2010). Thus, deficits in reward prediction and learning may be exacerbated by the inability to actively maintain rewarding information in WM, which may extend beyond simple appetitive stimuli to more abstract rewards. What is needed next is research that directly tests the ability to use and maintain internal representations of reward information to modulate behavior and brain function in schizophrenia, along with work that characterizes links between deficits in this ability and everyday function in this illness.

The previous discussion reviews the potential mechanisms of impairment in schizophrenia as potentially dissociable psychological and neural systems that may make independent contributions to impairments in goal directed behavior in schizophrenia. However, it is also possible that there are impairments in several of these functions and systems that reflect one or multiple common mechanisms. One potential common denominator that could lead to impairments in each of the functions (outside of hedonics) is altered DA function in both subcortical and cortical regions (e.g., Fusar-Poli and Meyer-Lindenberg, 2013; Howes et al., 2012). Almost all of the functions described earlier are heavily reliant on intact DA function, which has widespread influences on both cognitive and motivational systems. Thus, should future research indicate that many or all of the processes involved in translating reward into goal directed action are impaired in schizophrenia, it may suggest a role for a core deficit in DA function that modulates multiple components of the system as one parsimonious explanation. However, it is also possible that ongoing research will provide evidence for selective impairments or differential involvement of neurotransmitter systems in individual components of the system (e.g., GABA or glutamate to DLPFC deficits), providing important clues as to pathways for intervention. Further, antipsychotic medications that block DA receptors have the potential to impact these cognitive and motivational systems at several stages, and addressing potential medication confounds will therefore be critical to future work in this field. While practical and ethical constraints make controlled examination of medication effects difficult, there are several strategies that, when combined, may yield a fuller picture of how reward-related functions are affected by medications in this population. The reward prediction literature has begun to tackle these questions by examining unmedicated patients and comparing results between different medication types. Other approaches could include: examining genetically related, medication-naïve populations such as first-degree relatives and schizotypal personality disorder patients; delaying a dose of medication in order to perform within-subjects comparisons at high and low D2R blockade, and/or performing PET and fMRI studies in the same sample to gain information about individual levels of DA synthesis, availability, or receptor distribution to directly link DA function to behavior and brain responses associated with proactive control and motivation. Finally, due to well-known system-level DA and glutamate interactions (Coyle, 2006) it will be critical for future studies to fully disambiguate whether DA dysregulation, even

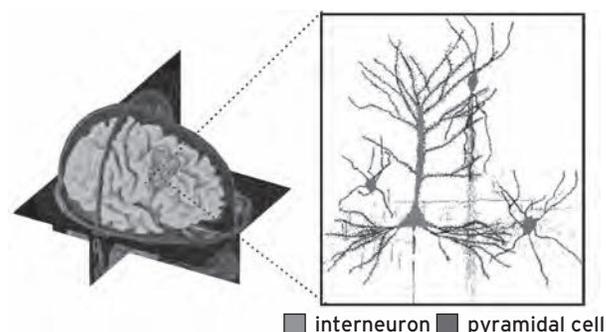

if functionally important for the aforementioned deficits, is the proximal cause of these deficits or a downstream abnormality of other neurotransmitter and microcircuit alterations (Lewis et al., 2012). Such complex multilevel integration, from synaptic mechanism to system-wide effects of interacting neurotransmitter abnormalities, will be vital to mechanistically understand emerging behavioral pathology in schizophrenia.

UNDERSTANDING AFFECTIVE AND COGNITIVE DEFICITS IN SCHIZOPHRENIA ACROSS LEVELS OF ANALYSES

Thus far we have discussed the complex cognitive and motivational processes affected in schizophrenia from the perspective of psychological processing as well as the brain regions and broadly defined neural and neurotransmitter systems that may support these processes. This is the level of analysis most commonly examined using cognitive neuroscience approaches, and the levels for which the most data exist about impairment in schizophrenia level, mainly due to the functional resolution of non-level human neuroimaging. Indeed, such approaches have honed our search for mechanisms involved in these behavioral deficits. However, such cognitive neuroscience approaches when used in isolation have more difficulty identifying underlying cellular mechanisms (in humans, and therefore patients suffering from mental illness, at least). Such a cellular and molecular level of understanding is crucial to identify effective pharmacological therapies that directly translate from an understanding of the impaired mechanisms leading to abnormal cognitive and motivational process. We believe it will be critical to close the existing gaps in our understanding of emotion and cognition in schizophrenia across levels of explanation: from synaptic signaling at the microcircuit level, to system-level disruptions and ultimately abnormal behavior. We acknowledge that a comprehensive review of the neurobiology and neurochemical alterations in schizophrenia is beyond the scope of the present chapter (see prior reviews for excellent treatments of this topic (e.g., Krystal et al., 2003; Lewis et al., 2012; Marin, 2012; Moghaddam and Javitt, 2012)). However, we briefly highlight how evolving cellular-level hypotheses of microcircuit disruptions offer a possible foundation for understanding higher-order emergent neural system and behavioral deficits in schizophrenia that demand mechanistic explanations.

As discussed in this chapter, the clinical cognitive and motivational neuroscience approach to schizophrenia has identified region-level abnormalities in both function and anatomy across areas such as DLPFC, hippocampus, amygdala, thalamus, and striatum (Fig. 21.2). Regions such as DLPFC, striatum, amygdala, and thalamus comprise a set of cortical-subcortical networks and loops, which function in concert and are influenced by multiple neuromodulatory signaling pathways (Fig. 21.2). Indeed, as reviewed previously, disruptions in numerous interacting neurotransmitter systems, including DA, GABA, and glutamate have been implicated in schizophrenia (e.g., Krystal et al., 2003; Lewis et al., 2012). For example, there is mounting evidence for DA alterations in the striatum of patients with schizophrenia that result in hyperactivity (e.g.,

(a) Micro-circuit level disturbances in cortical function

(b) Cortical-striatal-limbic circuit disruption in schizophrenia

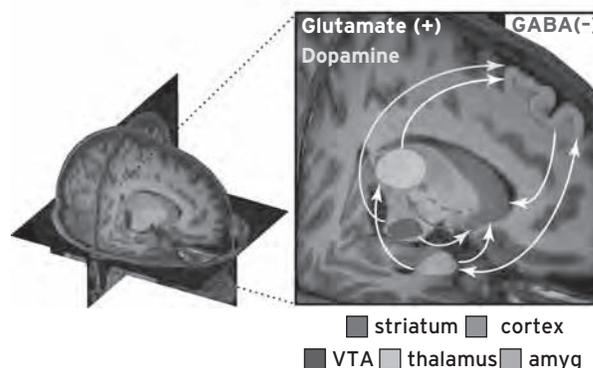

Figure 21.2 Conceptual illustration of neural circuitry across levels of computation that may be involved in affective and cognitive disturbances in schizophrenia. The figure highlights how, in order to explain deficits at the phenomenological/behavioral level, we need to bridge observations across multiple levels of analysis in schizophrenia. (a) At the regional level there is clear evidence for both structural and functional abnormalities in cortical and striatal/thalamic circuits in schizophrenia (Bora et al., 2011; Shepherd et al., 2012). Based on emerging findings from basic animal (e.g., Yizhar et al., 2011; Lewis et al., 2012), postmortem (e.g., Lewis et al., 2012), and pharmacological studies (Krystal et al., 2003), there is an increasing understanding of microcircuit abnormalities that may be at play in schizophrenia, contributing to regional abnormalities (Marin, 2012). One possibility is that that abnormalities in the balance of excitation/inhibition in cortical microcircuitry (E/I balance) contribute to downstream system-level disturbances that encompass distributed circuits and neurotransmitter systems. One leading hypothesis postulates an imbalance between cortical excitation and inhibition between pyramidal cells and interneurons, producing a state of “disinhibition,” which may in turn affect regional and neural system-level function in schizophrenia (Yizhar et al., 2011). (b) Less is known about how some of these regional deficits and microcircuit alterations manifest in possible system-level disruptions in functional loops between prefrontal, striatal, limbic, and thalamic nodes in schizophrenia (Lisman, 2012). Deficits in these interacting functional systems need to be considered when interpreting abnormalities between affective and cognitive operations in schizophrenia. Furthermore, there is known interplay between interacting neurotransmitter systems in cortico-striatal-thalamic loops that may be compromised in schizophrenia (e.g., Coyle, 2006). Considering effects across all of these levels will be critical to mechanistically understand complex schizophrenia phenomenology.

Fusar-Poli and Meyer-Lindenberg, 2013; Howes et al., 2012). Patients also present with reduced (in particular hypostimulation of D1 receptors in PFC; Abi-Dargham et al., 2002). Patients may also exhibit disruptions in glutamateric signaling at the NMDA receptor (Krystal et al., 2003), as well as disruptions in

GABA synthesis and signaling from interneurons onto pyramidal cells (e.g., Lewis et al., 2012) (Fig. 21.2b). As noted, there is still an ongoing debate as to which one of these disruptions may be the proximal cause of downstream symptoms (Coyle, 2006), but given that disruptions across interactive neurotransmitter systems are likely to contribute to dysfunction across the illness course (Marsman et al., 2013), considering these complex interactions will be vital as we move toward a more complete understanding of this illness.

One way to organize these multiple, interactive dysfunctions across levels of analysis is to consider how they may be impacted by pathology at the level of cortical microcircuitry (Fig. 21.2) (Lewis et al., 2012; Marin, 2012). That is, perhaps if we were to start from cellular-level hypotheses of disrupted cortical computations in schizophrenia, we may ultimately be able to better understand complex dynamics that emerge at higher levels of observation. Here we need to consider that optimal cortical function depends on the balanced interaction of pyramidal excitatory (glutamatergic) and inhibitory (GABAergic) neurons (Shadlen and Newsome, 1994) (i.e., excitation/inhibition balance—E/I balance). Disruptions of this E/I balance can have drastic behavioral consequences, with implications for a number of neuropsychiatric conditions (Marin, 2012; Yizhar et al., 2011). In schizophrenia specifically there may be a functional deficit in the interaction between excitatory and inhibitory cortical neurons (e.g., Lewis et al., 2012; Marin, 2012). This may arise from a disruption in cortical inhibition stemming perhaps from reduced inhibitory drive via GABA interneurons onto pyramidal cells and ultimately resulting in *disinhibition* of pyramidal cells (Lewis et al., 2012; Marin, 2012). One finding consistent with this possibility is that postmortem studies of patients with schizophrenia consistently show reduced levels of the mRNA for the 67-kilodalton isoform of glutamic acid decarboxylase (GAD67, encoded by *GAD1*), a key factor in optimal GABA levels, in the DLPFC (for review see Lewis et al., 2012). Importantly, it is well documented that GABAergic interneurons function by exerting lateral inhibition and synchronizing persistent firing of pyramidal cells in DLPFC (Rao et al., 2000), thus providing one potential mechanism for the tuning of representations across cortex. That is, lateral inhibition might enhance the processing and maintenance of salient information relative to less behaviorally relevant representations. Disruptions of this balance between pyramidal and GABA interneurons may be one crucial pathophysiological mechanism operating in schizophrenia, relevant to the patterns of neural and behavioral responses that we discuss presently.

At present, it is unknown how these cellular disruptions in E/I balance may manifest at the level of neural systems and ultimately diverse psychological processes compromised in this illness (Yizhar et al., 2011). The challenge facing the field is to close this gap and understand the pathways that lead to such disruptions, which will potentially allow for future hypothesis-driven compensations aimed at ameliorating such circuit abnormalities. There are multiple paths forward that can help close this gap:

1. One approach is to start at the level of cells and make predictions regarding the higher levels of analysis. A

way to accomplish this goal could involve computational modeling, particularly models that are rooted in neurophysiologic data and that build on assumptions based on molecular and systems neuroscience (e.g., Wang, 2010). We have, as proof-of-principle, applied this framework in the context of WM (Anticevic et al., 2012b), but more work will be needed to extend such tools to other psychological constructs and processes.

2. Another approach is to test hypotheses regarding neural dysfunction in schizophrenia via pharmacological manipulations in healthy adults (Corlett et al., 2007). This is accomplished through perturbations of the underlying circuitry thought to be compromised in individuals suffering from the illness, via relatively well understood neurochemical mechanisms. In turn, such manipulations may reveal clues regarding specific links between disruptions in neurotransmitter systems, which can be connected to system-level deficits and ultimately behavior.
3. Continued development of more sophisticated animal models of the neural pathology that may be present in this illness that are well linked to both intermediate and behavioral phenotypic markers should also be pursued (Yizhar et al., 2011). For instance, primate physiology experiments of WM, in combination with targeted neurochemical and optogenetic manipulations (Tye and Diesseroth, 2012), provide this framework (e.g., Arnsten and Rubia, 2012).
4. As articulated by the Research Domain Criteria (RDoC) initiative (Insel and Cuthbert, 2009), examining behavioral deficits and alterations in the underlying neural systems transdiagnostically (Anticevic et al., 2012b) and via continuous measures of symptom severity could provide further clues about common versus unique mechanisms that may co-occur in schizophrenia and other severe neuropsychiatric illnesses such as bipolar disorder.
5. Lastly, large-scale imaging genomic studies as well as detailed spatial and temporal genetic transcriptomics approaches (e.g., Kang et al., 2011) could hone our search for genes that influence cortical development, that may ultimately disrupt the cortical microcircuitry detailed in the preceding.

We argue that these and other complementary neuroscientific approaches will be critical to close our vast explanatory gaps in clinical neuroscience of schizophrenia.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

In this chapter, we have reviewed the extensive evidence that individuals with schizophrenia experience deficits in the active representation of information necessary to guide behavior, a critical aspect of proactive control and WM function (see Fig. 21.3). Further, we have also reviewed evidence that WM

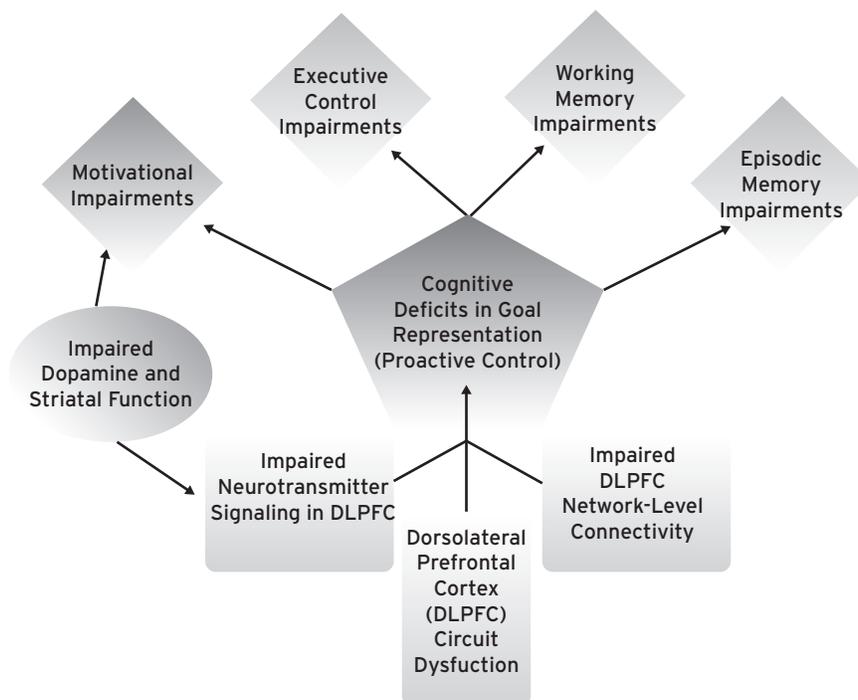

Figure 21.3 Goal representation, cognition, and motivation in schizophrenia. The figure highlights the complex multilevel interactions that need to be considered in the context of cognitive and motivational deficits in schizophrenia. For instance, regional deficits in prefrontal nodes such as DLPFC (bottom boxes) arising from multiple factors—namely disrupted local neurotransmission (e.g. GABA, dopamine, and glutamate), deficits in microcircuit computations, as well as network-level connectivity disturbances in key cortical nodes. Such regional abnormalities may be exacerbated by neurotransmitter disturbance in downstream circuits, such as dopamine signaling in striatum (oval), which also impact on motivational problems in schizophrenia (left diamond). Such region and system-level disturbances may converge on a “core” cognitive deficit in goal and context representation (center polygon), which is ultimately measurable via neurocognitive behavioral tests. Importantly, such a “core” deficit may impact various complex cognitive operations that rely and tap into similar circuits (top diamonds).

deficits in schizophrenia are associated with disturbances in a distributed cortical frontoparietal, striatal, and thalamic circuit, though impairments in DLPFC function may play a particularly key role. Such impairments may involve not only abnormalities in sustaining activation across a delay, but also breakdowns in interference resolution from incoming distraction. We have also discussed evidence suggesting that individuals with schizophrenia have deficits in episodic memory function that involve impairments in relational integration and retrieval. These deficits in relational processing of components of episodic memory appear to reflect impairments in both binding processes supported by the hippocampus and the types of beneficial encoding strategies supported by regions of PFC. Importantly, we have also suggested that impairments in DLPFC-mediated active maintenance of information may contribute to deficits in motivated behavior in schizophrenia, by interfering with the ability to use and/or maintain representations of rewards, incentives, or other affective information necessary to generate action plans needed to obtain positive outcomes. Although we realize that this is an oversimplification, as outlined in Figure 21.3, we have found it useful to conceptualize the common mechanisms that may be contributing to deficits across cognitive domains and which may link cognitive and motivational deficits. We have proposed proactive control and DLPFC dysfunction as one common mechanism,

as well as the possible contribution of impaired DA function along other interactive neurotransmitter systems. Other researchers will have suggestions about different types of common mechanisms; what we wish to emphasize here is the utility of a more unified account of the diversity of impairments in schizophrenia as a means to move forward our understanding of pathophysiology and treatment options.

There are several other important directions for future work in the cognitive and motivational neuroscience of schizophrenia. The first direction is to link this work back to genetics, risk for psychosis, and endophenotypic markers, so we can better understand the causal pathways leading to deficits in cognitive and motivational processes in psychosis, and their potential synergistic interactions. There is already a good deal of evidence that a variety of cognitive deficits present in schizophrenia may be associated with genetic risk for psychosis, as they are present in the first-degree relatives of individuals with schizophrenia who do not manifest psychotic symptoms. There is also some work beginning to link the severity of such impairment, at the neural and/or behavioral level with particular genetic risk factors. The second is closely aligned with the goals of the recently developed and aforementioned RDoC initiative, the aim of which is to redefine the structure of psychopathology based on known neural systems and neurobiological mechanisms. Deficits in the types and profiles of cognitive and motivational

processes described in this chapter are not limited to schizophrenia, and at least some are present (albeit sometimes in an attenuated form) across the spectrum of psychotic disorders (e.g., psychosis NOS, schizotypal personality disorder; e.g., Barch et al., 2003; Barch et al., 2004) and across the traditional divisions between affective and non-affective psychoses (e.g., Depp et al., 2007; Reichenberg et al., 2009). Such findings raise the possibility that there are common mechanisms that lead to cognitive dysfunction across psychotic disorders, a hypothesis that is consistent with a growing emphasis on identifying core neural systems that contribute to impairments that cut across traditional diagnostic boundaries (Insel, 2010). As such, much more research is needed that directly compares cognitive and motivational deficits across typical diagnostic boundaries, with a particular focus on understanding whether similar deficits at the behavioral level are linked to similar deficits at the neural level and with an emphasis on linking such impairments to specific psychopathological processes (e.g., anhedonia) or function. While there is clearly a need for continued research effort, we find that the field of schizophrenia research is at a truly exciting juncture where ever-expanding neuroimaging technologies, translational findings, computational modeling techniques, and genetic approaches provide true potential for hypothesis-driven rational treatment development based on understanding of disease mechanisms.

DISCLOSURES

Dr. Anticevic is funded by National Alliance for Research on Schizophrenia and Depression (NARSAD).

Dr. Dowd does not have any conflicts of interest to disclose.

Dr. Barch has been funded by National Institute of Mental Health (NIMH), National Alliance for Research on Schizophrenia and Depression (NARSAD), and National Institute on Aging (NIA), has received research grants from Allon and Novartis, and has consulted for Pfizer.

22 | MOUSE MODELS OF SCHIZOPHRENIA AND BIPOLAR DISORDER

MIKHAIL V. PLETNIKOV AND CHRISTOPHER A. ROSS

INTRODUCTION

Animal models are experimental systems that are developed to study particular aspects of a disease, as no model can accurately reflect all features of the disease. Modeling of human neuropsychiatric disorders in animals is especially challenging (Nestler and Hyman, 2010).

An example of both the opportunities and difficulties of mouse model research is seen with Huntington's disease (HD). HD is a single gene disorder whose genetics and neurobiology are relatively well understood (Ross and Tabrizi, 2011). The clinical symptoms of human HD include pathognomonic involuntary and voluntary movement disorders, cognitive decline, and emotional changes, with inexorable progression to death. These are accompanied by selective neuronal degeneration in the striatum and other brain regions. The disease is caused by a single mutation, a CAG repeat expansion at the *Huntingtin* locus. There have been over a dozen attempts to model this disease in mice (Crook and Housman, 2011). These models had some outstanding successes. For instance, the characteristic intranuclear inclusions containing aggregated Huntingtin protein were first discovered in the mouse model, and this discovery enabled their identification in humans. The mice generally do have some motor and cognitive abnormalities, and in some cases there is a progressive phenotype ending in early death. However, most of the models do not have the massive striatal neurodegeneration seen in the human disease. Most of the models do not have the involuntary movement disorder. Many of the models have weight gain instead of the progressive weight loss seen in most HD cases. Thus, it is important to keep in mind that even in a disorder that should be relatively straightforward, the mouse models have both strengths and weaknesses, and demand careful and cautious interpretation.

During the last three decades multiple animal models of schizophrenia and bipolar disorder have been generated, based on environmental exposures, drug-induced behaviors, or lesions. We might categorize different kinds of animal models in terms of their relationship to the cognate human diseases.

Phenotypic models attempt to model aspects of the phenotype of the disease, often picking behaviors that are reliably

measured in animals, such as motor activity, acoustic startle responses, or various kinds of learning. These may or may not reproduce the pathophysiology of the human disorder, but may be useful for pharmacology.

Pathophysiological models attempt to mimic some key aspect of the biology, though not necessarily the etiology of the human disorders. For instance, since abnormal neurodevelopment is increasingly seen as central to schizophrenia, perturbations of brain development (Lu, 2011) may model some aspects of the biology of the disorder. It is important to interpret developmental mouse models in the context of emerging knowledge of the circuitry of psychiatric disorders (Lewis and Sweet, 2009; Ross et al., 2006), including cortical and subcortical circuits. Much attention has been given to modeling alterations in dopamine signaling; however this may be more relevant to antipsychotic pharmacology than to human disease pathogenesis.

Finally, etiologic models have the potential to match most closely the human disorders. Presumably, the pathophysiology should also be congruent if the etiology is congruent. Etiologic models could be either environmental or genetic. However, while environmental factors, including pharmacologic exposure, clearly contribute to psychiatric disorders, the exact factors and their time course, are not yet well defined, and so it is difficult to model them. Therefore, taking into account the strong evidence for genetic contributions to the development of schizophrenia and bipolar disorder, genetic models may be the most specific way to attempt to match the human neurobiology, and hopefully model pathogenesis and, ideally, response to treatment.

In this review we will mention some of the non-genetic models, but focus on genetic mouse models, evaluate their advantages and limitations, and comment on potential new prospects for the field. We will focus on single gene alterations and attempts to model copy number variation. For most genetic contributors to human psychiatric disorder, the pathophysiologic mechanisms are poorly understood. For instance, genetic variation could lead to overall loss of function, gain of function, misregulation of gene expression and function, or other more complex changes. Until specific causative mutations are identified, models will have to depend on hypotheses about gain or loss of function or other alterations.

NON-GENETIC MODELS

PHARMACOLOGICAL MODELS

One approach to animal models of schizophrenia and bipolar disorders is based on use of pharmacological challenges. These models are mainly relatively acute phenotypic models, though exposure to psychostimulants, cannabis, PCP, and other drugs may contribute to susceptibility to human psychiatric disorders. In addition, these pharmacologic models may be able to mimic the behavioral effects of treatments used in clinic (pharmacological isomorphism) and to predict pharmacological effects of experimental compounds to become future therapeutics (predictive validity) (Matthyssse, 1986).

Among pharmacological animal models of schizophrenia, phencyclidine (PCP)- or amphetamine-induced hyperactivity are most popular. Similarly, amphetamine-induced hyperactivity has been widely used to model mania (Berggren et al., 1978; Davies et al., 1974; Gould et al., 2001; Kato et al., 2007), although lithium does not seem to attenuate amphetamine-induced changes in healthy volunteers (Silverstone, 1998). The major caveat of drug-induced hyperactivity models is that hyperactivity is one of a broad set of symptoms of several psychiatric diseases, including schizophrenia, attention-deficit hyperactivity disorder, and bipolar disorder (Young, 2011). Since pharmacological treatments of schizophrenia and bipolar disorder are largely symptom-based or palliative, animal models that mimic behavioral responses to drugs are less likely to provide insights into the pathogenic mechanisms of disease and more likely to illuminate behavior pharmacology (Elenbroek and Cools, 1995).

BEHAVIORAL OR SYMPTOM-ORIENTED MODELS

Another approach to animal models of schizophrenia and bipolar disorder mimics behavioral abnormalities of the disease. Critically, in addition to evaluation of how accurate modeled animal behaviors reflect human symptoms, animal models of face validity are also scrutinized in pharmacological studies to evaluate if an altered behavior is responsive to treatments also used in clinical settings. For example, disrupted prepulse inhibition (PPI) of the acoustic startle and abnormal social interaction mimic impaired sensorimotor gating and social withdrawal observed in schizophrenia patients and can be improved by typical and atypical antipsychotics). Symptoms of mania that can be modeled in animals include increased activity, irritability, reduced need for sleep (or other changes in sleep patterns), aggressive behavior, sexual drive, distractibility, and risk-taking behavior, all of which are commonly observed in human mania (Einat, 2006). Models of the depressive phase of bipolar disorder usually utilize models validated in the context of depression research (see the chapter on models of depression), such as models of anhedonia, sleep disorder, poor hygiene, and changes in appetite or weight (Cryan and Holmes, 2005).

However, key positive and negative symptoms of schizophrenia or mood swings in bipolar disorder cannot be fully reproduced in animals. Even when schizophrenia-like alterations such as hyperactivity or social behavior deficit are

modeled, it is unclear whether they arise from the same pathological processes, since hyperactivity can be induced by a great variety of drugs and manipulations irrelevant to the etiology and neuropathology of schizophrenia or bipolar disorder (Ridley and Baker, 1982).

PATHOGENIC NON-GENETIC MODELS

An additional approach to animal models involves attempts to reproduce pathogenic processes underlying the disease. These models are based on the concept that behavioral deficits in humans are due to disturbances in the brain functioning that could be modeled in animals (Elenbroek, 1995). Abnormal neurodevelopment is believed to be an important factor leading to behavioral deficits (Jaaro-Peled et al., 2010). Thus, animal models of abnormal brain and behavior development are likely to be most informative for our understanding of the neurobiology of schizophrenia and bipolar disorder (Insel, 2010; Kamiya et al., 2012).

During the last three decades several animal models of schizophrenia have been generated based on environmental exposures and lesions in developing and adult rodents (Lipska and Weinberger, 1993, 1995). The similar approaches have been utilized for neurodevelopmental models of bipolar disorder. For example, the exposure of the animals to early social isolation or early postnatal lesions in amygdala may produce the symptoms resembling aspects of mania, such as increased locomotor activity and enhanced sensitivity to the locomotor-activating effects of amphetamine (Swerdlow, 2001). In the context of recent reports on using transcranial magnetic stimulation as a treatment for depression, use of electrically or chemically induced kindling to study the development of new episodes in bipolar disorder is also of an interest (Kalynchuk, 2000). Still, all these non-genetic pathogenic animal models do not really address the etiology of the diseases and will unlikely advance uncovering new therapeutic targets.

GENETIC MOUSE MODELS OF SCHIZOPHRENIA

Genetic models have the potential to model both etiology and pathogenesis. Recent genetic studies are finally yielding replicable genetic loci for the human disorder. Most mouse work to date has relied on genes identified in linkage studies, which may contribute risk in small families though not necessarily in the entire population. However in other disorders, genes identified in small families have often turned out later to be relevant to the population at large. Since psychiatric genetics is still in a relatively early stage, it is difficult now to know which genes will confer the greatest amount of risk in different populations. Furthermore, alterations of genes whose gene products are involved in pathogenic pathways may be very useful even if the gene altered does not turn out to contribute a large amount of risk in human populations. In the future, likely more models will be available from loci confirmed in large GWAS or sequencing studies. For now, much of the work is on genes identified in smaller studies.

MODELS BASED ON GENES FROM GENOME-WIDE ASSOCIATION STUDIES

Most of the candidate genes studied to date emerged from relatively small linkage or association studies, and have not been seen in genome-wide association studies, so their relevance to schizophrenia in the population is uncertain (Sklar et al., 2008). Genome-wide association studies offer an unbiased assessment of variation across the entire genome, with the ability to identify specific disease variants (Bergen et al., 2012; Lee et al., 2012). A recent list of the risk genes associated with schizophrenia at genome-wide significance level includes zinc finger binding protein 804A (ZNF804A), the major histocompatibility (MHC) region on chromosome 6, neurogranin (NRGN), and transcription factor 4 (TCF4) (e.g., Lee et al., 2012). In addition, Ripke and colleagues have identified the microRNA MIR137 and its targets (Ripke et al., 2011). Generating animal models with the risk variants and characterizing molecular, cellular, behavioral, and other processes will help to link these genes to disease mechanisms. However, animal model research in this field is only starting. Here, we review a few experimental studies available in the literature to date (fall of 2012).

MHC

The most replicated schizophrenia GWAS association is the MHC locus, though multiple genes involved in immunity, neurodevelopment, synaptic plasticity, and other processes present a challenge for linking specific genes in this region to pathophysiology (Corriveau et al., 1998; Huh et al., 2000;). Many MHC mouse studies focus on species-specific recognition as a part of mating behavior (Hurst, 2009). A few investigations have been performed to address roles for this locus in other behaviors. For example, it has been reported that mice deficient for both H2-K(b) and H2-D(b)(K(b)D(b)-/-) have a lower threshold for induction of long-term depression (LTD) at parallel fiber to Purkinje cells synapses and improvement in acquisition and retention of a Rotarod behavioral task. These results suggest a role for classical MHCI molecules in synaptic plasticity and motor learning (McConnell et al., 2009). Unlike wild-type animals, mice lacking both β -2-microglobulin and transporter associated with antigen processing (β 2M-/-TAP-/-) showed a greater hypothalamic pituitary adrenal activation to saline injection, while lipopolysaccharide-induced cytokine expression in the hypothalamus was similar in β 2M-/-TAP-/- and wild type mice, suggesting that class I MHC plays a role in stress reactivity (Sankar et al., 2012).

An interesting approach to the behavioral effects of the MHC locus is to compare behaviors between MHC-congenic strains of mice or rats, which are genetically identical to each other except for the locus. Spatial learning and memory in male and female mice of two MHC-congenic strains (C57BL/6J and B6-H-2K) in two versions of the Hebb-Williams maze were evaluated. In the food-reward paradigm, males required fewer sessions to learn than females, but there were no strain differences in acquisition. The B6-H-2K mice reached the goal box faster than the C57BL/6J mice. In the water-escape paradigm, the C57BL/6J mice required more sessions than the B6-H-2K mice during acquisition. Thus, these two strains are comparable

in cognitive ability but still show differences in performance in the Hebb-Williams maze (Stanford et al., 2003).

TCF4

A putative role of the basic helix-loop-helix (bHLH) transcription factor TCF4 in the adult brain has been evaluated in transgenic mice that moderately overexpress TCF4 in the postnatal brain. TCF4 transgenic mice display profound deficits in contextual and cue-dependent fear conditioning and sensorimotor gating. Molecular analyses revealed the dynamic circadian deregulation of neuronal bHLH factors in the adult hippocampus. This study describes the first animal model relating to TCF4, and suggests that this transcriptional factor contributes to cognitive processing (Brzózka et al., 2010).

MODELS BASED ON COPY NUMBER VARIATION

Recent studies have implicated structural variations in the genome (copy number variations) in schizophrenia (Malhotra and Sebat, 2012). A 22q11 deletion has long been known to lead to 25-fold increase in the risk for schizophrenia (Murphy et al., 1999), though it is uncertain to what extent this corresponds to other forms of the disease. 22q11.2 deletion syndrome, DiGeorge syndrome (DGS), or velo-cardio-facial syndrome (VCFS) is associated with craniofacial and cardiovascular abnormalities, immunodeficiency, hypocalcemia, short stature, and cognitive dysfunctions (Karayiorgou et al., 2010). The orthologous region of the human 22q11.2 locus is located on mouse chromosome 16 with a high degree of conservation within the 22q11.2 region (Drew, 2011). Both long-range deletion models and single gene knockout (KO) preparations have been described. Here, we only briefly review mouse models related to the deletion. Comprehensive recent reviews of this topic are available elsewhere (e.g., Karayiorgou et al., 2010).

Two of the long-range deletion models—the *Df(16)A*-/- model (Stark, 2008) and the *LgDel*-/- model (Merscher et al., 2001)—lack the entire 1.5 Mb region on one chromosome, most closely modeling the human 22q11.2 deletion. These models have been reported to display impaired working memory and prepulse inhibition (PPI) of the acoustic startle, similar to the phenotypes of individuals with the 22q11.2 deletion syndrome (Paylor, 2006; Stark, 2008).

Among single gene KO mouse models involving the region of the deletion, *PRODH* is a promising candidate gene (Li, 2008) that encodes a mitochondrial enzyme to metabolize L-proline, a putative neuromodulator of Glu and GABA neurotransmission. Genetic variants in this gene have been associated with hyperprolinemia type 1 and schizophrenia (Harrison and Weinberger, 2005). Mutant mice with reduced *PRODH* enzymatic activity show abnormal associative conditioning (Gogos et al., 1999; Paterlini et al., 2005). These mutant mice were reported to have increased levels of COMT, possibly as a compensation for enhanced DA signaling in prefrontal cortex (PFC). Blockade of COMT in *PRODH* KO mice impairs learning in T-maze task (Paterlini et al., 2005). These results suggest an epistatic interaction between COMT and *PRODH* (Kvajo et al., 2011), consistent with a similar interaction reported for patients with 22q11.2 deletion (Raux, 2007). A growing

appreciation of the fact that a large number of schizophrenia cases result from copy number variations provides the good rationale for the development of models based on chromosomal engineering and other advanced techniques to manipulate sizable segments of DNA (Nomura and Takumi, 2012).

MODELS BASED ON GENES FROM LINKAGE STUDIES

Genetic models of candidate genes emerging from early linkage studies have been also generated, including dysbindin, neuregulin 1, and Disrupted-in-Schizophrenia-1 (DISC1), which have attracted the most attention and are described here in greater detail. It is notable that most candidate genes that have been studied to date have not been well supported by GWAS studies (Collins et al., 2012). These include COMT, dopamine receptors, neuregulin, dystrophin, BDNF, and other genes. It is possible that genes that do not have a signal in GWAS studies may still be important in familial or other subtypes of the disorder.

DYSBINDIN

Dystrobrevin-binding protein 1, or dysbindin, encoded by the *DTNBP1* gene and discovered through screening for binding partners of α -dystrobrevin (Benson et al., 2001) is a part of the dystrophin-associated protein complex (DPC) and of the biogenesis of lysosome-related organelles complex 1 (BLOC-1) (Nazarian et al., 2006). The dysbindin locus was first identified in an Irish study (Straub et al., 2002), and some research has supported relevance of this gene to schizophrenia, including haplotypes of the gene linked to the negative symptoms, or cognitive functioning in healthy people (Talbot, 2009). Postmortem studies also found reduced expression of the gene and protein in the hippocampus and PFC (Talbot, 2009; Weickert, 2008), where decreased expression of the protein can affect synaptic neurotransmission (Iizuka et al., 2007) and synaptic stability.

The role for dysbindin *in vivo* has been mainly evaluated using mice with spontaneous deletion in the *Dtnbp1* gene, leading to loss of dysbindin in “sandy” mice of DBA/2J strain (Li et al., 2003; Talbot, 2009). Sandy mice model type VII Hermansky-Pudlak syndrome, which is characterized by oculocutaneous albinism, prolonged bleeding, and pulmonary fibrosis. Earlier studies suggested that dysbindin can be involved in regulation of exocytosis and vesicle biogenesis in neurons and detected diminished levels of snapin (a SNAP25-binding protein) in sandy mice that may partially explain alteration in neurotransmission and behaviors (Chen et al., 2008; Feng et al., 2008). Nagai et al. (2010) observed decreased KCl-evoked DA release in prefrontal cortex, in line with attenuated behavioral sensitization after repeated methamphetamine. In addition, lower expression of dysbindin was associated with decreased NMDA-evoked currents in PFC neurons and decreased NRI expression that correlated with spatial working memory performance (Karlsborg et al., 2011). Parvalbumin (PV)-positive neurons were reported to be affected in these mutant mice as well, including impaired inhibition and decreased PV cell immunoreactivity, suggesting a link between this candidate gene and the auditory endophenotypes (Carlson et al., 2011).

These endophenotypic studies were further extended in a recent MRI analysis that found the structural volume deficits in cortical regions, subiculum and dentate gyrus, and the striatum were found in mutant mice (Lutkenhoff et al., 2012).

The molecular and neuronal abnormalities in sandy mice may underlie the behavioral phenotypes, including deficits in social interaction, long-term memory, novel object recognition, and working memory (Feng et al., 2008; Jentsch et al., 2009). Moreover, the most recent reports have described interaction of dysbindin with another candidate gene, Disrupted-in-Schizophrenia-1 (*DISC1*), suggesting overlapping intracellular signaling pathways for these two important proteins (Camargo et al., 2007; Ottis et al., 2011).

NEUREGULIN 1

Neuregulin 1 (*NRG1*) and its receptors, *ErbB2* and *ErbB4*, appeared in linkage studies (Stefansson et al., 2002), though again, not yet in genome-wide association studies. Thus, while there has been a large amount of interesting neurobiology brought forward to date, it is not yet clear how relevant it will be to human disease.

Neuregulin-1, also known as heregulin, acetylcholine receptor inducing activity (ARIA), glial growth factor (GGF), or sensory and motor neuron derived factor (SMDF), is encoded by the *NRG1* gene located on chromosome 8p13 (Law et al., 2006). Chromosome 8p, mainly the region around 8p21.1–22, has been implicated as a locus harboring one or more susceptibility genes by several linkage studies (Goes FS et al., 2008). Association of this gene with schizophrenia has been replicated, although some contradictions exist (Chen et al., 2006; Harrison and Law, 2006). The SNPs associated with schizophrenia were positioned either before exon 1 or in the introns, and no functional mutations have been identified (Gogos et al., 1999; Mei and Xiong, 2008). Polymorphisms in the intronic regions of this gene are associated with variation in cognitive functions in healthy individuals (Silberberg, 2006; Roussos et al., 2012) and may alter *NRG1* expression. Both upregulation and downregulation in expression of mRNA or protein in postmortem brain samples have been reported (Hashimoto et al., 2004; Law et al., 2006; Chong et al., 2008).

NRG1 has been implicated in neuronal migration, synaptogenesis, gliogenesis, neuron-glia interplay, myelin formation, and synaptic neurotransmission (Harrison, 2006). Recently, one of the *NRG1* isoforms has been found to be predominantly expressed prenatally, suggesting a role in neurodevelopment (Tan, 2007). Alternative splicing of *NRG1* results in at least 15 isoforms that all contain an extracellular epidermal growth factor (EGF)-like domain, which is sufficient for *NRG1* biological activity, and the transmembrane (TM) domain that is common to most *NRG1* isoforms (Mei, 2008). Deletion of *Nrg1* and its receptor, *ErbB4*, are lethal, and mice die before birth (Meyer and Birchmeier, 1995). Thus, most studies have been performed using either heterozygous mice or *Nrg1* hypomorphic mice that have mutations in the different domains of the gene.

Meyer and Birchmeier generated mice with targeted deletion of the EGF-like domain (*NRG1*-EGF+/-) by fusing exon 6 of the neuregulin gene to β -galactosidase, which results in

partial deletion of the EGF-like domain of all three major types of Nrg1 (Meyer and Birchmeier, 1995). These mice exhibited elevated activity in open field, improved rotorod performance, and a better performance in T-maze spontaneous alternation task that may be explained by hyperactivity (Gerlai et al., 2000) that can be partially reversed with clozapine (Stefansson et al., 2002). Nrg1 mutant mice also exhibit improved habituation to a new environment, and impairment in PPI after pharmacological challenge with psychostimulants (Duffy et al., 2008).

An NRG-1 KO mouse model that lacks the transmembrane domain was also generated. Heterozygous (HET) mice have no gross alterations in the appearance but display increased activity and deficient PPI reversible by clozapine (Karl, 2007). Mice have no abnormalities in spatial learning but are aggressive (O'Tuathaigh et al., 2007). Compared to wild-type mice, *Nrg1*^{+/-} mice display increased locomotor activity at 12–16 weeks of age, but not at 6 months. John Waddington and his associates evaluated *Nrg1* “knockouts” for four topographies of orofacial movement, both spontaneously and under challenge with the D(1)-like dopamine receptor agonist, SKF 83959. They report that mutants exhibit increased spontaneous and induced incisor chattering, vertical jaw movements, and tongue protrusions. The level of horizontal jaw movements was elevated, while that of tongue protrusions was decreased in mutants, suggesting that Nrg1 may be involved in the regulation of orofacial dyskinesia (Tomiya, 2012). Deletion of Nrg1 also leads to reduced thermal pain but does not alter the antinociceptive effects of tetrahydrocannabinol (THC) (Walsh, 2010). Another behavioral pharmacology study assessed the effects of MK-801 and phencyclidine (PCP) in these mice. Nrg1 male mutants display attenuated responses to the effects of acute PCP, while subchronic treatment with MK-801 and PCP comparably affect social behaviors in WT and KO mice. The total ventricular and olfactory bulb volumes were found decreased in mutants, but there were no group differences in levels of *N*-acetylaspartate, glutamate, or GABA (O'Tuathaigh et al., 2010).

The behavior of mice heterozygous for a mutation in neuregulin-1's immunoglobulin (Ig)-like domain (Ig-Nrg-1 mice) was also assessed. These mutants demonstrate clozapine suppression of open-field and running wheel activity and impaired latent inhibition. Unlike other Nrg-1 mutants, Ig-Nrg-1 mice are not hyperactive, suggesting a distinct contribution of this domain to behavioral phenotypes (Rimer et al., 2005). The relatively mild phenotypes of *Nrg1* HET mutants might be a result of functional compensation by Nrg2 and/or Nrg3.

A loss-of-function mouse model for type III Nrg1 was also generated. Type III NRG1 is transcribed by a different promoter and is expressed in mPFC, ventral hippocampus, and ventral subiculum. Adult type III Nrg1 HET mice have enlarged lateral ventricles and decreased dendritic spine density on pyramidal neurons. These brain abnormalities were associated with impaired spatial alternation and PPI rescued by chronic nicotine treatment. This model demonstrates a role of type III Nrg1 signaling in the neural circuits involved in sensorimotor gating and short-term memory (Chen et al., 2008).

Several studies evaluated the effects of increased Nrg1 expression using transgenic approaches. Overexpressing Nrg1 in all tissues increased locomotor activity, decreased fear conditioning,

and abnormal social behaviors (Kato et al., 2010). Transgenic Nrg1 mice were found to have more parvalbumin-positive neurons and elevated levels of myelination markers in PFC (Kato et al., 2010).

NRG1 acts by stimulating a family of single-transmembrane receptor tyrosine kinases called ErbB proteins (Mei and Xiong, 2008). ErbB proteins have homology with the EGF receptor (EGFR, also known as ErbB1). ErbB4 is the only autonomous NRG1-specific ErbB that can both interact with the ligand and become activated by it as a tyrosine kinase. NRG1 signaling is mediated by heterodimers of ErbB2–ErbB3, ErbB2–ErbB4 and ErbB3–ErbB4 and by the homodimer ErbB4–ErbB4. Consistently, ErbB2 and ErbB3 mutant mice, whose strain origin was identical to that of heregulin mutants, showed no sign of the behavioral alterations (Gerlai et al., 2000). In contrast, *ErbB4* heterozygous mice are hyperactive (Stefansson et al., 2002).

In order to study the role for the Nrg1 receptor in progenitor cells, a conditional KO model was generated using mice that express Cre under the nestin promoter. KO mice survived into adulthood and showed no behavioral deficits in locomotion. KO mice also display reduced grip strength compared to WT mice, while HET mice showed an intermediate phenotype. However, HET KO showed abnormalities in Morris water maze learning and memory task relative to WT (Golub et al., 2004).

Selective deletion of *ErbB4* in PV-positive neurons prevented NRG1 from promoting activity-dependent GABA release to inhibit the activity of pyramidal neurons. These mutant mice showed hyperactivity, impaired contextual and working memory, and disrupted PPI. Some of these phenotypes were ameliorated by acute treatment with a low dose of diazepam, consistent with impaired GABA neurotransmission. These results indicate that NRG1 regulates the activity of pyramidal neurons by promoting GABA release from PV-positive interneurons, identifying a critical function of NRG1 in balancing brain activity (Wen et al., 2010).

DISRUPTED-IN-SCHIZOPHRENIA-1 (DISC1)

The Disrupted-in-Schizophrenia-1 (DISC1) gene was discovered in a large Scottish family in which a balanced chromosomal translocation [t(1;11)] segregates with schizophrenia, bipolar disease, major depression, and anxiety disorders (St Clair et al., 1990). The translocation t(1;11) (q42;q14) disrupts two genes named *Disrupted in Schizophrenia 1* and 2 (*DISC1* and *DISC2*). In contrast to *DISC1*, the function of *DISC2* that encodes a non-coding RNA antisense to *DISC1* is unclear. The existence of a clear, identifiable mutation has put *DISC1* in a unique position in schizophrenia research (Chubb et al., 2008; Millar et al., 2001).

DISC1 is located within a chromosomal region that has been reported to harbor susceptibility genes for psychiatric illness in several populations (Ekelund et al., 2001; Hennah, 2005; Hennah et al., 2009). Several studies have also reported that healthy subjects and patients with schizophrenia carrying *DISC1* variants have alterations in gray matter volume of the hippocampus and PFC (Callicott et al., 2005; Cannon et al., 2005), deficient memory and attention (Cannon et al., 2005; Hennah, 2005), and hippocampal or PFC activation (Callicott et al., 2005). Still, there are also negative reports for linkage to

the *DISC1* locus), SNP associations (Lim, 2009; Sanders, 2008; Wood, 2007), and the rearrangements within the *DISC1* locus. Furthermore there is little support for the *DISC1* locus in large association studies to date.

DISC1 protein likely acts as a scaffold protein, with multiple motifs mediating binding to several proteins (Camargo, 2007). *DISC1* is expressed in adult rat heart, liver, kidney, brain, and thymus. Brain expression of *DISC1* encompasses the hippocampal dentate gyrus, cerebral cortex, hypothalamus, amygdala, cerebellum, and olfactory bulbs (as reviewed in Chubb et al., 2008; Mackie et al., 2007).

RNAi knockdown of *Disc1* in the embryonic cortex affects migration, produces mispositioning of neurons (Kamiya et al., 2005), decreases proliferation, and alters neuronal distribution in the developing cortex and adult hippocampus (Mao et al., 2009). In contrast, *Disc1* knockdown in proliferating neurons in the mature dentate gyrus enhances migration, growth of dendrites and axons, and maturation of granule neurons. In addition, transient knockdown of *DISC1* in the pre- and perinatal stages in pyramidal neurons of PFC leads to altered dopaminergic maturation and resultant behavioral abnormalities in adult mice (Niwa et al., 2010).

DISC1 mouse models have been instrumental in uncovering the mechanisms whereby this protein and its partners contribute to neurodevelopment with relevance to the pathogenesis of schizophrenia.

Risk Allele Model

Drs. Gogos and Karayiorgou have developed a *Disc1* mouse model based on the 129 mouse strain, in which a spontaneous 25-bp deletion in exon 6 induces a frame shift in the open reading frame, resulting in 13 novel amino acids, followed by a premature stop codon in exon 7. This strain was modified by homologous recombination to have a termination codon in exon 8 and a premature polyadenylation site in intron 8 to produce a truncated transcript (Koike et al., 2006). Western blot analysis of brain extracts from mutant mice demonstrated the absence of two major *Disc1* isoforms and the expression of short N-terminal isoforms (Koike et al., 2006). After backcrossing to the C57B6/j background, these mice show impaired working memory and no alterations in locomotion or PPI. Subsequent studies have found that mutants have disorganized newly born and mature neurons of the dentate gyrus and altered short-term plasticity. Recently, defects in axonal targeting and changes in short-term (Kvajo et al., 2008) plasticity at the mossy fiber/CA3 circuit have been presented for this mouse model as well as elevated levels of cAMP (Kvajo et al., 2011). Thus a natural polymorphism in *Disc1* gene may be responsible for the neural and behavioral abnormalities reminiscent of schizophrenia.

Disc1 KO Mice

Generation of *Disc1* knockout mice, lacking exons 2 and 3, has been recently reported (Kuroda et al., 2011). Mutant mice have no gross brain or behavior abnormalities but exhibit elevated anxiety and impulsivity (Kuroda et al., 2011). As expression of short transcripts in these KO mice is still observed, a mouse model with deletion of the entire genetic locus is needed to better decipher the function of *DISC1*.

ENU-Induced Model

Two mouse models based on mutations in the mouse *Disc1* gene as a result of *N*-nitroso-*N*-ethylurea (ENU) mutagenesis were also described (Clapcote et al., 2007). Two novel missense mutations lead to Q31L and L100P amino acid exchanges in the exon 2, respectively. Notably, these mouse models are characterized by distinct phenotypes. 31L mice display increased immobility in forced swim test (FST), decreased sociability and social novelty, and decreased sucrose consumption, L100P mutants demonstrate increased locomotor activity, decreased PPI, decreased LI, and decreased performance in T-maze were found in L100P mutant mice. These models demonstrate that polymorphisms in *Disc1* gene can produce variable behavioral alterations, consistent with distinct aspects of psychiatric disorders. Unfortunately, further study of some of the *DISC1* models has not clearly substantiated some of the initially reported behavioral phenotypes (Shoji et al., 2012).

An analysis of the brain abnormalities in *Disc1* mutants found a reduced neuronal number, decreased neurogenesis, and altered neuronal distribution and shorter dendrites and decreased surface area and spine density in cortical neurons of *Disc1* L100P mutant mice (Lee et al., 2011). Genetic variations in *DISC1* can influence interaction between PDE4, GSK-3, and *DISC1* (Lipina et al., 2012).

The chromosomal translocation affects the C-terminal of the three major isoforms (Millar et al., 2001). Possible outcomes of the translocation in the *DISC1* gene include haploinsufficiency or the production of a mutant truncated *DISC1* protein. Expression of truncated human *DISC1* in neuronal PC12 rat cells or mouse brain affects interacting partners via dominant-negative mechanisms, leading to altered levels and distribution of endogenous *Disc1* (Kamiya et al., 2005; Pletnikov et al., 2008). In this context, studying effects of mutant *DISC1* on neurodevelopment can provide valuable mechanistic insights into the pathogenesis of schizophrenia.

Constitutive Overexpression of Mutant *DISC1*

A transgenic mouse model with constitutive expression of mutant human *DISC1* was developed (Hikida et al., 2007). Transgenic mice express mutant human *DISC1* under regulation of the *CAMKII* promoter in forebrain neurons and exhibit elevated novelty-induced activity, impaired PPI, and more immobility in FST. Mutant mice also have decreased numbers of PV-positive neurons in the cortex and a transient enlargement of the lateral ventricles, demonstrating that forebrain neuronal expression of mutant human *DISC1* can produce subtle neurobehavioral alterations resembling aspects of major psychiatric diseases (Hikida et al., 2007).

A *BAC-transgenic mouse model* with expression of C-terminus truncated mouse *Disc1* under the endogenous *Disc1* promoter was also described (Shen et al., 2008). These mice have thinning of the cortex, enlarged lateral ventricles, corpus callosum agenesis, impaired LI, and greater immobility in FST.

Inducible C-Fragment *DISC1* Model

Silva and Cannon's groups have introduced a *DISC1* model in which the putative "translocated" C-terminus fragment

of DISC1 is expressed under regulation of the CAMKII promoter in forebrain neurons in an inducible manner (Li et al., 2007). Remarkably, early postnatal but not adult expression of the fragment produces impaired performance in a DNMP task, attenuated social interaction, and a shorter latency to immobilization in FST. These behavioral changes were accompanied by reduced dendritic complexity and decreased basal synaptic transmission in the hippocampus. This inducible model was the first to demonstrate that early postnatal perturbation in *Disc1* can lead to neurobehavioral changes, consistent with the neurodevelopmental hypothesis of schizophrenia.

Inducible Mutant Human DISC1 Model

A different mouse model of inducible expression of mutant human DISC1 in forebrain neurons was generated using the Tet-off system (Pletnikov et al., 2008). In this model, expression of mutant DISC1 is regulated by the CAMKII promoter and can be regulated with doxycycline. Expression of mutant DISC1 was described to produce no gross developmental defects but was associated with increased spontaneous locomotor activity in male but not female mice, decreased social interaction in male mice, enhanced aggressive behavior and poorer memory in Morris water maze task in female mice. In addition, expression of mutant DISC1 led to lateral ventricle enlargement in adult mice and reduced dendritic arborization in primary cortical neurons and decreased expression of a synaptic protein, SNAP-25, consistent with human post-mortem studies that show decreased dendritic length and dendritic arborization in frontal cortical areas (Harrison, 1999).

To evaluate the roles of DISC1 at various stages of neurodevelopment, the effects of mutant DISC1 were examined during prenatal and/or postnatal periods. Regardless of timing of expression, decreased levels of cortical dopamine (DA) and fewer parvalbumin-positive neurons in the cortex were found in mutant mice. Combined prenatal and postnatal expression produced increased aggression and enhanced response to psychostimulants in male mice along with increased linear density of dendritic spines on neurons of the dentate gyrus of the hippocampus, and lower levels of endogenous DISC1 and LIS1. Selective prenatal expression was associated with smaller brain volume, whereas postnatal expression gave rise to decreased social behavior in male mice and depression-like responses in female mice as well as enlarged lateral ventricles and decreased DA content in the hippocampus of female mice, and decreased level of endogenous DISC1. Mutant DISC1 affects methamphetamine-induced sensitization and conditioned place preference: a comorbidity model (Pogorelov et al., 2012). The diverse changes in mutant DISC1 mice are reminiscent of findings in major mental diseases.

DISC1 models may be as relevant to bipolar disorder and psychotic depression as to schizophrenia.

MOUSE MODELS OF BIPOLAR DISORDER

The human genetics of bipolar disorder is perhaps less well established compared to that of schizophrenia. However, a

number of genes have emerged from GWAS studies (Wellcome Trust Case Control Consortium, 2007; Sklar et al., 2008; Craddock and Sklar, 2009; Lichtenstein et al., 2009; Schulze et al., 2009; Green et al., 2010; Curtis et al., 2011; Psychiatric GWAS Consortium Bipolar Disorder Working Group 2011; Sullivan et al 2012), and the hope is that as the power of these studies increases, additional candidate genes will be forthcoming. Furthermore, the increasing sophistication of genetic analyses is making it possible to suggest possible pathways (Pandey et al., 2012), including Wnt signaling circadian rhythm pathways, cadherin signaling pathway, axonal guidance, and neuroactive ligand-receptor interactions.

One of the notable themes emerging from current psychiatric genetics is the overlap between schizophrenia and bipolar disorder as well as the overlap between schizophrenia and autism. We hypothesize that risk for schizophrenia is more related to neurodevelopmental brain changes, whereas risk for bipolar disorder may be more related to neuronal signaling and plasticity.

CACNA1C

Voltage-gated calcium channels have emerged from these studies as strong genetic candidates, with overlap for both schizophrenic and bipolar disorder. There is extensive knowledge of the biology of voltage-gated calcium channels, which will not be repeated in detail here. They are critical for neuronal-membrane-excitability regulated entry of calcium into cells, and are involved in regulation of many signaling pathways and activity related to gene transcription (Bhat et al., 2012). Intriguingly inhibitors of voltage-gated calcium channels have been used in treating bipolar disorder with some mixed success.

Mouse model studies related to voltage-gated calcium channels are just beginning to address issues of behavior related to psychiatric disorders. For instance, voltage-gated calcium channel CACNA1C haploinsufficiency was associated with decreased exploratory behavior, diminished response to amphetamine, and altered behavior in the forced swim and tail suspension tests with sex-specific differences (Dao et al., 2010). These studies though raise the issue of what mouse model is likely to be most appropriate given the human genetics. There is some genetic evidence that the genetic variation at the L-type calcium channel may be a partial gain of function. Thus, mouse models of the disorder may be most appropriately established using transgenic overexpression or other comparable genetic modifications.

ANKYRIN-G

Another very intriguing genetic association in bipolar disorder is with the ANK3 locus, which codes for the ankyrin-G protein. This was found to be the strongest risk factor in one of the initial GWAS studies or is replicated more modestly or variably in subsequent GWAS studies, but has more recently emerged again as a leading candidate gene in population studies.

Ankyrin-G is an especially intriguing candidate as it has well-established roles in maintenance of the structure of the axon initial segment, and in maintenance of axodendritic polarity *in vivo* (Pan et al., 2006; Roussos et al., 2012; Sobotzik et al., 2009;

Zhou et al., 1998). Ankyrin-G maintains voltage-gated sodium channels and potassium channels at the axon initial segment, and thus is critical for generation and regulation of the axon potential. It is also critical for axon potential transmission, since it is located at nodes of Ranvier as well. Intriguingly ankyrin-G also appears to be relevant for functional localization of dystrophin complexes (Ayalon et al., 2008), potentially suggesting the relationship between these two risk genes.

The genetic organization of the ankyrin gene locus is complex (Rueckert et al., 2012). Most of the bipolar disorder genetic variation at the ANK3 locus is in the promoter region, suggesting alterations of expression, though it is possible there are also alterations in splicing given the complex splice and promoter usage variation. Thus, for this gene again it is unclear what genetic manipulation may be most relevant to the human disorder; however, partial loss of function would appear to be a good candidate. There has been one knockout mouse model generated in which one of the isoforms has been deleted (Pan et al., 2006; Zhou et al., 1998). This isoform is highly expressed in cerebellum, so the animals have a significant degree of ataxia, making other behavioral tests difficult to interpret. Recent data suggest that these animals may have cognitive and emotional changes as well as motor changes. In addition, they have intriguing alterations in cerebellar circuitry. The loss of ankyrin-G expression in Purkinje cells leads to a redistribution of synaptic input onto Purkinje cells, presumably with profound alterations for neuronal connectivity in signaling. In addition, an ankyrin mouse model with knockout of most isoforms expressed in brain has recently been generated. A conditional knockout enables the deletion of ankyrin-G in the forebrain. Preliminary data suggest that this model may have hyperactivity and alterations in cognitive and emotional behavior consistent with some aspects of human psychiatric disorder.

NEUROCAN

Several studies have found strong associations between the Neurocan (NCAN) gene and bipolar disorder (e.g., Cichon et al., 2011). Neurocan is a component of the extracellular matrix in brain and CNS, expressed at highest levels around birth in the mouse, and may be involved with regulation of synaptic connectivity and plasticity.

A recent study (Miro et al., 2012) combined clinical analyses and mouse behavioral studies. Genotype/phenotype correlations were tested in patients with bipolar disorder, depression, and schizophrenia. Instead of using DSM4 diagnoses, the clinical features were factor-analyzed. In the combined patient sample, the NCAN risk allele was significantly associated with the “mania” factor, in particular “overactivity.” A mouse with genetic deletion of neurocan was available (Zhou et al., 2001), and had no gross developmental abnormalities, though altered synaptic transmission and plasticity had been observed. Behavior of the NCAN KO mice was then studied in more detail (Miro et al., 2012). The NCAN KO mice were hyperactive and showed more frequent “risk-taking” behaviors, less “depression-like” conduct, greater amphetamine hypersensitivity, and increased saccharin

preference. These behavioral changes were ameliorated by lithium treatment.

DIACYLGLYCEROL KINASE

A locus that has recently been identified in relation to bipolar disorder is the diacylglycerol kinase DGK locus. Behavioral tests using DGK beta knockout mice showed hyperactivity reduced anxiety and reduced “depression”-like behaviors. These behaviors were attenuated by the administration of lithium. These mice also showed impairment in GSK3 beta signaling (Kakefuda et al., 2010). Taken together these data suggest that DGK beta knockout mice have some behavioral abnormalities that could be relevant to human psychiatric disorders, and these mice merit further study.

ODZ4

Recent GWAS studies have identified the ODZ4 or teneurin-4. Relatively little attention has been paid to this gene to date. A mouse mutation designated *furue* has some behavioral changes and substantial alterations in myelination of small diameter axons and differentiation of oligodendrocytes. Given that white matter changes have been detected in human psychiatric disorders, this model may also merit further study.

OTHER GENES AND PATHWAYS

There is some support for the role of circadian-rhythm-related genes in risk for affective disorder, though perhaps more for depression than bipolar disorder (Kennaway, 2010), and of course sleep and circadian rhythm disturbances are notable in human affective disorder. Several different mouse models of alterations of clock genes have been reported with changes in anxiety, exploratory behavior, activity, and cognitive behavior as well as alterations in circadian periodicity (Arey and McClung, 2012; Keers et al., 2012; Kozikoski et al., 2011; McClung, 2011). Pharmacologic data and some studies of gamma oscillations suggest possible translation to human psychiatric disorder (Dzirasa et al., 2011).

The beta-catenin pathway has recently emerged in genetic studies and also has pharmacologic data to support it. Interestingly, overexpression of beta catenin results in behavioral changes including alterations in the forced swim test and alterations in drug response (Gould et al., 2007).

Other studies have modeled pathways that may be relevant to psychiatric disorders such as the GSK3 beta pathway (Ackermann et al., 2010). Polymorphisms in DISC1 have also been reported to disrupt Wnt and GSK3 beta signaling (Singh et al., 2011).

It has been claimed that a mouse strain termed “Madison” shows behavioral changes reminiscent of mania. Gene expression array changes and drug responses may also be comparable to the human disorder; however, it is unclear if there is any genetic convergence with human genetic risk factors (Saul et al., 2012; Scotti et al., 2011).

As noted above, numerous studies have implicated glutamate signaling, and some studies have suggested that glutamate receptors are relevant for bipolar disorder (Knight et al., 2011). A number of studies of glutamate receptor mouse models have been generated. A detailed consideration of these

studies is beyond the scope of this current chapter, since the genetic correlation is not clear. There is an extensive literature on dopamine transporter knockout mice. These have dramatic hyperactivity and other behavioral changes reminiscent of affective disorder. However, the relationship to the human genetics is still unclear.

FUTURE DEVELOPMENTS

Psychiatric genetics is still in its infancy, with replicable risk loci just beginning to be identified. Functional genomics studies, including better mouse models, will have greater opportunities when mutations with clear effects on gene transcription, splicing, translation, and regulation are identified. Even the knowledge of whether genetic variation leads broadly to loss or gain of function will be helpful, though either can lead to failure of neuronal homeostasis (Ramocki and Zoghbi, 2008). Although the current models have advanced our understanding of the neurobiology of schizophrenia and bipolar disorder, there are still many issues that need to be addressed in the future research.

The methodologies to manipulate the mouse genome at different levels of its organization are constantly improving (see Chapter 8). Simple knockout and transgenic technologies produce artificial systems with the deletion of one or both copies of a gene, or with its overexpression. New models with

point mutations in coding sequence or mutations in regulatory elements will better reflect the complex molecular processes implicated in schizophrenia or bipolar disorder (Chen, 2006). The use of zinc finger nucleases and transcription activator-like effector nucleases to manipulate the genome (Cheng et al., 2012) may provide additional options. Inducible and conditional systems allow the alteration to be expressed in a time-dependent and specially controlled fashion.

A drawback of current mouse models is related to the fact that schizophrenia and bipolar disorder are polygenic diseases, and current techniques alter the genome one gene at a time. Combining multiple genetic mutations in a single model could be more informative. Attempts to model neuropsychiatric disorders based on gene expression changes (Lin et al., 2012) may be very difficult to interpret, but targeting several susceptibility genes that belong to different signaling pathways may be a promising direction. Once single gene models are well characterized, it may be possible to perform genetic crosses or other attempts to model polygenic inheritance.

Alternatively it may be possible to make single manipulations at key regulatory positions with pleomorphic effects.

An important aspect of the complex etiology of schizophrenia and bipolar disorder is a contribution of environmental factors (Brown, 2010; van Os et al., 2008). Combining both genetic and environmental risk factors by exposing genetically altered mice to adverse environments at different times across

TABLE 22.1. Behavioral tests used in animal models of schizophrenia (adapted from Nestler and Hyman 2010, used with permission)

TEST	MEASURES	STRENGTHS	WEAKNESSES
Stimulant-induced hyperactivity	Locomotion and stereotypy	Translational potential as can be observed in humans Quantifiable and objectively assessed Easily performed	Acute challenges with drugs do not reflect the pathogenesis Use for testing antipsychotics is based on circularity
Habituation and prepulse inhibition (PPI) of the acoustic startle Latent inhibition	Sensorimotor gating Attention, impulsivity	Translational potential as can be observed in humans Quantifiable and objectively assessed	Weak specificity as PPI and latent inhibition impairment can be observed in several neurological and psychiatric conditions
Social interaction tests relevant to schizophrenia – 3-chamber test – Male-male dyadic interaction in open field – Intruder-resident test – Social approach-avoidance – Social play	Non-aggressive and aggressive species-specific social behaviors, including following, sniffing, crawl-over and crawl-under; attacking, biting, tail-rattling, play activity in juveniles	Easily performed	Face validity is unclear The brain mechanisms may be species-specific (olfaction in mice vs. vision and language in humans) Difficult to automate Not specific to schizophrenia
Progressive ratio schedule procedures to evaluate motivation (avolition?)	Operant tasks to assess relationship between increase in reward and response demands	Translational potential as can be observed in humans Quantifiable and objectively assessed	Not specific to schizophrenia Levels of motivation can vary across animals, while perseveration in response may reflect enhanced impulsivity Require substantial expertise
Cognitive paradigms	Various measures of attention, different types of learning and memory	Several validated tests Can be measured objectively Strong translational potential	Time consuming Easily influenced by environmental conditions Requires substantial behavioral expertise

TABLE 22.2. Behavioral tests used in animal models of mood disorders (Adapted from Nestler and Hyman 2010, used with permission)

TEST	MEASURES	STRENGTHS	WEAKNESSES
Behavioral “despair” – Forced swim – Tail suspension – Learned helplessness	Antidepressant effects	Easily performed	Unclear relation to depressive states Sensitive to a limited set of antidepressants
Anhedonia – Sucrose preference – Sexual behavior	Preference for positive (i.e., pleasurable) stimuli	Face validity Can be objectively measured Do not require sophisticated equipment	Not specific to mood disorders Time consuming
Novelty-suppressed feeding	Latency to feeding and time of food consumption in open field	Easily performed Objective assessment Sensitivity to chronic antidepressant administration	Can be associated with anxiety rather than depression
Social defeat paradigm	Long-term inhibition of social interaction	Objective assessment Sensitivity to chronic antidepressant administration	Can be associated with anxiety as well Time consuming
Maternal deprivation	Stress calls by pups (ultrasonic vocalization)	Objective assessment Easily performed	Not specific to mood disorders Easily influenced changes in test conditions
Elevated plus maze	Risk-taking behavior measures such as forward stretches, head down turns	Easily performed	Require some experience to detect these behaviors Also associated with anxiety
Sleep deprivation-induced behavioral changes	Home cage activity Weight monitoring Eating and drinking monitoring	Easily performed Objective	Require home cage activity monitoring equipment Time consuming Difficult to control the individual effects of deprivation

the life span of the mouse could better reflect the complexity of the pathogenesis of these diseases. Although still in infancy, the initial gene-environment interaction studies have already revealed some issues important for future research. For example, combining an environmental challenge with a genetic mutation in the susceptibility gene can produce both protective and pathogenic effects, depending on the type of adverse environment and the time of interaction. Combinations of genetic and environmental factors can also result in new phenotypes previously unseen in unchallenged mutant mice or wild-type mice exposed the environmental insult (Abazyan et al., 2010; Behan et al., 2012; O’Tuathaigh et al., 2010). Given that simple laboratory environmental changes could be responsible for appreciable variations in the mouse behavior (Crabbe et al., 1999), one needs to be extremely cautious in interpretations of the changes produced in genetic mouse models due to environmental factors.

Behavior readouts have limitations (see Tables 22.1 and 22.2 and Box 22.1). Many of the behavioral tests currently in use were developed for pharmacological studies. As new genetic and environmental models are developed, there should be an iterative process of developing and refining behavioral tests. Brain imaging, electrophysiology, or other endophenotypes are likely to provide additional information, which may be more translatable to the human diseases.

Most studies to date have focused on neuronal functions of susceptibility genes. However, many of the candidate genes are

also expressed by glial cells (Iijima et al., 2009). Manipulation of expression in non-neuronal cells may be important. For example, a recent study has provided the first evidence for interaction between DISC1 and serine racemase in astrocytes, connecting DISC1 and D-serine/NMDA receptor hypofunction (Ma, 2012).

Thus, genetic mouse models will continue to be important tools for psychiatric research. They have been illuminating the functions of candidate genes in neurodevelopment and are stimulating a search for future pathogenic treatments. The approach of using factor analysis of human clinical phenotypic features, association with genetic risk loci, and then in turn correlating with phenotypes of mice with alterations at the same loci (e.g., Miro et al., 2012) is intriguing. More sophisticated and advanced genetic manipulations in combination with better understanding of the human clinical phenotypes will be needed to refine the present models to make them more relevant to human psychiatric diseases.

DISCLOSURES

Dr. Pletnikov has no conflicts of interest to disclose. He is funded by NIH only. Grant Support: NIH (P50MH084018 and 5R01MH083728-04).

Dr. Ross has no conflicts of interest to disclose.

We propose the following considerations for future animal models of schizophrenia and bipolar disorder:

CONSTRUCT VALIDITY

- Construct validity based on human genetic studies
 - Manipulation at a locus identified in human population genetic (e.g., GWAS or sequencing) studies
 - Manipulation using a specific causative point or deletion mutation
 - Copy number variation models
- Construct validity based on human environmental studies
 - Human environmental stressors such as prenatal immune activation
- Construct validity based on interaction of genetic and environmental factors

FACE VALIDITY

- Behavioral features
 - For schizophrenia
 - Behavioral and social changes (social withdrawal, anhedonia)
 - Cognitive deficits (working memory)
 - For affective disorder
 - Mania-like alterations, such as hyperactivity and hypersexuality, risk-taking behavior, and impulsivity
 - Depression-like behaviors
 - Altered circadian rhythms, sleep disorders
- Endophenotypes
 - Structural brain change including lateral ventricle enlargement
 - Functional and chemical brain changes (e.g., fMRI, micro-PET, MRS)
 - Electrophysiological changes such as reduced N100, mismatch negativity (MMN), changed theta and gamma oscillation
 - Histological changes such as
 - Interneuron and synaptic pathology
 - Abnormal neurogenesis
 - Molecular and cell signaling changes

PHARMACOLOGICAL VALIDITY FOR EXISTING MEDICATIONS

- Antipsychotics for schizophrenia models
- Lithium and valproate for bipolar models
- Antidepressant for depression models

PREDICTION OF NEW FEATURES THAT ARE SUBSEQUENTLY VALIDATED IN HUMAN

- Novel endophenotypes
- Novel neuropathology
- Novel pharmacological targets

23 | CORTICAL GABA NEURONS IN SCHIZOPHRENIA

ALLISON A. CURLEY AND DAVID A. LEWIS

Cognitive impairments are a core feature of schizophrenia and the best predictor of functional outcome; however, current pharmacotherapies offer only limited cognitive improvement. Therefore, knowledge of the abnormalities in brain circuitry that give rise to the cognitive abnormalities is critical for developing new treatments. Higher order cognitive processes, such as working memory, the ability to transiently retain and manipulate a limited amount of information in order to guide thought or behavior, are strongly associated with neural network oscillations, the synchronized firing of large assemblies of cells, that are dependent on signaling via the inhibitory neurotransmitter γ -aminobutyric acid (GABA) (Bartos and Elgueta, 2012). The cells that synthesize and release GABA, appropriately termed GABA neurons (or interneurons), exhibit a variety of abnormalities in schizophrenia. Thus, alterations in GABA neurons are thought to, at least in part, underlie the cognitive deficits of schizophrenia. Consequently, in this chapter we provide: (1) an introduction to interneurons and their role in cognition, (2) a description of the GABAergic alterations found in schizophrenia, (3) a review of potential mechanisms underlying these alterations, and (4) a discussion of the consequences of impaired GABA signaling. The prefrontal cortex (PFC) is a brain area especially critical for cognition, and where interneurons have been most extensively studied in schizophrenia, and thus we concentrate on this region here.

INTRODUCTION TO INTERNEURONS

SUBTYPES OF GABA NEURONS

Excitatory pyramidal cells comprise 75–80% of the neurons in the primate neocortex, and the remaining 20–25% are GABA neurons. In contrast to pyramidal cells that mainly send their axons over long distances, interneurons primarily project locally. GABA neurons in the cerebral cortex can be divided into different subclasses based on their electrophysiological, molecular, and anatomical properties (Ascoli et al., 2008) (Fig. 23.1). Electrophysiologically, interneurons are classified as fast-spiking (FS) or non-fast-spiking (non-FS), based on their firing patterns in response to depolarization above spiking threshold. FS cells exhibit a nearly constant interval between spikes. In contrast, non-FS cells typically show an adapting firing pattern, such that the interspike interval increases with stimulus duration. Interneuron subpopulations can also be distinguished by the molecular markers they express. With a few exceptions, the calcium binding proteins parvalbumin (PV),

calbindin (CB), and calretinin (CR) are found in distinct cell types. FS cells contain PV (hereafter referred to as PV neurons), do not contain any neuropeptides, and give rise to axons that target the perisomatic region, the cell body and proximal dendrites, of pyramidal cells. PV neurons comprise ~25% GABA neurons in the primate PFC (but a much larger proportion of GABA neurons in rodent cortex), and PV-positive cell bodies and axon terminals are present in the highest density in layers deep 3–4. PV cells are divided into two main classes: (1) basket (PV_b) cells, whose axons target the soma, proximal dendrites, and spines of pyramidal cells, and (2) chandelier (PV_{ch}) cells, whose axon terminals form distinctive vertical arrays termed cartridges that exclusively target the axon initial segment (AIS) of pyramidal cells.

Non-FS cells are more heterogeneous and include a number of distinct subpopulations (Fig. 23.1). One subpopulation contains the neuropeptide cholecystokinin (CCK). A subset of these cells also contains CR, and a separate subset expresses the cannabinoid 1 receptor (CB1R). The latter are known as CCK basket (CCK_b) cells. All CCK_b cells target the perisomatic region of pyramidal cells, and in the primate neocortex, CCK-immunoreactive cell bodies are principally localized to layers 2–superficial 3, and their axon terminals are present mainly in layers 2, 4, and 6. A second subtype of non-FS cells expresses CB and the neuropeptide somatostatin (SST), and furnishes axons that synapse onto the distal dendrites of pyramidal cells. SST cells are present in all layers of the cortex, as well as the underlying white matter. A third subtype contains CR, is found primarily in layers 1 and 2, and provides axon terminals that mainly innervate pyramidal neuron dendrites and other interneurons.

GABA SYNTHESIS

GABA is synthesized by the 67 kiloDalton and 65 kiloDalton isoforms of glutamic acid decarboxylase (GAD67 and GAD65, respectively) which decarboxylate glutamate to produce GABA (Fig. 23.2). GAD65 and GAD67 are encoded by separate genes (GAD1 and GAD2, respectively) on different chromosomes, and undergo different posttranslational modifications (Akbarian and Huang, 2006). Many, but not all, GABA neurons appear to contain both isoforms. GAD67 is distributed throughout the neuron, whereas GAD65 is primarily located in axon terminals. The activity of both enzymes is regulated by their cofactor pyridoxal 5'-phosphate, which activates or inactivates the enzyme when it is bound and released, respectively. GAD67 is saturated with cofactor and therefore largely exists in the active form, while

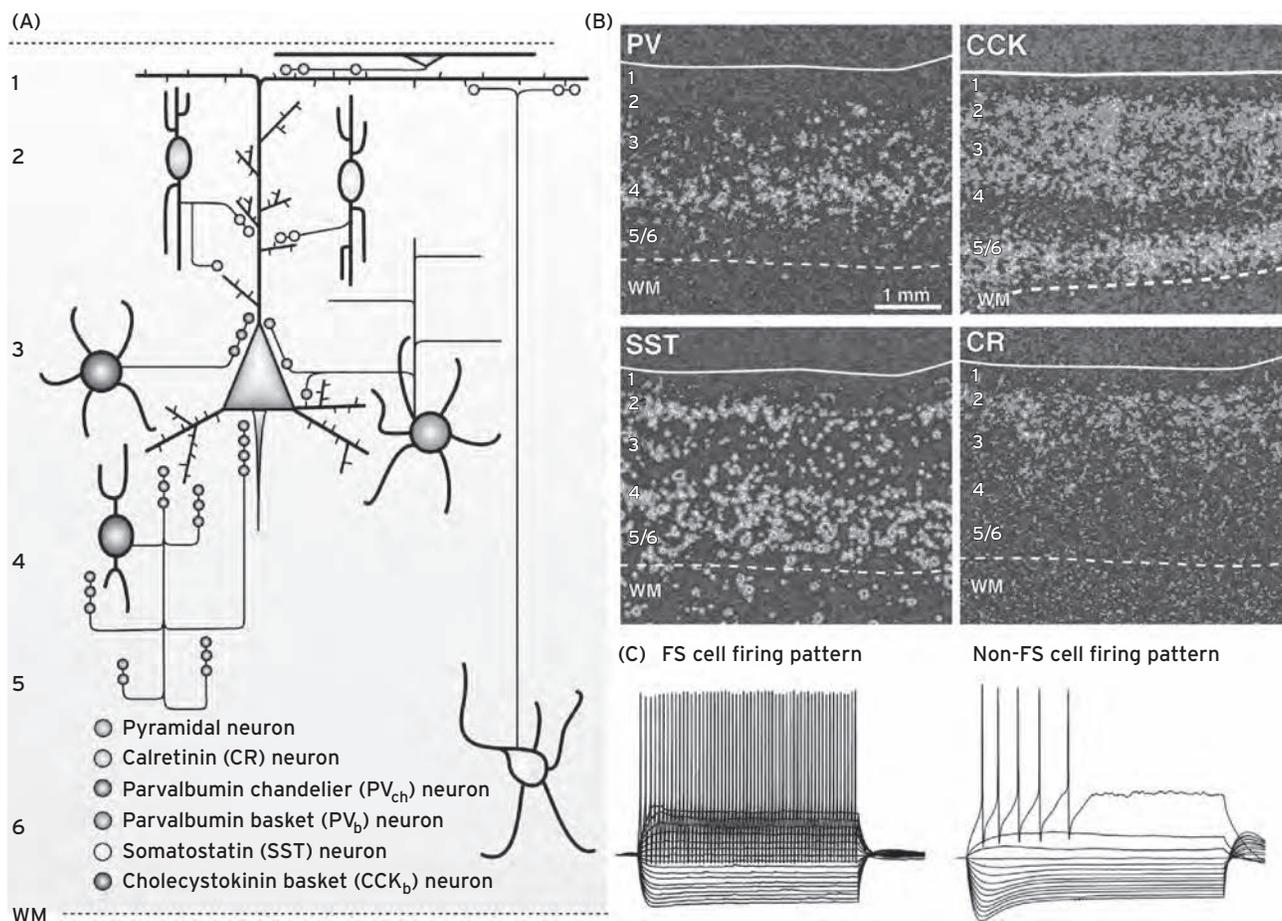

Figure 23.1 Diversity of cortical GABA neurons. GABAergic interneurons can be classified based on morphological (A), molecular (B), and electrophysiological (C) properties. Some interneurons express the calcium binding proteins parvalbumin (PV) or calretinin (CR), whereas others contain the neuropeptides somatostatin (SST) or cholecystokinin (CCK). (A) PV and CCK neurons target the perisomatic region of pyramidal cells, while SST and CR neurons target pyramidal neuron dendrites. PV neurons can be divided into chandelier (PV_{ch}) and basket (PV_b) cells based on their morphology. The axon terminals of PV_{ch} cells exclusively target the pyramidal cell axon initial segment, while the terminals of PV_b cells synapse onto the soma and proximal dendrites. (B) The different interneuron subtypes are distributed distinctively across the layers of the cortex, as evidenced by the different expression patterns of their mRNAs. (C) PV cells exhibit a fast spiking (FS) firing pattern, characterized by a high firing frequency and constant interval between action potentials, while the remaining subclasses are classified as non-FS cells that fire at a lower frequency and exhibit progressively increasing intervals between action potentials. (Image adapted from Gonzalez-Burgos et al. *Am J Psychiatry* (2007) 164 (1):12; and Hashimoto et al. *Mol Psychiatry* (2008) 13:147–161.) (See color insert.)

GAD65 is mostly inactive (with low levels of cofactor binding). Thus, the activity of GAD67 is principally regulated by expression and appears to be responsible for the majority of cortical GABA synthesis, producing up to 90% of the GABA in mouse brain. In contrast, GAD65 seems to be mainly active during conditions of high synaptic demand (Patel et al., 2006).

GABA RECEPTORS

Released GABA exerts its effects through binding to the two major types of GABA receptors—GABA_A and GABA_B receptors (Fig. 23.2). The ionotropic GABA_A receptor is composed of 5 subunits that form a central ion pore, with the most common composition being two α , two β , and one γ subunit. The subunit composition of GABA_A receptors determines important functional and pharmacological properties, such as the kinetics of the postsynaptic signal decay (Gonzalez-Burgos et al., 2011). Activation of these receptors results in an increased chloride conductance, with the direction of ion flow being

determined by the intracellular chloride concentration resulting from the activity of the chloride transporters NKCC1 and KCC2, that bring chloride into and out of the cell, respectively. In the majority of cases, chloride flows inward through GABA_A receptors and hyperpolarizes the membrane, producing the classic inhibitory postsynaptic response (Fig. 23.2).

GABA_B receptors form heterodimers, each composed of a GABA_{B1} and GABA_{B2} subunit, and both subunits are required to produce a functional receptor. Activation of metabotropic GABA_B receptors stimulates the opening of potassium channels and closing of calcium channels via G proteins, resulting in hyperpolarization. GABA_B receptors are located both pre- and postsynaptically.

ROLE OF GABA NEURONS IN NETWORK OSCILLATIONS AND COGNITION

A single interneuron not only makes multiple contacts onto a pyramidal cell, but also contacts many different pyramidal

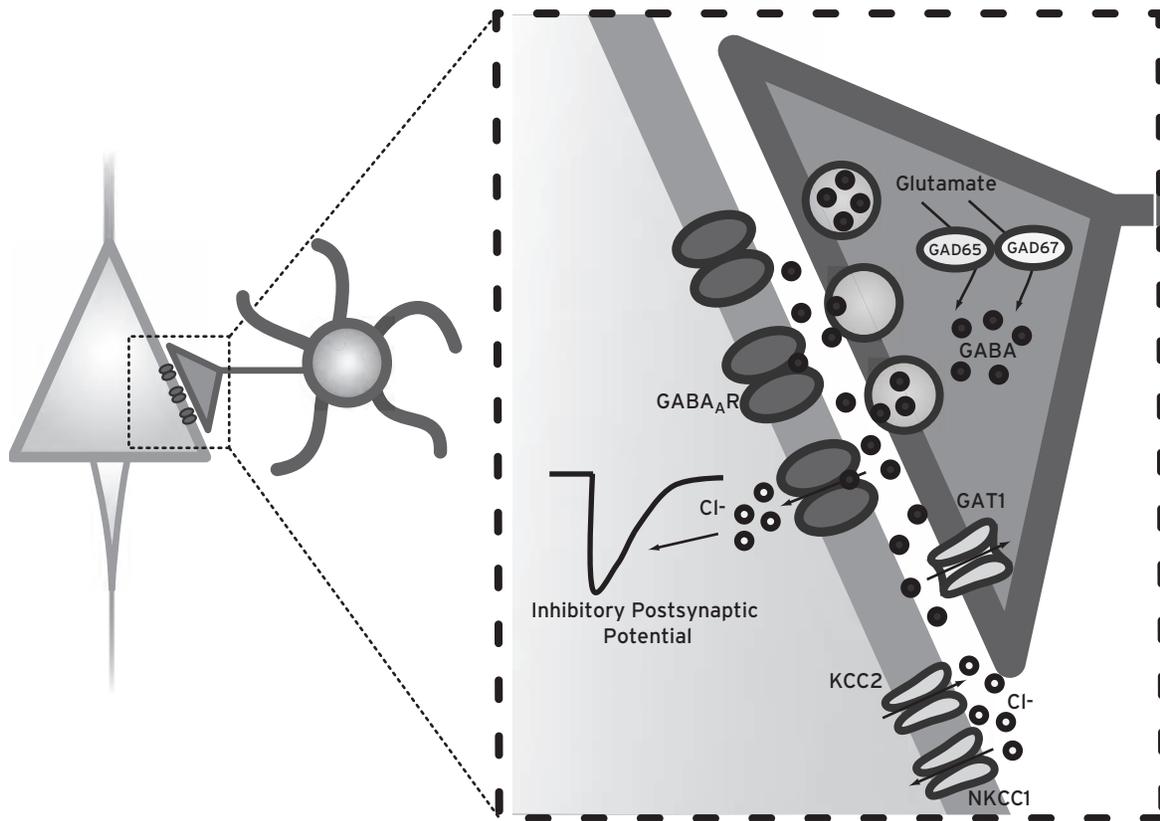

Figure 23.2 Basics of ionotropic GABA neurotransmission. GABA is synthesized from glutamate by the enzyme GAD67 or GAD65. After release from synaptic vesicles into the synaptic cleft, GABA binds to postsynaptic GABA_A receptors. GABA_A receptor activation stimulates the opening of chloride channels. The direction and magnitude of the chloride current produced by GABA_A receptor activation is regulated by the transporters NKCC1 and KCC2, which uptake and extrude chloride, respectively. In the majority of cases, chloride flows inward and hyperpolarizes the membrane, producing the classic inhibitory postsynaptic potential. GABA membrane transporter 1 (GAT1) removes GABA from the synaptic cleft, thereby regulating the concentration of GABA that reaches postsynaptic receptors.

cells (Gonzalez-Burgos and Lewis, 2008). This places interneurons in a position to exert strong inhibitory control over large numbers of pyramidal cells, so that the firing of a single interneuron transiently silences many pyramidal cells. When the pyramidal cells are then released from inhibition, they fire in concert. This inhibitory mechanism of controlling and timing the activity of large numbers of pyramidal cells by interneurons is crucial for proper cortical function. It maintains neural activity within a functional range, preventing the runaway cortical activity of seizures, and exerts an important influence on the timing of neural activity. In addition, the synchronized firing of networks of interconnected interneurons and pyramidal cells produces rhythmic oscillations of different frequencies.

Different subtypes of GABA neurons appear to play distinct roles in the generation of oscillations of different frequencies (Klausberger and Somogyi, 2008). PV_b neurons are known to be crucial in the generation of γ oscillations, the synchronized activity of networks of pyramidal neurons at 30–80 Hz (Gonzalez-Burgos et al., 2010). For example, although the activity of multiple interneuron subtypes is associated with γ oscillations, they are most tightly coupled to the firing of PV_b neurons. Moreover, recent evidence using optogenetic

techniques has demonstrated that suppression and activation of PV neurons suppresses and generates, respectively, γ activity *in vivo*, indicating that PV neurons are both necessary and sufficient for the generation of γ oscillations (Sohal et al., 2009). The GABA_A α 1-containing receptors that predominate at PV_b cell synapses exhibit a fast decay of the inhibitory synaptic potential (IPSP) that is consistent with the firing rate of γ oscillations (Gonzalez-Burgos and Lewis, 2008). In contrast, CCK_b neurons are the interneuron subtype that is most strongly coupled to the slower θ oscillations (4–7 Hz) (Klausberger and Somogyi, 2008). In addition, the GABA_A α 2-containing receptors that are prominent at CCK_b synapses onto pyramidal cells in rodents exhibit a slower IPSP decay, consistent with θ oscillations.

PFC θ and γ oscillations are associated with higher order cognitive processes such as working memory (Curley and Lewis, 2012). For example, θ and γ band activity is induced during the delay period of working memory tasks, and the power of θ and γ synchrony increases in proportion to working memory load. In addition, injection of a GABA_A receptor antagonist into the PFC disrupts working memory performance in monkeys (Lewis et al., 2005). Thus, CCK_b- and PV_b-mediated θ and γ oscillations, respectively, are crucial to normal cognitive function.

INTERNEURON ALTERATIONS IN SCHIZOPHRENIA

CORTICAL GABA SYNTHESIS AND UPTAKE ARE ALTERED

The first evidence of altered cortical GABA signaling in schizophrenia came from early findings of decreased activity of GAD and reduced GABA release and uptake in postmortem tissue samples (Blum and Mann, 2002). However, the most consistent evidence supporting altered GABA neurotransmission is reports of lower levels of the mRNA encoding GAD67 in the PFC of subjects with schizophrenia. Lower GAD67 mRNA in the PFC was first demonstrated in 1995 by Akbarian and colleagues using *in situ* hybridization, and has since been widely replicated using DNA microarray, quantitative PCR (qPCR), and *in situ* hybridization (Blum and Mann, 2002; Gonzalez-Burgos et al., 2010). Thus far, 10 studies have found deficits in tissue-level GAD67 mRNA in the PFC in schizophrenia, with the average deficit ranging in magnitude from 12% to 68%.

On a cellular level, the density of GAD67 mRNA-positive neurons is approximately 25–35% lower across PFC layers 1–5 of subjects with schizophrenia (Lewis et al., 2005). In the remaining GAD67-positive neurons, the expression level per neuron is not different from that of comparison subjects. Since total neuron number is unaltered in the PFC, these data suggest that GABA neurons are not missing in schizophrenia, but that the majority express normal levels of GAD67 mRNA and a subset express levels so low as to not be detectable.

Although a GAD67 mRNA deficit in the PFC has been widely and consistently reported, knowledge of protein levels is of particular importance given that mRNA and protein levels are not necessarily correlated, since a number of factors regulate transcription and translation (Blum and Mann, 2002). For example, pharmacological manipulation of GABA levels is associated with changes in GAD67 protein but not mRNA. However, similar to the mRNA deficit, levels of GAD67 protein are also lower in the PFC in schizophrenia, and in the largest study to date, the magnitudes of the tissue-level reductions in mRNA and protein (15% and 10%, respectively) were similar (Curley et al., 2011).

In contrast to the reductions in GAD67, the mRNA and protein levels of GAD65 have been reported to be unchanged or only slightly reduced in the PFC in schizophrenia (Lewis et al., 2012). Moreover, the density of GAD65-immunoreactive (-IR) terminals is also unaltered. Thus, schizophrenia is characterized by a preferential deficit of GAD67, but not of GAD65, in the PFC. Given that GAD67 mediates the majority of GABA synthesis in the cortex, lower GAD67 in schizophrenia is thought to result in a reduction of cortical GABA levels that significantly impairs synaptic transmission and inhibition of postsynaptic targets.

Although it is possible that compensatory increases in GAD65 may normalize GABA levels in the illness, this scenario is unlikely for a number of reasons. First, as described earlier, most reports of GAD65 levels in schizophrenia have found no alteration. Second, GAD67 knockout mice exhibit normal

levels of GAD65 mRNA and protein, and markedly lower levels of GABA (Asada et al., 1997). Third, recent data indicate that some interneurons primarily use GAD67 while others rely mainly on GAD65 (Lewis et al., 2012), suggesting that interneurons do not use GAD65 and GAD67 interchangeably.

Other aspects of GABA neurotransmission in the PFC are also altered in schizophrenia. For example, expression of the mRNA encoding the GABA membrane transporter 1 (GAT1), which removes GABA from the extracellular space, is decreased in the PFC of schizophrenia subjects, and the density of GAT1 mRNA-positive neurons is lower (Lewis et al., 2005). In concert with the findings of unchanged neuron number in the PFC, this latter finding suggests lower GAT1 expression per neuron, such that in some neurons the level falls below detectability, rather than a reduction in the number of GAT1-expressing neurons in schizophrenia. The deficits in GAD67 and GAT1 may be occurring in the same cells, since examination of the same matched pairs of control and schizophrenia subjects found that the within-pair differences in GAD67 mRNA-positive and GAT1 mRNA-positive neuron density were similar in laminar pattern and significantly correlated in the same cohort of subjects. Thus, schizophrenia is characterized by alterations in both the synthesis and reuptake of cortical GABA (Lewis et al., 2005).

PARVALBUMIN NEURONS ARE PARTICULARLY AFFECTED IN SCHIZOPHRENIA

Given that different subtypes of interneurons possess distinct electrical, molecular, and anatomical properties, the functional outcome of impaired GABA neurotransmission in schizophrenia depends on the subpopulation(s) of neurons affected. PV cells are one subtype of GABA neuron that is known to contain lower GAD67 mRNA in schizophrenia (Lewis et al., 2012). Dual label *in situ* hybridization has shown that approximately 50% of PV mRNA-positive neurons lack detectable levels of GAD67. In addition, PV mRNA levels are significantly decreased, and laminar analyses have revealed that this reduction occurs principally in layers 3 and 4, layers where lower GAD67 mRNA is also present.

However, in contrast to GAD67 mRNA, although the expression of PV mRNA per neuron is decreased, neither the density of neurons with detectable levels of PV mRNA nor the density of PV-immunoreactive neurons is altered in schizophrenia (Lewis et al., 2012). Although some studies have reported a lower density of PV-immunoreactive neurons in schizophrenia, these results may have been confounded by a reduced sensitivity for PV immunoreactivity resulting from the tissue processing method utilized. Moreover, the lower density of PV-immunoreactive neurons was reported in layers 3–5, where the largest decrement in PV mRNA is found. Thus, levels of PV protein are likely to have fallen below detectability in conditions of reduced sensitivity, and thus the reported findings likely do not reflect lower PV neuron number, but rather an inability to visualize all of the neurons that are present (Stan and Lewis, 2012). In addition, in matched pairs of schizophrenia and control subjects, the within-subject pair difference in

PV mRNA expression per neuron was positively correlated with the difference in density of GAD67 mRNA-positive neurons, suggesting that GAD67 is dramatically lower in a subpopulation of neurons that contain lower, but still detectable, levels of PV mRNA (Lewis et al., 2005).

CONVERGENT EVIDENCE POINTS TO WEAKER INHIBITION FROM PV BASKET CELLS

A recent study demonstrated that the axon terminals of PV_b cells exhibit an approximately 50% reduction in GAD67 protein (Lewis et al., 2012). In addition to lower GABA synthesis, several lines of evidence suggest that PV_b cells exhibit other presynaptic alterations that result in weaker inhibition onto pyramidal cells in the PFC of subjects with schizophrenia (Lewis et al., 2012) (Fig. 23.3). First, mRNA and protein levels

of μ opioid receptors are increased in the PFC of subjects with schizophrenia. Perisomatic μ opioid receptors, which are localized to PV_b cells, hyperpolarize the cell body through the activation of inwardly rectifying potassium channels, making the cell less likely to fire, and μ opioid receptors localized to axon terminals lead to the suppression of vesicular GABA release. Therefore, the greater complement of μ opioid receptors in schizophrenia could contribute to increased suppression of GABA release and result in deficient PV_b cell output (Lewis et al., 2012).

On the postsynaptic side of the PV_b-pyramidal cell synapse, additional alterations are present that may further lower the PV_b-mediated inhibition of pyramidal neurons (Fig. 23.3). First, PV_b-pyramidal neuron synapses are populated by $\alpha 1$ -containing GABA_A receptors, and lower $\alpha 1$ mRNA has been demonstrated in schizophrenia PFC by several studies

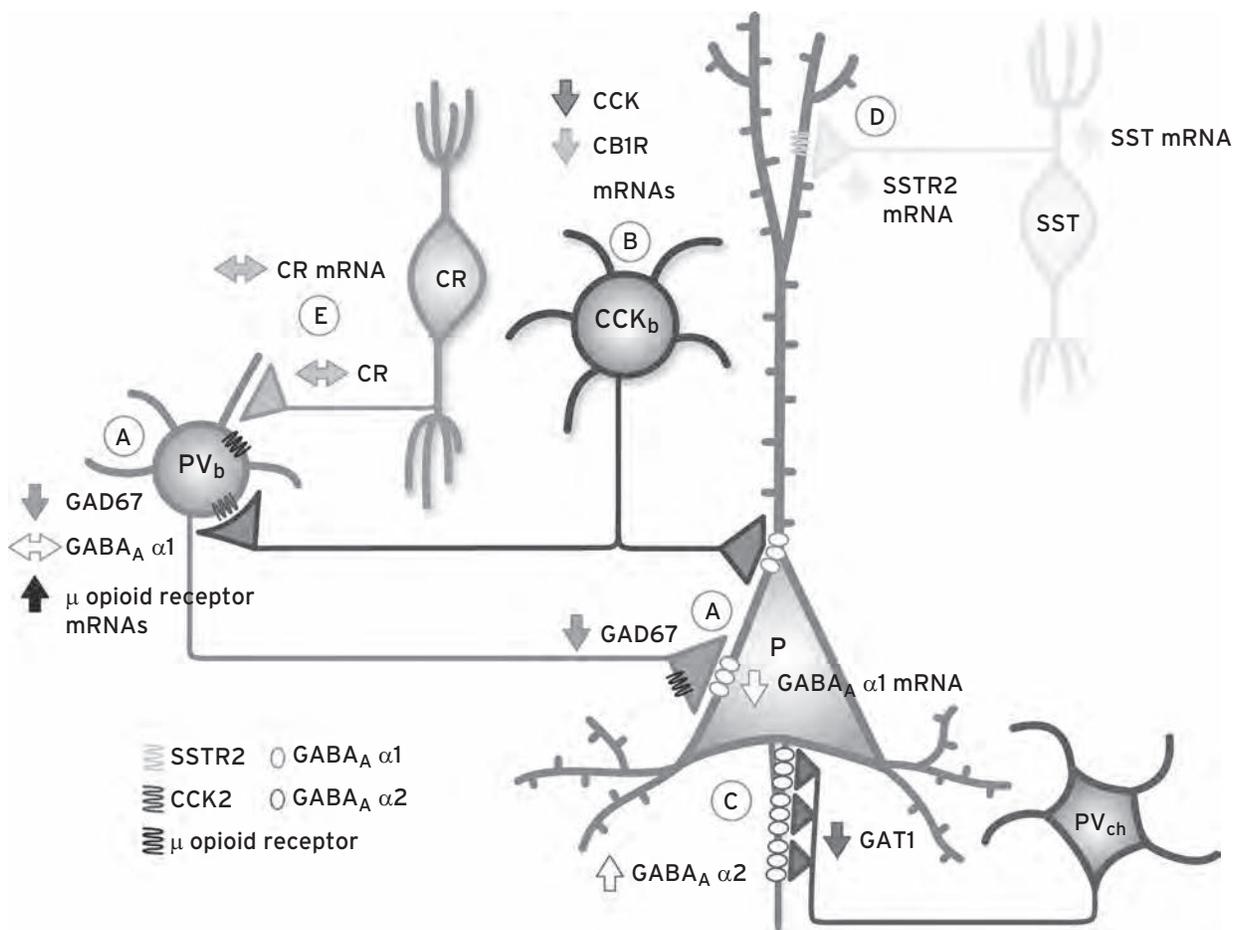

Figure 23.3 Schematic summary of alterations in neuronal circuitry in the PFC of subjects with schizophrenia. (A) The perisomatic inhibition of pyramidal (P) neurons by parvalbumin basket (PV_b) cells is lower due to (1) lower GAD67 mRNA and protein, and therefore less GABA synthesis; (2) higher levels of μ opioid receptor expression in PV_b cells that reduces their activity and suppresses GABA release; (3) reduced expression of cholecystokinin (CCK) mRNA, which stimulates the activity of, and GABA release from, PV_b cells; and (4) less mRNA for, and presumably fewer, postsynaptic GABA_A $\alpha 1$ receptors in pyramidal neurons. (B) The perisomatic inhibition of pyramidal neurons by cholecystokinin-expressing basket (CCK_b) cells is enhanced due to lower levels of CCK and cannabinoid 1 receptor (CB1R) mRNAs that reduce depolarization-induced suppression of inhibition (DSI). Levels of GAD67 in CCK_b cells are unknown, but are thought to be very low, relative to PV cells, in the healthy state. (C) PV-expressing chandelier (PV_{ch}) cells have decreased GABA membrane transporter 1 (GAT1) protein in their axon terminals and increased postsynaptic GABA_A $\alpha 2$ -containing receptors at pyramidal neuron axon initial segments. The levels of GAD67 protein in PV_{ch} cells in schizophrenia are not known. (D) Somatostatin (SST)-containing cells contain lower mRNA levels of SST, and expression of its receptor, SSTR2, is also lower. Levels of GAD67 in SST cells have not been measured. (E) Calretinin (CR)-containing cells are thought to be unaffected, since levels of CR mRNA and protein are unchanged. GAD67 levels in CR cells are unknown. (See color insert.)

(Lewis et al., 2012). In addition, mRNA levels of the $\beta 2$ and $\gamma 2$ subunits, which coassemble with the $\alpha 1$ subunit, are also lower in schizophrenia. The lower levels of $\alpha 1$ and $\beta 2$ are most prominent in layers 3–4, exhibiting the same laminar pattern as the PV mRNA deficit. Furthermore, in PFC layer 3, $\alpha 1$ mRNA levels are significantly reduced by 40% in pyramidal cells, but unchanged in interneurons. These data suggest that the number of GABA_A receptors postsynaptic to PV_b cell inputs is selectively lower in pyramidal cells, contributing to weaker PV_b inhibition of pyramidal cells in schizophrenia (Lewis et al., 2012).

Finally, inhibitory inputs onto pyramidal cells may be less hyperpolarizing in schizophrenia. The chloride transporters NKCC1 and KCC2 partially control the driving force of chloride entry into pyramidal neurons, thereby determining the strength of the postsynaptic response to GABA. The mRNA levels of two phosphatases, OSXR1 and WNK3, which phosphorylate NKCC1 and KCC2, increasing and decreasing their function, respectively, are markedly elevated in the PFC of subjects with schizophrenia. Thus, increased activity of NKCC1 and decreased activity of KCC2 in schizophrenia would result in a higher than normal intracellular chloride concentration, leading to a reduced chloride driving force, and subsequently less hyperpolarization of pyramidal neurons when GABA is released from PV_b cells (Lewis et al., 2012).

PV CHANDELIER CELLS ARE ALSO ALTERED IN SCHIZOPHRENIA

PV_{ch} cells also exhibit alterations in schizophrenia (Fig. 23.3) (Lewis et al., 2012). The density of PV_{ch} cartridges that are immunoreactive for GAT1 is 40% lower in schizophrenia, although the density of other GAT1-immunoreactive structures is unchanged. In addition, the density of GABA_A $\alpha 2$ -containing axon initial segments is increased in the PFC of subjects with schizophrenia, and this increase is significantly correlated with the reduced density of GAT1 cartridges. These reciprocal alterations have been interpreted as coordinated compensations attempting to counteract a deficit in GAD67 in PV_{ch} cells, since lower GABA reuptake and an increased probability of GABA_A receptor binding would both augment GABA signaling. However, to date, GAD67 levels in PV_{ch} cells have not been measured.

CCK BASKET CELLS ARE ALSO ALTERED IN SCHIZOPHRENIA

Abnormalities in PV neurons alone may not account for the lower GAD67 mRNA and protein levels observed in schizophrenia. In addition to the reductions in layers 3–4 in the PFC, lower levels of GAD67 mRNA have also been observed in layers 1, 2, and 5, where relatively few PV-expressing GABA neurons are located and where PV mRNA expression is unaltered in schizophrenia (Lewis et al., 2005). These findings suggest that other subsets of interneurons residing outside layers 3–4 may also exhibit reductions in GAD67. One candidate population is CCK_b cells, whose cell bodies are principally localized to layers 2–superficial 3 (Fig. 23.3). Lower levels of CCK and

CB1R mRNAs, and lower CB1R protein levels, are present in the PFC of schizophrenia subjects. Furthermore, in matched pairs of schizophrenia and control subjects, the within-subject pair difference in GAD67 mRNA levels was positively correlated with differences in both CCK and CB1 mRNAs, suggesting that the GAD67 mRNA deficit in layers 2–3 is present in CCK_b cells. However, GAD67 levels have not yet been directly assessed in CCK_b cells in schizophrenia. A recent finding that CB1R-expressing axon terminals in monkey PFC tissue have very low levels of GAD67 protein suggests that CCK_b cells may rely mainly on GAD65 for GABA synthesis. Consistent with this hypothesis, nearly all CCK-expressing, but only a few PV-expressing, cells in mouse neocortex express GAD65. Thus, CCK_b cells may not contain lower GAD67 in schizophrenia (Curley and Lewis, 2012).

CCK_b cells are known to participate in a process termed depolarization-induced suppression of inhibition (DSI). In this phenomenon, elevated calcium levels produced from depolarization stimulate the retrograde release of endocannabinoids from pyramidal cells. The resulting binding of endocannabinoids to presynaptic CB1Rs located on CCK_b cell terminals activates the receptors, inhibits presynaptic calcium channels, and suppresses GABA release from CCK_b terminals, producing a reduced inhibition of the original depolarized pyramidal cell and other nearby cells (Wilson and Nicoll, 2002). DSI is present throughout development and into adulthood in monkey PFC. Thus, the lower levels of CB1R present in schizophrenia may result in less DSI and consequently greater inhibition of pyramidal cells by CCK_b cells (Curley and Lewis, 2012). In fact, markers of endocannabinoid synthesis and degradation are unaltered in schizophrenia, consistent with the idea that lower CB1R levels in the illness are not downregulated in response to increased endocannabinoid levels. Furthermore, endocannabinoid-mediated suppression of GABA release from CCK_b cells can also be accomplished through application of CCK, and therefore lower CCK levels in schizophrenia may also contribute to increased CCK_b cell output (Curley and Lewis, 2012). In addition, since CCK_b cell synapses onto pyramidal cells predominantly feature GABA_A $\alpha 2$ -containing receptors, the increased expression of $\alpha 2$ mRNA that is present in the PFC of subjects with schizophrenia is consistent with an increased inhibitory effect of CCK_b cells. However, since $\alpha 2$ -containing receptors are also present at PV_{ch} cell synapses, whether the higher levels of GABA_A $\alpha 2$ -containing receptors are also present at CCK_b cell synapses remains to be determined (Curley and Lewis, 2012).

Alternatively, if GAD67 is lower in CCK_b cells in schizophrenia, reduced CCK and CB1R levels may represent a compensation designed to increase GABA neurotransmission. Consistent with this idea, germ-line reductions of GAD67 in mouse PFC are associated with lower CB1R levels, and the alterations in GAD67 and CB1R are positively correlated, similar to schizophrenia. However, since GAD67 protein levels are normally very low in CCK_b axon terminals from monkey PFC, germ-line reductions in GAD67 may lower CB1R levels by acting at the circuit level rather than within CCK_b cells (Curley and Lewis, 2012).

SST NEURONS ARE ALSO AFFECTED IN SCHIZOPHRENIA

A fourth population of interneurons that exhibit alterations in schizophrenia is cells expressing SST (Fig. 23.3). Lower SST mRNA is present in the PFC of subjects with schizophrenia (Fung et al., 2010), and the reductions are significantly correlated with the deficit observed in GAD67 mRNA in the same subject cohort. Lower levels of somatostatin receptor 2 mRNA are also present in the PFC of subjects with schizophrenia (Beneyto et al., 2012). However, GAD67 levels in SST cells have not been directly examined in schizophrenia, and thus the nature of their involvement in the disease pathology is currently unclear.

CALRETININ CELLS DO NOT SEEM TO BE ALTERED IN SCHIZOPHRENIA

The ~40–50% of interneurons that express CR in the primate PFC do not appear to be affected in schizophrenia (Fig. 23.3). CR mRNA, CR-immunoreactive neurons, and CR-immunoreactive axon terminals are all unaltered in the illness (Lewis et al., 2005). In contrast to PV_b, PV_{ch}, CCK_b, and SST cells, CR cells primarily target other GABA neurons, and thus the fact that these cells seem to be spared in schizophrenia is suggestive of a selective deficit in the inhibition of pyramidal cells, but not of interneurons, in the illness.

ALTERATIONS IN GABA NEURONS ARE FOUND IN OTHER BRAIN REGIONS

An important question that arises from the findings of GABA neuron abnormalities in the PFC is whether these changes are specific to this brain region or are also present in other cortical areas. In fact, reductions in GAD67 mRNA have been reported (although not yet replicated in every location) in the primary motor, primary visual, anterior cingulate, and orbitofrontal cortices, as well as the superior temporal gyrus and hippocampus (Gonzalez-Burgos et al., 2010; Thompson Ray et al., 2011). In addition, other markers of GABA neurotransmission, including PV, GAT1, SST, and GABA_A α 1, are lower across multiple cortical regions in schizophrenia, with similar magnitudes of reduction observed across brain regions for each transcript (Lewis et al., 2012). Lower GABA_B receptor immunoreactivity has been reported in the hippocampus, entorhinal cortex, and inferior temporal cortex of subjects with schizophrenia (Mizukami et al., 2002). Importantly, similar to the PFC, CR and GAD65 mRNA are unaltered across multiple cortical regions (Lewis et al., 2012; although axon terminal GAD65 protein levels are lower in primary auditory cortex, see Moyer et al., 2012). Thus, the changes observed in the PFC do not appear to be specific to this brain region, and similar GABA neuron alterations are likely to be present in a variety of cortical regions.

IN VIVO MEASUREMENT OF GABA LEVELS HAS YIELDED INCONSISTENT RESULTS

Despite an abundance of postmortem data suggesting reduced GABA synthesis and alterations in other aspects of GABA

neurotransmission in the illness, *in vivo* measurements of cortical GABA using proton magnetic resonance spectroscopy have yielded conflicting results, with decreased, increased, and unchanged levels reported in different cortical regions (Kegeles et al., 2012; Maddock and Buonocore, 2012). Thus, it is currently unknown whether impaired GABA synthesis is accompanied by lower GABA levels in schizophrenia. Further complicating the issue, magnetic resonance spectroscopy studies assess total tissue levels of GABA, not those associated with synapses, and therefore the relationship between these studies and GABAergic neurotransmission in schizophrenia remains unclear.

ALTERATIONS IN GABA NEURONS ARE DUE TO THE DISEASE PROCESS OF SCHIZOPHRENIA

An important consideration is whether the alterations in markers of GABA neurotransmission described earlier are specific to the disease process of schizophrenia, or represent a consequence of illness chronicity, treatment, or comorbid diagnoses (Lewis et al., 2005). In general, studies in animals exposed to medications used in the treatment of schizophrenia, and the comparison of subjects with schizophrenia on or off such medications at the time of death, suggest that altered GABA-related gene expression in schizophrenia is not attributable to medication effects. Similarly, alcohol use does not seem to affect GAD67, PV, or GAT1 mRNA levels (Lewis et al., 2005), and nicotine and cannabis use also do not account for the lower GAD67 mRNA levels in schizophrenia (Curley et al., 2011).

Furthermore, since GAD67 expression is activity-dependent (Akbarian and Huang, 2006), lower expression might just index the less stimulating social, occupational, and intellectual environment associated with illness chronicity. However, a recent study found no association between GAD67 mRNA expression and age-corrected length of illness (Curley et al., 2011). In addition, the same study found no association between predictors of illness severity or measures of functional outcome and GAD67 mRNA levels.

Another important consideration is whether the observations in schizophrenia are specific to the illness, or are shared among other psychiatric diseases such as bipolar disorder (BPD) and major depressive disorder (MDD). Current evidence suggests that all three disorders do share some common GABAergic alterations, although they are also characterized by differences in their pattern of alterations, and by substantial heterogeneity in findings across studies. For example, lower GAD67 has also been found in BPD and MDD (Guidotti et al., 2000; Thompson Ray et al., 2011), and lower PV has been reported in BPD (Torrey et al., 2005) but not MDD (Beasley et al., 2002; Rajkowska et al., 2007). In contrast, another recent study in the PFC found lower SST levels in MDD and reduced PV in BPD, but no change in GAD67, GAD65, or CR mRNA expression in either illness (Sibille et al., 2011). In addition, microarray studies that examined the expression patterns of large groups of genes have found alterations in a number of GABA-related genes in MDD and BPD (Kato et al., 2007; Klempan et al., 2009). Thus, while these major psychiatric illnesses do seem to be characterized by alterations in GABA

neurons, the exact degree of overlap between illnesses remains to be determined.

MECHANISMS UNDERLYING ALTERATIONS IN GABA NEUROTRANSMISSION IN SCHIZOPHRENIA

A thorough interpretation of the GABA neurotransmission deficit in schizophrenia requires knowledge of the underlying mechanism(s). Since lower GAD67 is the most robust finding in postmortem tissue, here we consider some of the candidate mechanisms for this reduction.

ALLELIC VARIATION IN GAD1

GAD1, the gene that encodes GAD67, is located on chromosome 2q31 (Akbarian and Huang, 2006). Single nucleotide polymorphisms (SNPs) in GAD1 have been implicated in the risk for adult- and childhood-onset schizophrenia (Marenco et al., 2010), and have also been associated with GAD67 mRNA levels (Straub et al., 2007), indicating that alterations in the gene may underlie lower GAD67 mRNA levels in schizophrenia. Existing data suggest several possible mechanisms by which these allelic variants may alter GAD67 mRNA levels. For example, although no risk SNPs are located within the coding region of GAD1 (Akbarian and Huang, 2006), one located in the promoter region is associated with altered transcription factor binding, which may lead to impaired promoter function (Zhao et al., 2007). In addition, epigenetic mechanisms, which control gene activity without altering DNA sequence, may also contribute. Methylation of certain lysine residues on nuclear histone proteins, around which DNA is wound, result in shifts between active and repressed transcription (Tsankova et al., 2007). In female schizophrenia subjects, GAD1 risk SNPs are associated with lower PFC GAD67 mRNA and a shift from active to repressed histone methylation (Huang et al., 2007), providing a potential mechanism through which allelic variation may lower GAD67 mRNA levels. However, this mechanism may be specific to females, and thus the exact role of epigenetic mechanisms in GAD1 transcription requires further study.

Despite this evidence, low penetrance, small effect sizes, and a lack of concordance between studies regarding the specific SNPs involved suggest that allelic variation in the GAD1 gene likely plays only a minor role as a causative factor underlying lower GAD67 in schizophrenia (Insel, 2010). Further confusing the issue, schizophrenia GAD1 risk alleles have recently been associated with *increased* GABA levels in healthy subjects (Marenco et al., 2010), and therefore the exact role of GAD1 risk alleles in the pathogenesis of GAD67 deficits in schizophrenia remains to be determined.

REDUCED SIGNALING THROUGH TRKB

In contrast to a primary genetic effect, lower GAD67 expression may be a consequence of an upstream mechanism. One such mechanism that could lead to a reduction in GAD67, as

well as in PV and GAT1, in schizophrenia is reduced signaling through the TrkB receptor and its ligand brain-derived neurotrophic factor (BDNF) (Lewis et al., 2005). TrkB/BDNF signaling is crucial for interneuron development, especially in PV cells, which comprise the majority of TrkB-expressing interneurons. Treatment with BDNF *in vitro* upregulates GAD and promotes GABA release, and BDNF-overexpressing mice exhibit accelerated PV interneuron maturation (Balu and Coyle, 2011).

Both TrkB and BDNF mRNA and protein are lower in the PFC of subjects with schizophrenia (Balu and Coyle, 2011). In fact, in matched pairs of control and schizophrenia subjects, the within-pair differences in TrkB mRNA are positively correlated with those of both GAD67 and PV mRNAs. In addition, mice with a genetic knockdown of TrkB, but not BDNF, exhibit lower levels of GAD67 and PV mRNAs, suggesting that reduced signaling through the TrkB receptor may underlie lower levels of both mRNAs in schizophrenia. Furthermore, knockdown of TrkB produces a reduced density of GAD67 mRNA-positive cells, without a change in the mRNA levels per cell, similar to the pattern observed in schizophrenia. Although GAT1 expression has not been examined in these animals, it also appears to be modulated by the TrkB/BDNF signaling pathway. In hippocampal cells, inhibition of tyrosine kinases lowers GAT1 phosphorylation and GABA reuptake, while application of BDNF increases GAT1 function (Law et al., 2000).

NMDA HYPOFUNCTION IN PV NEURONS

Glutamate-mediated excitatory neurotransmission occurs through a variety of fast ionotropic receptors (NMDA, AMPA, and kainate), as well as the slower G protein-coupled metabotropic receptors. The NMDA receptor hypofunction hypothesis of schizophrenia originated from the observation that NMDA receptor antagonists recapitulate many clinical features of schizophrenia. Although attempts to document alterations in the level of NMDA receptor subunits in schizophrenia have been mixed, the hypothesis has been strengthened by findings that several schizophrenia risk genes, such as neuregulin 1 and ErbB4, affect NMDA receptor signaling, and by preclinical and clinical studies demonstrating that NMDA receptor enhancement ameliorates disease symptoms (Gonzalez-Burgos and Lewis, 2012).

Interneurons are known to depend on NMDA-mediated excitation, and thus lower glutamatergic drive onto GABA neurons may result in subsequent reductions in markers of inhibitory neurotransmission (Lewis and Moghaddam, 2006). The vast majority (80–90%) of PV neurons express NR1 receptors (Huntley et al., 1994; González-Albo et al., 2001), and so PV neurons are thought to be particularly affected by lower NMDA receptor signaling. In fact, NMDA receptor antagonists lower GAD67, PV, and GAT1 mRNAs (Behrens and Sejnowski, 2009; Bullock et al., 2009). In addition, reduced levels of GAD67 and PV protein are observed in mice with a selective knockout of the NR1 receptor on ~50% of cortical and hippocampal interneurons, presumably mostly PV neurons, during early postnatal development (Gonzalez-Burgos and Lewis, 2012).

CONSEQUENCE OF REDUCED EXCITATION

GAD67 is activity-dependent (Akbarian and Huang, 2006), and reductions in excitatory signaling have been shown to produce many of the same alterations in inhibitory function observed in schizophrenia. For example, monocular deprivation of the lateral geniculate nucleus of the thalamus results in lower GAD67 mRNA in the primary visual cortex of primates. Thus, one hypothesis is that the reduced excitatory activity in schizophrenia is an “upstream” pathology that produces a compensatory downregulation of inhibitory activity, in an attempt to maintain the balance of excitatory and inhibitory activity (E/I balance) needed for proper cortical functioning. E/I balance is important to prevent both runaway excitatory activity (too much excitation) and a dying out of cortical activity (too much inhibition). Thus, reduced excitatory activity of pyramidal cells may result in a compensatory downregulation of inhibitory activity onto these neurons, as evidenced by the multiple different types of reductions in effectors of GABA neurotransmission (Lewis et al., 2012).

In fact, a number of alterations are present in excitatory pyramidal cells in schizophrenia (Glausier and Lewis, 2012). First, there is a significant reduction in the density of dendritic spines, a finding that is most pronounced in layer 3. In addition, although the total number of pyramidal neurons is unchanged in the PFC, somal size is significantly lower, and neuropil and dendritic tree size are reduced. In conjunction with these morphological alterations, certain molecules that regulate spine formation and maintenance are also altered in schizophrenia. For example, mRNA levels of the Rho GTPase cell division cycle 42 (Cdc42), which promotes spine formation, are lower in the PFC of subjects with schizophrenia, and the decrease in Cdc42 mRNA is significantly correlated with the reduction in layer 3 spine density. The inhibition of Cdc42 effector protein 3 (Cdc42EP3) by Cdc42 is thought to enable synaptic potentiation, and mRNA levels of Cdc42EP3 are increased in schizophrenia. Thus, the combination of lower Cdc42 and higher Cdc42EP3 levels may contribute to the spine loss observed in schizophrenia (Glausier and Lewis, 2012).

CONSEQUENCES OF ALTERATIONS IN GABA NEURONS IN SCHIZOPHRENIA: NETWORK OSCILLATIONS AND WORKING MEMORY

As previously reviewed, schizophrenia is associated with alterations in a variety of interneuron subtypes. The abnormalities in two of these cell types, PV_b and CCK_b cells, are particularly interesting in light of their role in neural network oscillations associated with cognition, and here we consider the consequences of alterations in these cells in schizophrenia. Lower levels of CCK and CB1R in CCK_b cells are hypothesized to strengthen the inhibition of postsynaptic pyramidal cells. On the other hand, lower levels of GAD67 and increased levels of μ opioid receptors in PV_b cells are thought to weaken the inhibition of postsynaptic pyramidal cells. In addition, PV_b cells receive input from CCK_b cells, and application of CCK can activate PV neurons (Krook-Magnuson et al., 2012); thus, lower

CCK in schizophrenia may also contribute to weaker PV_b cell activity. Lower levels of GABA_A α 1-containing receptors and a reduced chloride driving force in pyramidal neurons may also decrease the strength of hyperpolarizing inputs from PV_b cells and exacerbate this reduction in inhibition. Thus, a convergence of evidence suggests that the relative strengths of pyramidal cell inhibition from CCK_b and PV_b cells are increased and decreased, respectively, in schizophrenia (Curley and Lewis, 2012).

An important determinant of the functional consequences of these alterations is whether the disturbances in each cell type affect the same pyramidal neurons (Curley and Lewis, 2012). Although CCK mRNA levels in schizophrenia have not been examined in a laminar fashion, CB1R immunoreactivity is significantly lower in layers deep 3–4 and 6. The density of PV-immunoreactive axon terminals is also lower in layers deep 3–4, suggesting that the alterations in both PV_b and CCK_b terminals are present in the middle cortical layers, despite the locations of their cell bodies in different layers. On the other hand, recent data suggest that all pyramidal neurons receive PV_b cell inputs, whereas only some receive CCK_b inputs and show DSI (Krook-Magnuson et al., 2012), which may indicate that, while all pyramidal cells are affected by impaired inhibition from PV_b cells, only some are affected by alterations in CCK_b cell inputs. However, whether the affected PV_b and CCK_b cells target the same pyramidal neurons in schizophrenia remains to be determined (Curley and Lewis, 2012).

CCK_b and PV_b cells play an important role in the θ and γ oscillations, respectively (Klausberger and Somogyi, 2008), that underlie working memory function. Although in healthy subjects the amplitude of θ and γ oscillations increases in proportion to working memory load, subjects with schizophrenia exhibit impairments in θ and γ band power and working memory performance. Thus, changes in the inhibitory output from CCK_b and PV_b cells, and the resulting shift in their relative control of pyramidal cells, could disrupt normal network functioning and θ and γ band power. Moreover, since θ and γ oscillations are coupled during memory tasks, a disturbance in one frequency may result in corresponding deficits in the other frequency. Thus, alterations in the perisomatic inhibition of PFC pyramidal neurons by CCK_b and PV_b neurons are a plausible mechanism underlying θ and γ oscillation deficits and cognitive impairments in schizophrenia (Curley and Lewis, 2012).

CONCLUSIONS

Schizophrenia is characterized by a number of cortical interneuron alterations. Abnormalities are present in PV_b, PV_{ch}, CCK_b, and SST, but not CR cells, and occur in a number of cortical regions in addition to the PFC. These alterations appear to reflect the disease process of schizophrenia, as they are not a consequence of illness chronicity, treatment, or comorbid diagnoses. A number of plausible mechanisms could underlie the most robust finding, a reduction in GAD67 mRNA and protein, including allelic variation in GAD1, reduced signaling through the TrkB receptor, NMDA receptor hypofunction in PV neurons, or reduced excitation. The alterations in two cell types in particular, PV_b and CCK_b cells, are particularly

important given their roles in θ and γ oscillations, respectively, and provide a possible mechanism underlying the oscillation deficits and cognitive impairments of schizophrenia.

DISCLOSURES

Dr. Lewis currently receives grant/research support from Bristol-Myers Squibb and Pfizer. He is a consultant for Bristol-Myers Squibb and Concert.

Dr. Curley has no conflicts of interest to disclose.

24 | SYNAPTIC DISEASE IN PSYCHIATRY

SETH G. N. GRANT

INTRODUCTION

Synapses are the junctions between nerve cells. A single neuron can have thousands of synapses, and the overall number in the human brain is estimated to be around a million billion (10^{15}). Pathology of synapses is known as “synaptopathy” and there are over 100 nervous system diseases caused by mutations disrupting synaptic proteins (Bayes et al., 2011). Single gene mutations have been described in over 200 synapse genes causing a wide variety of psychiatric, neurological, and developmental diseases. Synaptopathy is now recognized as a major cause of common and rare brain diseases.

The complete set of proteins found within synapses is known as the synapse proteome (Bayes and Grant, 2009). This is further divided into the presynaptic and postsynaptic proteomes, referring to the sets of proteins in the presynaptic terminal on the axon and the postsynaptic terminal on the dendrite (Fig. 24.1). The size of the synapse proteome is around 2,000 proteins, representing about 10% of the human genome.

The understanding of synaptopathy requires an appreciation of the basic organization of proteins within the synapse proteome. There is a need to understand the classes (or types) of proteins, how they are physically organized and assembled together, and in which parts of the brain they are expressed. These organizational principles aid in understanding why mutations in particular proteins produce particular phenotypes and diseases.

This chapter will introduce the reader to the molecular science of synaptic disease. The focus will be on the relationship between mutations and the proteins that are found in synapses, and how these mutations cause the phenotypes that comprise the clinical symptoms and signs of the diseases. The chapter will not provide exhaustive lists of gene mutations, as these are constantly being updated. The reader can find lists of synaptic proteome components and their disease mutations on the Genes to Cognition Website (www.genes2cognition.org/synaptopathy). The reader is directed toward specialist chapters for descriptions of the genetics of psychiatric disease and to general neuroscience textbooks for descriptions of the basic physiology and function of synapses.

BRIEF HISTORICAL PERSPECTIVES ON SYNAPTIC DISEASE IN THE PREMOLECULAR ERA

The great dispute between Cajal and Golgi, the two leading neuroanatomists of the 19th century, centered on whether the

axons and dendrites of neurons were in continuity or physically separated (DeFelipe, 2010). The importance of this question echoes today because it is the molecular specialization of the contact made between the two separated nerve cells—the structure that Sherrington called the synapse—that is the key to the etiology of many brain diseases.

Until the arrival of electron microscopy in the mid-20th century, neuroanatomical observations of synapses were at the limit of light microscopic methods and discriminating the size and shape of different synapses was difficult. Although these methods revealed that some brain diseases, such as forms of intellectual disability, display morphological abnormalities in synapse structure, there was no systematic way for neuropathologists to use microscopy to classify synaptopathies and thereby determine how many diseases involve pathology at synapses.

Pharmacological studies were more successful in invoking the possibility that synapse disease was involved in psychiatric illness. Evidence such as changes in levels of neurotransmitters or the striking behavioral effects of drugs that modulate the levels or action of neurotransmitters led to the view that an imbalance of neurotransmitter function was either of primary etiological significance or a secondary manifestation of synapses adjusting to the primary disease process. The inability of either neuropharmacology or neuroanatomy to distinguish between the cause or effect has been an obstacle to understanding the relevance of changes in synapses in disease.

Another impediment to scientific advancement was the lack of systematic knowledge about the molecules that are found at synapses. As recently as the 1990s, there was only partial understanding of all the neurotransmitter receptors and even less known about the enzymes and structural proteins found in synapses. As a result of proteomic and genomic studies, there has been at least a 10-fold increase in the number of proteins discovered at the synapse. We now have comprehensive lists of all synaptic proteins and their gene sequences and thus the fundamental “parts list” of synapses (Bayes and Grant, 2009).

ORGANIZATION OF SYNAPSE PROTEOME

The synapse proteome is organized into a hierarchy of structures: genes and RNA encode individual proteins that are organized into macromolecular assemblies, and ultimately these assemblies are organized into the overall subcellular structure of the presynaptic and postsynaptic terminal (Fig. 24.1). The

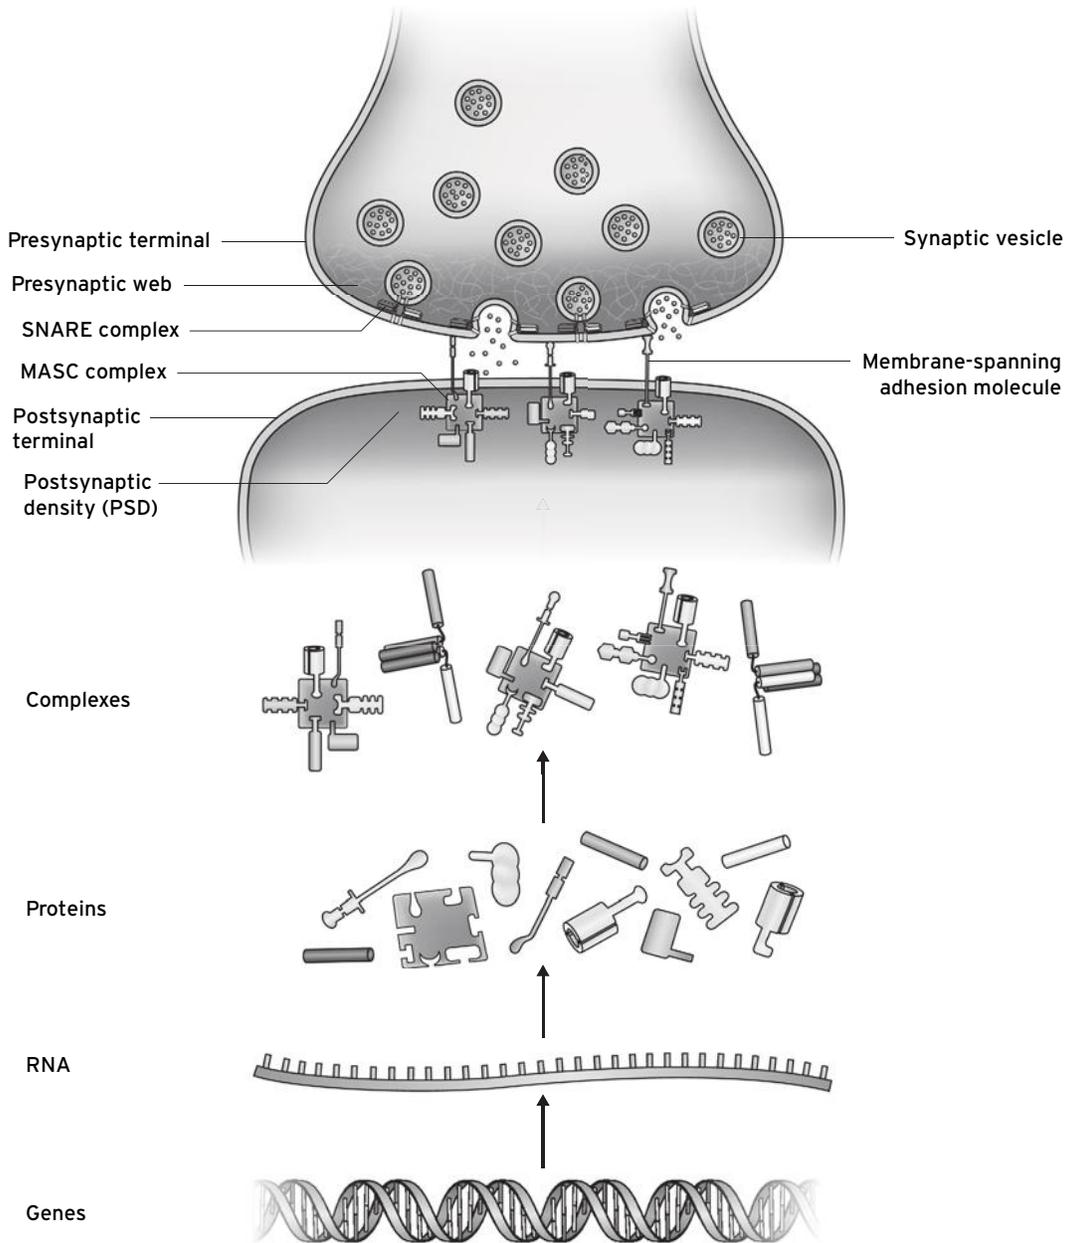

Figure 24.1 The synapse proteome. A simplified molecular hierarchy linking genes to synapse structure emphasizing the importance of multiprotein complexes is shown. SNARE and MASC are two prototype complexes in the presynaptic and postsynaptic terminal respectively. The presynaptic web and postsynaptic density (shaded areas) are zones where the complexes are found and visible with electron microscopy. The presynaptic and postsynaptic terminals are interlinked by membrane spanning adhesion molecules that connect the protein assemblies within each neuron.

subcellular structure of the synapse is visible with electron microscopy (EM), and landmark features of the presynaptic terminal are synaptic vesicles and an electron-dense region beneath the presynaptic membrane (referred to as the presynaptic web). Within the postsynaptic terminal the characteristic feature at the EM level is another electron-dense region described as the postsynaptic density (PSD). Within these microscopic features are specialized multiprotein complexes, each of which is an assembly of dozens of proteins in the MegaDalton size range like that of ribosomes (Husi and Grant, 2001). The presynaptic and postsynaptic terminals are interlinked by membrane spanning adhesion molecules that connect the protein assemblies within each neuron.

Synaptic disease results from the disruption in the proteins and structures in the hierarchy of the synapse proteome, and it is important to understand general principles of proteome organization and in particular the nature of its constituent multiprotein complexes. There are two prototype complexes at synapses: in the postsynaptic terminal the complexes known as MASC (MAGUK Associated Signaling Complexes) link neurotransmitter receptors and ion channels to intracellular signaling enzymes and adhesion proteins (Husi et al., 2000); and within the presynaptic terminal, synaptic vesicle release is mediated by the SNARE (Soluble NSF-Attachment protein REceptor) protein complexes (Sudhof and Rizo, 2011). MASC and SNARE complexes together are

responsible for organizing at least 15% of all the synapse proteome (over 300 proteins) and comparative genomic studies reveal they are some of the most highly conserved proteins in the brain (Bayes et al., 2011; Emes and Grant, 2011, 2012). MASCs are important in neurotransmitter receptor function and disease and will be described in greater detail to illustrate general principles of multiprotein complex structure and function.

Neurotransmitter receptors, ion channels, and other membrane proteins play the vital role of detecting the signals in the milieu surrounding the synapse, which are principally the dynamic fluctuations in the concentration of neurotransmitter released from the presynaptic terminal. Although neurotransmitter receptors are responsible for binding the ligand, it is now known that their regulation of intracellular biochemical events is mediated by the proteins that physically couple to the receptors (Komiyama et al., 2002; Migaud et al., 1998). A plethora of intracellular and other extracellular adhesion proteins are brought into proximity to the receptor through scaffold proteins (Fig. 24.2) (Fernandez et al., 2009). This clustering of signaling proteins into “particles” confers far more sophisticated signaling properties than an ion channel in isolation. Signaling complexes are widespread in eukaryotes and play a vital role in coordinating communication between cells of metazoans and in unicellular eukaryotes for detecting changes in the external environment (Good et al., 2011; Nourry et al., 2003).

The most widely studied example of a postsynaptic MASC is that formed between the glutamate receptors of the *N*-methyl-D-aspartate (NMDA) family and the scaffold protein Post Synaptic Density 95 (PSD95). PSD95 is a Membrane Associated Guanylate Kinase (MAGUK) family protein and known to interact with over 100 postsynaptic proteins (Fernandez et al., 2009; Husi et al., 2000). These include a variety of signaling, adhesion, and cytoskeletal proteins (Table 24.1). MASC is highly sensitive to the patterns of neuronal activity, which it senses by its neurotransmitter receptor components. The signals from the neurotransmitter receptors are transmitted to the cytoplasmic proteins in part through the influx of Ca^{2+} , which then binds to Ca^{2+} -sensitive proteins that are tethered to PSD95. These in turn catalyze intracellular signaling events such as kinase mediated phosphorylation regulating downstream biochemical pathways. For example, SynGAP is a Ras-GTPase activating protein that regulates the ERK/MAPKinase pathway and it is itself activated by Ca^{2+} influx through the NMDA receptor, which is also tethered to PSD95 (Komiyama et al., 2002). The enzymes in MASC thus engage and drive cell biological pathways that change the properties of the synapse, regulate local protein synthesis, and also transmit signals into the nucleus. It is important to emphasize that the signaling complexes can simultaneously orchestrate and coordinate multiple different downstream signaling pathways that form a network (Coba et al., 2009; Pocklington et al., 2006). Thus MASC is a signal detector and processor that monitors

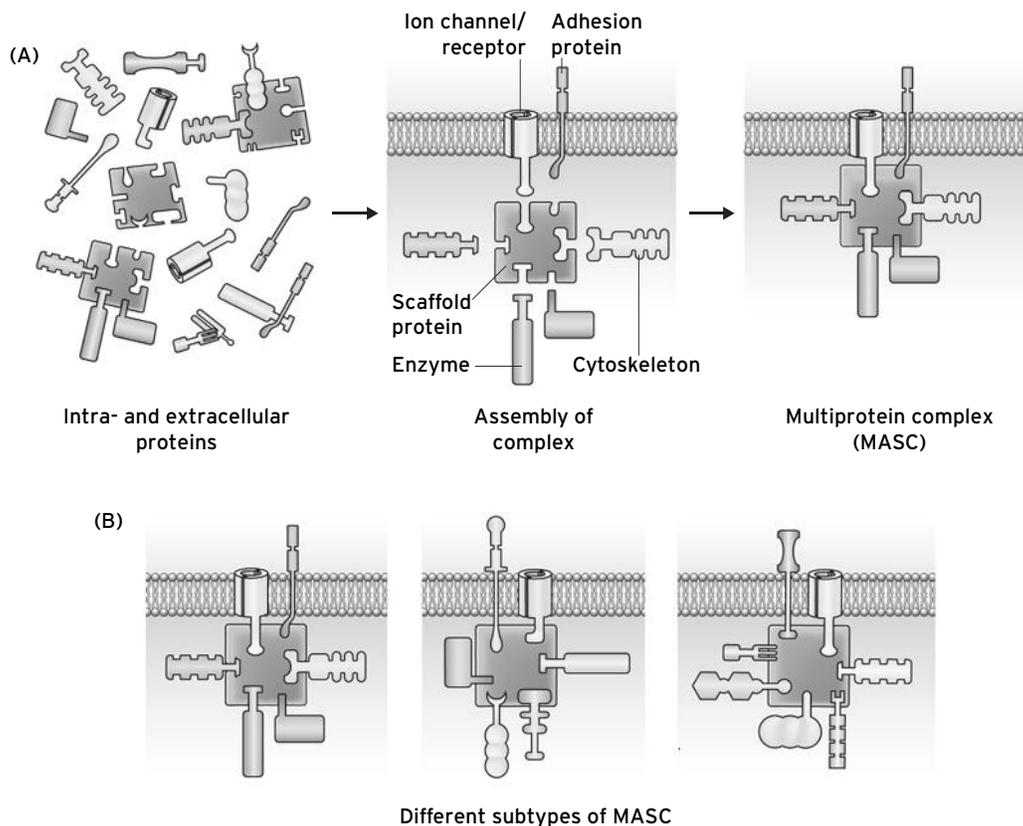

Figure 24.2 Composition of MAGUK associated signaling complexes. (A) Assembly of MASC requires scaffold proteins that bind to a variety of intracellular and extracellular proteins. (B) Different combinations of the binding proteins can assemble into different subtypes of MASC.

TABLE 24.1. Genes encoding proteins in MAGUK Associated Signaling Complexes (MASC) are involved in many neurological and psychiatric diseases. Diseases were annotated from the Genetic Association Database and by manual curation. Genes and Protein identifiers are shown (Gene Name, Entrez Gene ID, UniProt). Molecular Function curated from GO (Gene ontology) and Reference number from PubMed.

neuronal activity and organizes the functional state of the synapse and nerve cell.

Analysis of MASC from brain tissue has shown there is a very large number of proteins (100–300) and it is clear that these are not all found within a single physical complex. Rather, they are shared into different complexes or subtypes forming a family of MASCs (Fig. 24.2). Recent large-scale systematic studies examining the neuroanatomical distribution of gene expression reveal differences in the levels of synapse proteins in different parts of the mouse and human brain (Emes et al., 2008; Hawrylycz, 2012). From these data

it is evident that the various MASC subtypes are differentially distributed in the brain, with some components expressed in particular synapses and neurons and others in different locations (Fig. 24.2B) (Emes et al., 2008). The differential expression of MASC components has implications for disease because mutations in proteins will therefore not affect all synapses and neurons equally. While this is not well documented in humans, studies in genetically modified mice show that mutations that interfere with core MASC components, such as the MAGUK proteins that assemble the complexes, have pronounced electrophysiological and behavioral phenotypes

(Carlisle et al., 2008; Cuthbert et al., 2007; Migaud et al., 1998; Nithianantharajah et al., 2012).

In contrast to the signal transduction complexes formed by neurotransmitters, the complexes in the presynaptic terminal for neurotransmitter release have a mechanical role in catalyzing the fusion of the presynaptic membrane with synaptic vesicles (Sudhof and Rizo, 2011). Core proteins include the SNARE and SM (Sec1/Munc18-like) proteins. These proteins form a helical complex bringing the membranes together and are later dissociated by additional proteins (NSF, *N*-ethylmaleimide sensitive factor). Further interacting proteins including chaperones, synaptotagmin, Munc, and RIM proteins play key roles in tethering to Ca²⁺ channels (that permit Ca²⁺ entry following the arrival of the action potential) and triggering the SNARE proteins.

In addition to signaling complexes and synaptic vesicle complexes, there are also other types of complexes or assemblies at synapses. For example, the multiprotein complexes regulating the synthesis and turnover of proteins including ribosomes and proteasomes are present in the postsynaptic terminal (Haas and Broadie, 2008; Steward et al., 1996; Zalfa et al., 2006). Dysfunction in protein metabolism impacts on many different postsynaptic proteins and thereby produces general debilitating effects. For example, a genetic disorder of cognition involving dysregulation of protein synthesis is Fragile X syndrome. The gene encoding FMRP (Fragile X Mental Retardation Protein) regulates mRNA translation, and its disruption results in widespread changes in MASC and PSD proteins (Darnell et al., 2011). FMRP is also found within multiprotein complexes with CYFIP and other proteins (Schenck et al., 2001; Zalfa et al., 2006; Zalfa et al., 2007). Thus the overall organization and function within the postsynaptic terminal is carried out by sets of large multiprotein machines. The relevance of these complexes to disease will be highlighted in the

following sections by studies showing that multiple mutations impact on these complexes.

SYNAPSE MUTATIONS CAUSE A WIDE RANGE OF DISEASES

The first global view of genetic disease burden on the human synapse proteome came from the systematic characterization of the postsynaptic proteome (Bayes et al., 2011). The study discovered a total of 1,461 PSD proteins from the neocortex, of which a “consensus set” of 748 were common to all samples and subjects. Each PSD gene was annotated to known monogenic diseases identified from the Online Mendelian Inheritance in Man (OMIM) database: 269 monogenic diseases were encoded by 199 genes from the total PSD, and 155 diseases were encoded from 110 genes in the consensus PSD, overall representing ~14% of PSD proteins. The number of disease relevant mutations is continuing to increase with new sequencing data. Diseases with primary symptoms in the nervous system represented ~50% of the total diseases in both PSD sets (133 diseases in total PSD and 82 in consensus PSD) and of all nervous system diseases, ~80% were central nervous system disorders.

Many of these diseases are rare single gene disorders, and others are more common diseases, such as epilepsy and mental retardation, which were caused by mutations in multiple PSD genes (Fig. 24.3). Classifications of human diseases rely on the *International Classification of Diseases*, now in its 10th revision (ICD10). ICD10 relies primarily on overall disease description and from the total of 22 ICD10 disease categories (chapters), PSD diseases mapped primarily to four chapters with most in *Diseases of the nervous system*, which includes neurological disorders: epilepsies, atrophies, paralytic, movement disorders, and neurodegenerative conditions including

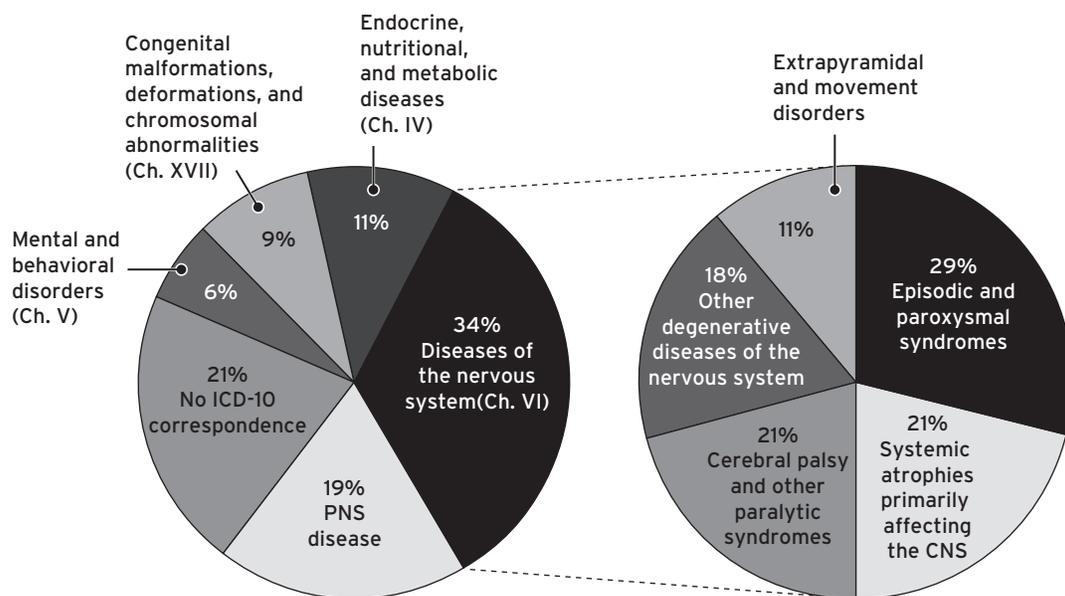

Figure 24.3 Diseases of the human postsynaptic density. Over 130 brain diseases caused by mutations disrupt the human postsynaptic proteome and are here categorized according to the International Classification of Disease chapter system. The left chart shows the distribution into all disease categories with four chapters (IV-VII) representing those affecting the brain. Note that peripheral nervous system (PNS) is also affected. The right chart is an expansion of the disease subclassifications within Chapter VI. (Further details can be found in Bayes et al., 2011, from which this was adapted.)

Alzheimer's and Parkinson's disease. Other major categories of human CNS disorders were also represented, including psychiatric, developmental, and metabolic diseases. The broad range of diseases caused by mutations disrupting the PSD show that neurological and psychiatric diseases have a common etiology in synaptopathy.

DISEASE MUTATIONS CONVERGE ON SYNAPTIC PROTEIN COMPLEXES

Schizophrenia and autism are two diseases that together afflict several percent of the population and produce lifelong problems in cognitive functioning. Large-scale genome-wide studies have excluded the possibility that all patients have a mutation in a single gene and the prevailing view is that each of these diseases arises from mutations in multiple different genes. The study of *de novo* copy number variation has recently become a powerful tool for identifying pathogenic mutations in diseases that have complex multigenic genetics. The essence of the approach is to compare the genome of patients with their normal parents and seek the *de novo* mutations that arose with the disease: these are more likely to be causal than (inherited) genetic variants found using other approaches (Vissers et al., 2010). In a study of hundreds of families with an affected offspring with schizophrenia, *de novo* mutations were identified in many genes, and it was found that there was a highly significant enrichment of mutations in synapse proteins, and in particular the MASC proteins in the PSD (Fig. 24.4) (Kirov et al., 2012).

The convergence of many mutations causing schizophrenia onto MASC strongly supports the view that these complexes are the level in the molecular hierarchy at which the disease and its phenotypes are regulated. In other words, the disease is caused by disruptions to a set of proteins that form MASC—the disease is a “postsynaptic complexopathy.” Similar studies of autism *de novo* CNVs also reported mutations in these postsynaptic signaling complexes and the postsynaptic density (Levy et al., 2011; Pinto et al., 2010). Not only were the same complexes impacted by mutations in these diseases, but some of the same genes. Another similar study of attention-deficit hyperactivity disorder (Elia et al., 2011) and Tourette's syndrome (Fernandez et al., 2011) identified *de novo* mutations that also overlapped with these sets. Thus these genetic and proteomic data reveal that these diseases, which have similar clinical manifestations must have a common underlying etiology, and this etiology is in the disruption of the synaptic signaling complexes.

These examples have emphasized that different *single* gene mutations disrupting the complexes can result in disease in the individual patient. Another genetic mechanism relevant to the model of genetic convergence on multiprotein complexes is to have two or more weaker mutations in different proteins that together have an additive effect—a phenomenon known as epistasis. An example of this type of analysis on glutamate receptors and interacting MAGUK proteins was recently reported in a cohort of schizophrenia and bipolar disorder patients (Frank et al., 2011). Another genetic mechanism

whereby a “spectrum” of related phenotypes can arise is through different mutations (including deletions and duplications) in the same gene as exemplified in Charcot-Marie-Tooth disease (Shchelochkov et al., 2010). It is likely that all of these genetic mechanisms acting on the complexes will be a source of the spectrum of clinical disorders.

While there may be many important disease mutations impacting on synaptic signaling complexes these findings do not imply that other genes such as those encoding proteins in other complexes cannot also produce some of the same diseases and phenotypes. As noted earlier, FMRP when mutated results in the Fragile X syndrome, a relatively common cause of intellectual impairment with autism-like features. Another example would be mutations in transcription factors or genes that regulate transcription such as EHMT1 or MECP2 that could disrupt the expression of proteins in the synapse (Kirov et al., 2012). As a result of the rapid progress in genome sequencing, there are new mutations in psychiatric diseases being discovered each month. Biochemical characterization of the synaptic complexes that these genes regulate is expected to expand in coming years.

A GENETIC AND PROTEOMIC ARCHITECTURE OF BRAIN DISEASE PHENOTYPES

The following section aims to take the reader away from the use of the term “disease” to a more fundamental and reductionist descriptive approach of behavior phenotypes. There are two essential concepts to embrace. First, the clinical manifestation of a disease is a constellation or set of abnormal symptoms or signs. For example, Huntington's disease (HD) is a description of a set of motoric and cognitive impairments. Second, mutations produce phenotypes (because of the disruption of the proteins controlling that behavior or physiological function), and any mutation usually produces multiple phenotypes. The mutation in the Huntington gene that results in HD is an excellent example. Thus a simple hierarchy where diseases are on top and beneath them are the specific phenotypes and beneath these are the genes (and their mutations) can be constructed as shown in Fig. 24.5.

With available knowledge of gene mutations and their phenotypes a map of gene-phenotype-disease relationship can be constructed for any set of genes, such as the postsynaptic proteome (Bayes et al., 2011). This not only permits the identification of the sets of proteins directly relevant to a phenotype (and disease) but can be used to reveal other proteins that interact with them, which may be new disease candidates. Using the knowledge of the postsynaptic proteome all the known Mendelian diseases were cataloged from OMIM, and all the relevant phenotypes identified using the Human Phenotype Ontology (HPO) (Robinson and Mundlos, 2010), which is another catalog that systematically lists all the phenotypes for OMIM diseases. This showed that mutations in 80 PSD genes resulted in 115 human neural phenotypes. Since there are more phenotypes than genes, it is clear that some mutations produce multiple phenotypes. Conversely, many

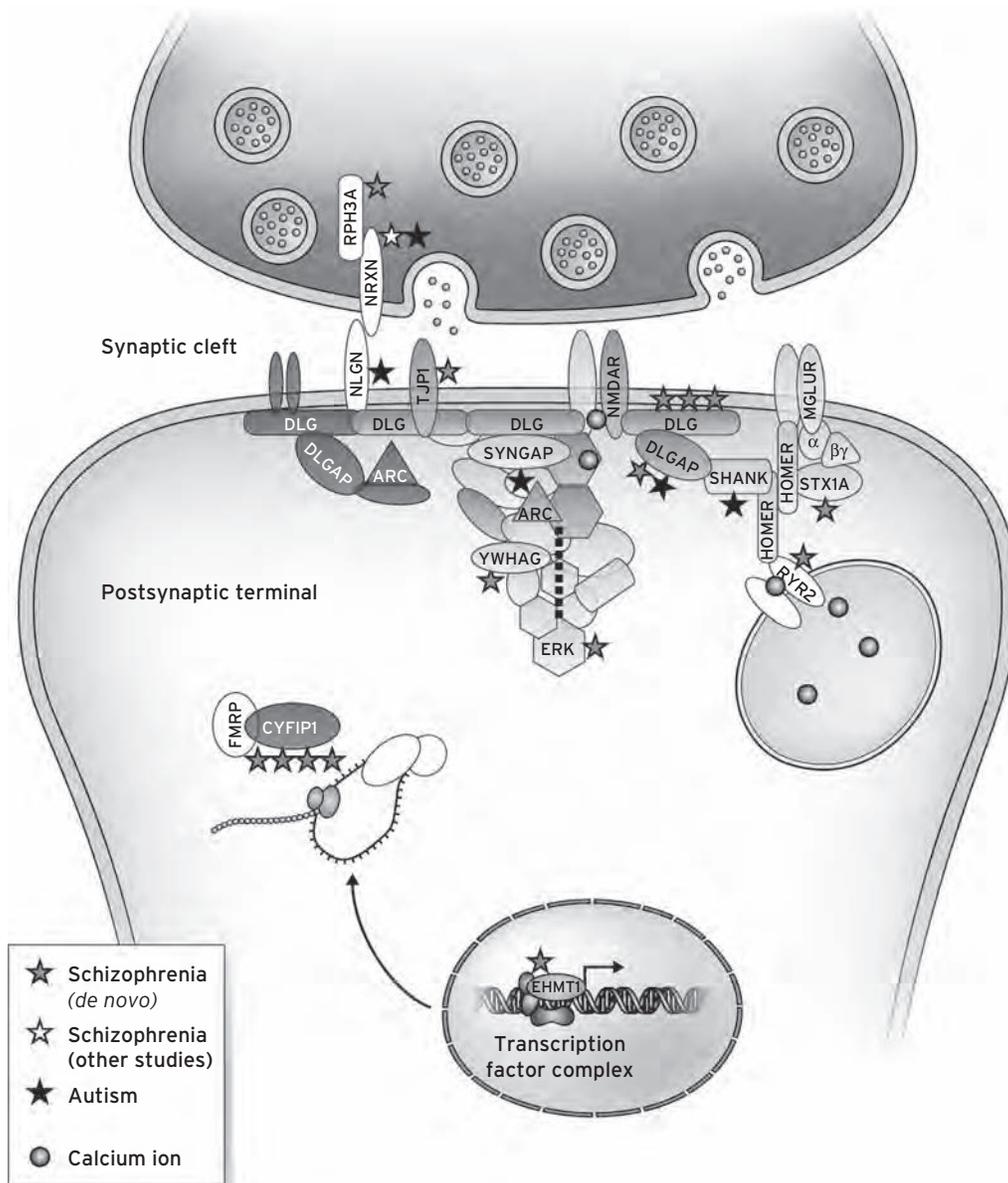

Figure 24.4 Schizophrenia and autism mutations at the synapse. Schematic of the synapse proteome showing individual proteins and complexes impacted by mutations in schizophrenia and autism. From a study of *de novo* copy number variation in 662 schizophrenia proband-parent trios (Kirov et al., 2012) multiple mutations in MASC proteins were found (indicated by gray star). Other studies of schizophrenia and autism have identified mutations in the same sets of proteins (light and dark stars respectively) (See Table 24.1). These disease mutations also impact on presynaptic proteins including those linked to MASC across the synaptic cleft by the adhesion proteins. Within the postsynaptic terminal the complex formed by FMRP and CYFIP1 that controls protein translation is shown with mRNA. This complex is important in schizophrenia and autism (Fragile X Mental Retardation) for controlling synthesis of MASC and PSD proteins. Calcium ions are important in activating postsynaptic signaling proteins in the complexes and these flow into the cytoplasm from the synaptic cleft via the NMDA receptor and other membrane channels as well as from internal membrane-bound stores. The transcription factor complexes in the nucleus are also shown. Individual shapes are specific proteins and relevant names are included and correspond to Table 24.1.

(over 100) phenotypes were caused by mutations in more than one PSD gene and some of these involved large subsets of genes. For example, 40 known mutations cause mental retardation, 29 cause seizures, and 20 cause spasticity. These kinds of studies were also performed in mice, where the genetic mutations are well controlled and the phenotypes accurately measured with similar results. For example, 57 postsynaptic gene mutations result in learning and memory phenotypes, 38 in emotion, and 21 in the phenotype of impaired social interaction.

This large-scale phenotype mapping shows that the symptoms and signs that are the diagnostic features of a disease will depend on which subset of PSD proteins is disrupted. For example, mutations affecting a “cognitive subset of proteins” will result in more cognitive symptoms, and mutations in a “motor subset” will present with more motor symptoms. This is shown in Fig. 24.5, where subnetworks of the postsynaptic proteome comprising interacting proteins control these different phenotypes. Because a protein may be in two phenotype networks, a single mutation can produce two phenotypes. Thus

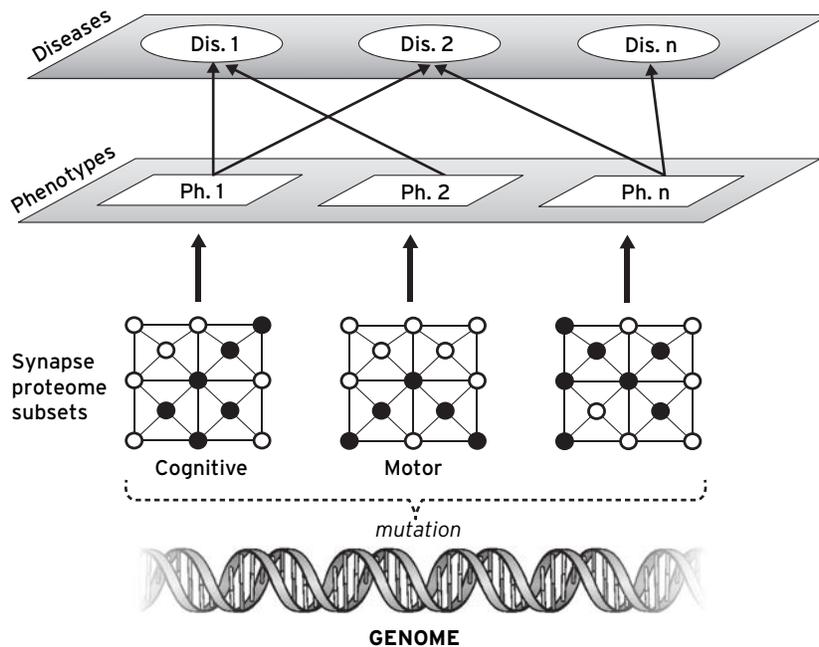

Figure 24.5 Diseases are sets of phenotypes regulated by sets of proteins. Any single disease is defined by a set of clinical symptoms and signs or phenotypes. Proteins in complexes are interconnected (shown by synapse proteome subsets where each protein is a circle) and mutations in subsets of these proteins (shaded circles) cause specific phenotypes (e.g., cognitive or motor, as indicated). Mutations at the level of the genome produce the altered protein function within these proteins. This hierarchy aims to explain how multiple different gene mutations result in disease phenotypes through their convergent effect on specific subsets of proteins within the synapse proteome.

the phenotype spectrum or constellation is dependent not only on the gene, but also on the interactions of its encoded protein with other synaptic proteins. These subsets also help explain why some phenotypes are common to multiple diseases. From this outline, it will be possible in future to develop a molecular categorization of PSD diseases mapping diseases and phenotypes onto protein complexes or networks of PSD proteins.

These studies of the genetic and proteomic architecture of the whole postsynaptic proteome also apply to sets of proteins found in physical complexes such as MASC, and reveal their role in the etiology of multiple diseases. As shown in Table 24.1 and Fig. 24.4, disruption of the different proteins in MASC results in a set of diseases. This indicates a common molecular etiology at the level of the multiprotein complexes for diseases that have heretofore been considered to be separate. This helps explain why these diseases are similar and in some instances very difficult to distinguish, as well as why the same gene mutation can be found in two diseases.

FUTURE PERSPECTIVES

The present era of psychiatry is one where genome sequencing is having a major impact by identifying DNA variants in disease. It is clear that genetic based diagnosis will be a major asset in the future, but alone will not be sufficient for classification of the disease. It will also be necessary to use new behavioral diagnostic approaches that go beyond interviews, such as the computerized touchscreen based methods of cognitive testing (Barnett et al., 2010; Nithianantharajah et al., 2012). Together

with genome sequencing, there will be a more definitive definition of both the underlying molecular mechanisms as well as phenotypic characteristics that may indicate degree or extent of disease progression. These types of measure will also be necessary to assess outcomes in clinical trials.

The identification of the phenotypes that comprise the disease (sometimes called endophenotypes) and their specific molecular basis will focus attention on new therapeutic targets. Targets that are within the subsets of proteins controlling a phenotype could be used to treat all the diseases that share that phenotype. Progress in this area will require more research toward understanding the organization of the sets of proteins into multiprotein complexes and new types of drug screening assays.

The recognition that synaptopathies are important in neurology and psychiatry and in pediatric disorders of the nervous system suggests that there are avenues for changing the structure of clinical training programs around synapses. Clinicians who are experts on synaptic diseases could cross the traditional boundaries between psychiatry and neurology. This would require training programs based on fundamental neuroscience of synapses together with a rigorous understanding of human genetics.

25 | NEURODEVELOPMENT AND SCHIZOPHRENIA

ESTER J. KWON,* TAKAHIRO SODA,* AND LI-HUEI TSAI

INTRODUCTION

Schizophrenia affects approximately 1% of the world's population and is a major contributor to both years lost to disability and health care costs. Despite the significant impetus to understand the etiology of schizophrenia and to develop therapeutics to ease the burden of disease, progress has been limited. This may be due to the complexity of the underlying genetics as well as heterogeneity within and between psychiatric diagnoses. What is clear is that there is a genetic component to schizophrenia risk as well as environmental factors that are important for the manifestation of disease. At this point, the genetic causes of schizophrenia remain largely elusive except for highly penetrant but rare variants, which account only for a small fraction of schizophrenia cases. The most notable example is disrupted in schizophrenia-1 (DISC1), which was identified in a Scottish family with a near Mendelian inheritance of psychiatric diseases. Although rare variants are not the genetic cause of schizophrenia for the vast majority of cases, they may be instructive for the identification of underlying pathways that are dysregulated in schizophrenia.

A NEURODEVELOPMENTAL MODEL OF SCHIZOPHRENIA

A neurodevelopmental model of schizophrenia has been hypothesized by numerous researchers. This model postulates that some of the key aspects of brain development that normally occur both pre- and postnatally are not occurring correctly, either in time or space. Complex neural circuitry needs to form and be modulated by experience. Classically, proliferation, migration, arborization and myelination occur prenatally. Elaboration and refining of dendritic trees and synapses as well as myelination of the nervous system continues through the first two-decades of life. There are opportunities for genetic and environmental abnormalities and variation to profoundly influence the trajectories of all of these critical functional processes. Temporal correlation is noted between the prodromal aspects of schizophrenia, in particular abnormalities in cognition and in the neuroanatomic development of regions of the cerebral cortex. As reviewed in earlier chapters, there is some evidence suggesting that reduced interneuron activity may be involved. Some of the key evidence that developmental processes are awry and their potential causes is reviewed in the following and in the subsequent two chapters.

* Authors contributed equally and are presented in alphabetical order.

ENVIRONMENTAL EFFECTS DURING DEVELOPMENT

The 50% concordance of schizophrenia between monozygotic twins demonstrates that there is a clear genetic component to disease onset, and the incomplete concordance highlights that there are also other factors in play. Many epidemiological observations associated with increased risk of schizophrenia suggest exposures that might influence brain development. For a comprehensive review see Brown (2011).

Significant effort has been put into correlating pre- and perinatal disturbances to the development of schizophrenia. Numerous studies have linked phenomena such as maternal nutrition and infection, season of birth, and obstetrical complications to the manifestation of schizophrenia later in life (Lewis and Levitt, 2002). Studies of children born from mothers who were in early pregnancy during the Dutch Hunger winter have shown association with schizophrenia, as well as with depression and mood disorders, increasing the risk of schizophrenia approximately twofold. The association of famine with schizophrenia was also observed in the 1959–1961 Chinese famines in two separate regions, Liuzhou and Wuhu (Rapoport et al., 2012). Improvements in imaging technology and longitudinal studies with collection of tissue and blood samples will aid the understanding of how these factors contribute to schizophrenia onset in the future.

An example of association with an environmental factor that may be present during adolescence, and that has now been replicated in several carefully controlled studies is being in a minority group position. Studies examining association of schizophrenia with being in a minority group position show that development of psychosis is dependent on the proportion of their own ethnic group present in the area. Furthermore, the association is seen in first- and second-generation migrants and across several ethnic groups, indicating that it is not the ethnicity or migration itself that is causing the association. Other examples include growing up in an urban environment and experiencing developmental trauma (van Os et al., 2010). These three factors clearly have components of stress, although it is still not understood what types of stress and during which developmental times stresses occur that are related to the onset of psychosis. In addition to these environmental factors, there are also examples of more acute triggers that track with schizophrenia. A meta-analysis of people who have antibodies to *Toxoplasma gondii* has found associations to schizophrenia that replicated previous findings, showing that *Toxoplasma gondii* infection conferred an odds ratio of ~2.7 (Torrey et al., 2012).

The presence of antibodies indicated an infection up to the point of analysis, which was after onset of disease; work remains to be done pinpointing whether there is a time window of infection that is relevant for the development of psychosis. Another factor thought to be associated with the onset of psychosis is the use of cannabis. Although reverse causation is a concern when studying cannabis use, a meta-analysis of studies where baseline psychosis was a criterion for exclusion found that there was an increased risk of psychosis with cannabis use associated with an odds ratio of 1.4 (Moore et al., 2007).

Each of these associations implicate periods of stress, for example, nutritional, immunological, or social, in the onset of schizophrenia. These associated factors serve as proxies for what stimulus is really affecting the molecular basis of schizophrenia progression, which remains to be uncovered in future studies. Epigenetics (e.g., DNA methylation, histone acetylation, and noncoding RNA) has been shown to be able to have a strong influence in the case of maternal nutrition and the development of obesity and diabetes and may be important in the role of neurodevelopmental influences in schizophrenia (Bale et al., 2010).

NEUROPATHOLOGY ASSOCIATED WITH SCHIZOPHRENIA

The macroscopic phenotypes that have most predictably tracked with schizophrenia are ventricular enlargement and slight reductions in brain volume and weight as measured in whole brain imaging studies or in postmortem samples (Lawrie and Abukmeil, 1998). Other endophenotypes of schizophrenia include structural changes in various brain regions, changes in gray matter volume, cortical thickness, and neuronal integrity (Harrison and Weinberger, 2005).

Brain imaging studies of rare childhood onset schizophrenia cases (1/500 cases of schizophrenia), which are often similar to more severe outcomes of schizophrenia, provide an opportunity to understand how brain development may be perturbed in schizophrenia, and they are less likely to be influenced by environmental factors such as substance abuse, which is known to cause structural changes to the brain. Longitudinal studies were conducted starting in 1991 at the NIMH, where more than 100 child-onset schizophrenia patients and their siblings underwent brain imaging four–five times every two years. The average age of onset was 10 years, and there was an equal distribution between males and females (Gogtay et al., 2011). These studies show that phenotypes are preserved between child and adult onset schizophrenia, such as increased lateral ventricular sizes, and decreased overall gray matter, hippocampus, and amygdala volumes (Gogtay and Rapoport, 2008). In the course of normal development, gray matter volumes follow an inverted U-shape curve, where they increase throughout childhood and peak at puberty, whereas white matter volumes steadily increase into adulthood. The NIH longitudinal study showed that in child onset schizophrenia gray matter loss occurs throughout development and that white matter development is retarded when compared with control cases. These data support the concept that schizophrenia is a progressive

disease with perturbations throughout neurodevelopment that lead up to its onset in early adulthood.

Another longitudinal study was conducted on ultra-high-risk schizophrenia candidates, as determined by their mental health state and family history of mental illness, in Melbourne, Australia (Gogtay et al., 2011). The candidates were on average 19 years of age and 40% developed schizophrenia within 12 months of the initiation of the study, allowing for the imaging of brains and discovery of perturbations during the period of onset between those candidates who developed psychosis and those who did not. They found that there was gray matter loss in the left medial and inferior temporal regions, the anterior cingulate cortex, and in the left orbitofrontal cortex in patients who developed psychosis, which was not seen in those who did not develop psychosis (Gogtay et al., 2011).

Although there is a decrease in brain volume, a significant change in number of neurons has not been observed. One hypothesis is that the decrease in volume is due to the loss of neuronal processes, such as axons, dendrites, and dendritic spines, referred to collectively as the neuropil. Analyses of postmortem brains have shown a marked decrease in dendritic spines in schizophrenic patients when compared with controls, especially in cortical pyramidal neurons (Garey, 2010). A diffusion-weighted magnetic resonance imaging technique called diffusion tensor imaging (DTI) is used to image fiber pathways and connection integrity of white matter in living subjects. In white matter, the flow of water is largely restricted to the tracts and therefore has directionality that can be used as a proxy for the integrity of the fibers.

Before the onset of the majority of schizophrenia cases in late adolescence/early adulthood, there are cognitive deficits that can be observed before diagnosis is made (Gold and Weinberger, 1995). Furthermore, these cognitive deficits are found in undiagnosed family members who have not been exposed to treatment, indicating that there is a genetic disposition for cognitive dysfunction that may be used as a hallmark of severity of disease. The most consistent finding resulting from functional magnetic resonance imaging (fMRI) studies in schizophrenic patients is changes in activity in the dorsolateral prefrontal cortex (DLPFC) during working memory tasks. Schizophrenic patients have decreased performance on working memory tasks, which is correlated with decreased activity in the DLPFC. One nuance is that for tasks in which schizophrenic patients have similar performance as control subjects, there is an increased activity in the DLPFC (Lewis et al., 2005). The impairment in working memory has led investigators to posit several hypotheses based on neurotransmitters and connectivity.

OLIGODENDROCYTES, MYELIN, DEVELOPMENT, AND SCHIZOPHRENIA

White matter integrity is measured in DTI by fractional anisotropy, which is representative of myelination and tract organization. Over the many DTI studies performed on schizophrenia cohorts, there are decreases in fractional anisotropy measurements in white matter across many brain

regions, most consistently in the cingulate, corpus callosum, and frontal lobes (Thomason and Thompson, 2011). Moreover, in a study of prodromal ultra-high-risk psychosis candidates, there were decreases in fractional anisotropy that preceded disease onset (Karlsgodt et al., 2009). In addition, there is a well-characterized reduction in expression of oligodendrocytes and myelin related genes in postmortem brain samples. Structural analyses in postmortem brain have also shown both a decreased density of oligodendrocytes and damaged myelin sheaths in schizophrenia cases compared to controls. Furthermore, a wide variety of candidate genes involved in oligodendrocyte development have found modest associations with increased risk of schizophrenia (see Takahashi et al., 2011, for review).

The temporal process of myelination is correlated with the developmental trajectory of schizophrenia. Myelination is incomplete at birth and develops gradually, with some cortical areas not being completed until adulthood. For example, regions expected to be of particular relevance to schizophrenia such as cortical and hippocampal pathways are not fully myelinated until adulthood. Diseases whose primary pathology is in white matter, such as the leukodystrophies, are often accompanied by psychosis, which suggests a shared altered basic role for myelination and oligodendrocytes. Furthermore, an appealing hypothesis is that oligodendrocyte and myelin dysfunction exerts its role in schizophrenia by altering key features of synaptic activity such as synaptic plasticity or the production of synchronous oscillating activities implicated in establishing aspects of cognition (Walterfang et al., 2011).

NEUROTRANSMITTERS AND ANTIPSYCHOTIC DRUGS

There are several theories associating dysfunction of neurotransmitter pathways and schizophrenia based on neuropharmacological studies, which include the GABA, NMDA, and dopamine theories. It is important to note that none of these are theories are exclusive, neither among themselves nor to the other theories presented, which will be discussed in a subsequent chapter.

Antipsychotic drugs used to treat schizophrenia are effective in mitigating the positive symptoms, such as hallucinations and delusions. The first widely used antipsychotic, chlorpromazine, blocks the dopamine D2 receptor. Derivative first- and second-generation antipsychotics by and large also target the dopamine D2 receptor. Though the D2 receptor has been generally established as the site of action for antipsychotics, the mechanism of action is less clear. There are several pathways downstream of the dopamine D2 receptor, and it is becoming apparent that the localization of dopamine D2 receptor interaction proteins, in addition to the location of the D2 receptor itself, may impact which downstream pathways become affected.

The D2 receptor acts as a classical G protein-coupled receptor, and has been associated with the $G_{\alpha i/o} G_{\beta\gamma}$ heterotrimeric G protein complex. Activation of this pathway is associated with the inhibition of downstream cAMP signaling. Coupling

of these receptors to presynaptic K^+ channels has been shown to lead to the inhibition of neurotransmitter release. In addition, it has been reported that these receptors and D1/D2 heterooligomeric receptors activate downstream Ca^{2+} signaling via coupling to $G_qG_{\beta\gamma}$ and the activation of phospholipase C.

The D2 receptor has also been shown to activate another signaling pathway, the phosphatidylinositol (3,4,5)-triphosphate kinase (PI3K)/AKT/mammalian Target of Rapamycin (mTOR) pathway, a pathway that regulates the Wnt signaling cascade. The PI3K/AKT/mTOR pathway is also activated by another class of membrane-bound receptors, the receptor tyrosine kinases. In the baseline state, AKT is bound to phosphatidylinositol(3,4)-bisphosphate (PIP2). Upon activation of a receptor tyrosine kinase or a G protein-coupled receptor, PI3K phosphorylates PIP2 to form PIP3. AKT bound to PIP3 is then phosphorylated by mTOR complex 2 (mTORC2), then phosphorylated by phosphoinositide dependent kinase 1 (PDK1). The phosphorylation by both kinases activates AKT to then phosphorylate its many downstream targets, including mTOR (implicated in autism), GSK3 β (involved in the Wnt signaling cascade), BAD (a pro-apoptotic mitochondrial protein), and I κ B kinase (IKK; regulator of NF κ B mediated transcription).

The intersection of the AKT pathway with the pharmacology of psychiatric disorder treatment is notable. Dopamine D2 receptors have been shown to modulate AKT signaling by recruiting a signaling complex that results in the inactivation of AKT. Upon D2 receptor activation and phosphorylation by G protein-coupled receptor kinase (GRK), β -arrestin and protein phosphatase 2A (PP2A) are recruited to the cell membrane, where they interact with and dephosphorylate AKT. Antipsychotics, which are antagonists to the D2 receptor, block this signaling cascade and allow AKT to remain active (Freyberg et al., 2010).

Lithium, a treatment for bipolar disorder that can also be prescribed in conjunction with antipsychotics for the treatment of schizophrenia, is shown to lead to inhibition of glycogen synthase kinase β (GSK3 β). It has been shown that lithium activates AKT to phosphorylate GSK3 β , leading to GSK3 β inhibition. Lithium has also been proposed to solubilize AKT from the β -arrestin/PP2A complex, which mediates portions of downstream D2 receptor signaling functions (Beaulieu, 2012). Thus, both antipsychotic and lithium treatments secondarily affect the Wnt pathway via affecting AKT activity.

RARE AND COMMON GENETIC VARIATION IN SCHIZOPHRENIA

Recent genetic evidence has found that *de novo* duplications and deletions of DNA, termed copy number variations (CNVs), increase the risk of schizophrenia. As noted in an earlier chapter, many of these CNVs have been associated with a wide variety of developmental phenotypes. One early CNV study found novel CNVs greater than 100 kilobases in schizophrenic patients and their families and found an increased number of CNVs in patients, with a disproportionate number in genes related to neurodevelopmental pathways (Walsh et al., 2008).

International collaborative efforts have resulted in findings from genome-wide association studies (GWASs) with cohorts on the scale of tens of thousands of control and schizophrenia cases (Ripke et al., 2011; Stefansson et al., 2009). While further GWAS findings are anticipated, even the early studies suggest that there may be some convergence of gene candidates involved in neurodevelopmental phenomena and synaptic processes. The haploinsufficiency of one identified gene identified as genome-wide significant by GWAS, *TCF4*, leads to Pitt-Hopkins mental retardation in humans (Brockschmidt et al., 2007) and is also involved in the specification of specific subsets of neural progenitors in the mouse (Flora et al., 2007). Another genome-wide significant GWAS identified gene, *CACNA1C*, encodes a subunit of an L-type calcium channel leading to the intriguing theory that there may be aberrant synaptic transmission underlying the brain activation changes observed in functional neuroimaging studies (Bigos et al., 2010). There is a major ongoing effort to understand the biology of schizophrenia GWAS candidates and whether they are dysregulated and/or dysfunctional in the context of human disease.

Collectively, gene candidates of schizophrenia identified by studying both CNVs and common risk SNPs are converging on pathways that regulate neurodevelopmental and synaptic phenomena. It is also important to note that there is emerging evidence of a shared set of risk factors between psychiatric disorders including schizophrenia and bipolar, as well as autism. There are also several recurrent CNVs that are common between schizophrenic and autistic patients, such as 1q21.1, 15q11.2, 15q13.3, 17q12 (Malhotra and Sebat, 2012; Mefford et al., 2008; Stefansson et al., 2008).

PATHWAYS

Based on the neuropharmacology and neuropathological findings, there have been several theories suggested to understand the etiology of schizophrenia including the GABA, dopamine, and glutamate hypotheses. Although each of these pathways is likely to contribute to and/or be resultant from schizophrenia pathology, none alone is sufficient to explain the onset of disease and the presence of the spectrum of symptoms displayed by schizophrenic patients. An alternative way of understanding the etiology of schizophrenia and disease-associated genetic loci is to examine their involvement in dysregulated biochemical pathways. One such study compared significant and non-significant SNPs from the International Schizophrenia Consortium to pathways described in the Kyoto Encyclopaedia of Genes and Genomes (O'Dushlaine et al., 2011). The only significantly associated pathway found was the cell-adhesion molecule pathway, which is important for synaptic formation and cell signaling. One caveat to this approach is that the functions of many genes identified in CNV and GWAS studies are yet unknown, and thus insights gained from these types of analyses are just emerging. It may therefore be more fruitful at this early stage of understanding schizophrenia genetics to specify genes that are unmistakably linked to disease and study

their function as a starting point to understand the context of common risk alleles that have lower effect sizes and occur in complex constellations.

As noted earlier, perturbation of neurodevelopmental processes in schizophrenia is a theory that is accumulating supporting evidence. There are pre- and perinatal environmental factors described in the preceding that are thought to associate with risk of schizophrenia as well as the changes in neuroanatomical structures and cognition observed before the manifestation of disease. There are also many gene candidates of neuropsychiatric disease that perturb biochemical pathways associated with neurogenesis and neuronal migration as well as spine morphogenesis, which are discussed in the following and are summarized in Table 25.1. The confluence of genetic and environmental factors on neurodevelopmental pathways is depicted in Figure 25.1.

EARLY DEVELOPMENT PATHWAYS

DISC1

DISC1 was identified in a Scottish pedigree in which it was disrupted by a balanced translocation, t(1:11)(q42.1;q14.3). The translocation segregated with psychiatric disorders such as schizophrenia, major depression, and bipolar disease with a combined OR 7.1. Mouse models expressing a transgene of human DISC1 recapitulating the Scottish translocation exhibit increased ventricle size, decreased gray matter volume, and changes in dendritic arborization in cortical and hippocampal neurons, mimicking the endophenotypes found in humans. Mouse models of DISC1 and their neuroanatomical, behavioral, and cellular phenotypes are summarized in the review by Jaaro-Peled (2009). The mice also exhibit behavioral abnormalities such as hyperactivity, increased immobility in the forced swim test, decreased sociability, and impaired working memory. Mouse models have also been demonstrated to have reduced embryonic and adult hippocampal neurogenesis. DISC1 is also implicated in proper integration of newborn neurons in the adult dentate gyrus.

DISC1 is a pleiotropic protein with numerous interaction partners affecting multiple biochemical signaling pathways that impact neuronal development and function. Some validated interacting partners for DISC1 include NDE1, NDEL1, LIS1, Kalirin-7, ATF4/5, GSK3 β , and the PDE4 family of phosphodiesterases. The study of DISC1 is instructive since it is implicated in psychiatric disease and has a major role in early developmental phenomena and synaptic pathways.

WNT PATHWAY

The Wnt family consists of 19 secreted lipoproteins that act as morphogens and play important roles in the development and patterning of various limbs and organs. Wnts bind to their cell surface receptor, the Frizzled (Fz) family of seven transmembrane G protein-coupled receptors, of which 10 have been identified to date. The various Wnt and Fz proteins have

TABLE 25.1. Genetic loci, effect size, affected genes, and their known role in neuronal development. A select table highlighting the known risk loci with putative effects on genes affecting neuronal development

distinct and overlapping patterns throughout the body, which is thought to account for the variability of phenotypes that result upon loss of function, and multiple downstream pathways have been shown to be activated downstream of Wnt binding.

CANONICAL WNT SIGNALING

The canonical Wnt signaling pathway is defined by the involvement of the transcriptional coactivator β -catenin and the downstream signaling cascades that are associated with it. β -catenin is normally confined to the cell membrane as part

of the adherens junctions complex in neuronal progenitors in the central nervous system. Upon Wnt ligand binding, Fz proteins bind to dishevelled proteins (Dvl). In the absence of Wnt binding, Dvl is part of a destruction complex in conjunction with axis inhibitor (Axin), adenomatous polyposis coli (APC), casein kinase 1 alpha (CK1 α), and GSK3 β . This destruction complex binds and phosphorylates β -catenin at multiple sites, designating it for proteosomal degradation and preventing the accumulation of β -catenin in the absence of Wnt. In the presence of Wnt stimulation, Fz-associated Dvl polymerizes and binds Axin through DIX domains. Axin binding recruits

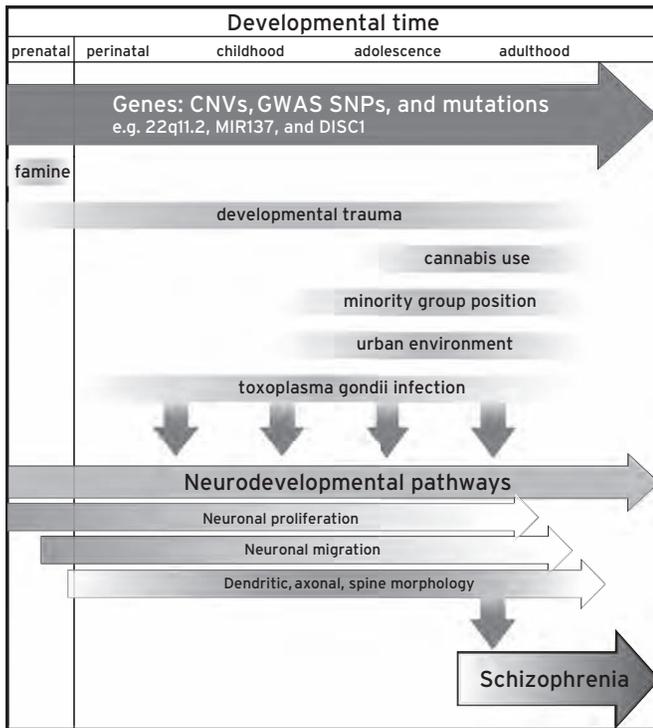

Figure 25.1 Factors that influence schizophrenia. Genes and environmental components affect neurodevelopmental pathways throughout life spans.

CK1 α and GSK3 β to the LRP5/6 complex, resulting in their phosphorylation and increased affinity for Axin. The interaction with LRP5/6 directly inhibits the phosphorylation of β -catenin by GSK3 β , allowing for the cytosolic accumulation of β -catenin and its subsequent nuclear localization.

In the nucleus, β -catenin acts as a transcriptional co-activator of the T-cell factor and lymphoid enhancer-binding protein (TCF/LEF) transcription factors, which control the dynamics of the cell cycle partly via the regulation of cyclinD1. TCF/LEF has three identified domains: a high mobility group (HMG) box domain that is crucial for DNA interaction, a caspase activated deoxyribonuclease (CAD) domain necessary for binding to Groucho/TLE, and an N-terminal β -catenin binding domain. In the absence of nuclear β -catenin, the TCF/LEF occupying TCF/LEF DNA binding sites is bound to tetrameric Groucho/TLE, which recruits transcriptional repressors, such as histone deacetylases (HDACs), keeping the DNA in a condensed, repressed state. β -catenin directly competes with, and displaces Groucho/TLE (Daniels and Weis, 2005), and recruits general transcriptional activators such as the histone acetyltransferase CBP, the SWI/SNF complex protein Brg-1, and TATA-binding protein, as well as a more specific core complex consisting of Pygopus and Legless/BCL9 (Logan and Nusse, 2004). CBP acetylates histone residues in the promoter region, and the recruitment of Pygopus and Legless/BCL9 leads to the methylation of H3K9 residues by SET-1 methyltransferases, altering the chromatin structure from a condensed, transcriptionally repressed state to a more relaxed and open state, allowing for transcription (Fiedler et al., 2008). A comprehensive review of the Wnt signaling pathway in development can be found here (van Amerongen and Nusse, 2009).

ROLE OF THE CANONICAL WNT SIGNALING PATHWAY IN NEURONAL DEVELOPMENT

Numerous proteins within the canonical Wnt signaling pathway have been linked with neuronal development. GSK3 inactivation, achieved by a conditional knockout of both GSK3 α and β resulted in a larger brain with an expansion of the progenitor pool with a concomitant reduction in the thickness of the cortex, indicating that GSK3 promotes progenitor proliferation while suppressing neuronal differentiation (Kim et al., 2009). Overexpression of stabilized β -catenin also results in mice with an increase in brain size, and an increased fraction of cells reentering the cell cycle, essentially phenocopy the GSK3 knockout phenotype, while mice with β -catenin mutations which selectively abolish its transactivation function have defects in forebrain development, accompanied by a decrease in the neuronal progenitor pool (Valenta et al., 2011), reiterating the crucial role of the proteins in the canonical Wnt pathway in the maintenance of the neuronal progenitor pool.

In summary, many factors crucial to the canonical Wnt pathway, as well as numerous interacting proteins with the pathway, have been shown to play crucial roles in neurogenesis, neuronal migration, axon/dendrite growth and morphology, and synaptic development. For a more extensive review of Wnt signaling and development, see Kim and Snider (2011).

DISC1 AND THE WNT SIGNALING PATHWAY

DISC1 has been shown to bind to and inhibit the activity of GSK3 β , one of two forms of an enzyme that is known to lead to the phosphorylation of many downstream proteins that are crucial for the pathophysiology of many nervous system disorders. One GSK3 β target is TAU, which forms aggregates in many nervous system disorders including Alzheimer's disease (TAU forms the neurofibrillary tangles that are used in the Braak and Braak postmortem staging of disease progress), Parkinson's disease, and tuberous sclerosis. Another GSK3 β target is β -catenin, the crucial component of the canonical Wnt signaling pathway. DISC1 promotes the maintenance of the neuronal progenitor pool by inhibiting GSK3 β , allowing cytoplasmic β -catenin to accumulate, and transduce canonical Wnt signaling. The loss of DISC1 leads to decreased neuronal progenitor proliferation by promoting early cell cycle exit in neurons (Mao et al., 2009; Ming and Song, 2009). DISC1 provides further evidence that the Wnt signaling pathway may be involved in both neurodevelopment and psychiatric disorders.

WNT PATHWAY AND PSYCHIATRIC DISEASE GENE CANDIDATES

Several players in the Wnt signaling pathways have been associated with psychiatric disease, in addition to DISC1 (Fig. 25.2). Glycosylation is a form of regulation of Wnt ligands and their receptors, and perturbations of glycosylation are known to affect their function, localization, and signaling. SNPs in genes that are involved in glycan synthesis (Kegg pathway: hsa01030) associate with schizophrenia (O'Dushlaine et al., 2011), which raises a possibility that a part of the phenotypes caused by perturbations in this molecular pathway act via disruption of

the Wnt pathway. Furthermore, several candidate genes, such as MMP16 and Tbx1, are transcriptionally regulated via Wnt activation of TCF/LEF transcription (Huh and Ornitz, 2010; Lowy et al., 2006). Mice hemizygous for Tbx1, located in the 22q11.2 microdeletion, display behavioral phenotypes that are associated with psychiatric disease (Hiramoto et al., 2011; Paylor et al., 2006).

Chromodomain helicase DNA binding protein 8 (CHD8), associated with autism in several exome sequencing studies (Neale et al., 2012; O’Roak et al., 2012), is also recruited to TCF/LEF sites along with β -catenin. CHD8 has been shown to counter the activating activity of β -catenin, by binding to β -catenin and also Histone1, and thus limiting the relaxation of chromatin. BCL9, mentioned earlier as a core component of the transcriptional complex mediating Wnt signaling, is one of the genes in the 1q21.1 recurrent CNV, in which microdeletions have been associated with schizophrenia and microcephaly, and microduplications associated with autism and macrocephaly. Furthermore, ADA2A, in the 17q12 microdeletion associated with autism, is known to be an acetyltransferase required for transcriptional activity and proliferative effects mediated by β -catenin (Yang et al., 2008).

Microdeletions of 3q29 have been associated with microencephaly, dysmorphology, and autistic features, and more recently schizophrenia (Mulle et al., 2010). Several genes in this locus have roles in the Wnt pathway. Discs, large homolog 1 (DLG1 or Sap97) is one of the binding partners of Fz and

is known to signal downstream of Wnt binding by binding to APC, affecting cell proliferation. p21 protein (Cdc42/Rac)-activated kinase 2 (PAK2), also in the 3q29 CNV, also serves to phosphorylate and promote the nuclear localization of β -catenin (Zhou et al., 2011).

Neuregulin 1 and its receptor ErbB4, are other well-studied candidates found to have SNPs associated with schizophrenia and play roles in neuronal migration and synapse formation (Mei and Xiong, 2008). ErbB4 is a receptor tyrosine kinase, and its family members have been shown to activate cascades that phosphorylate and lead to the intracellular localization of β -catenin: overexpression of ErbB4 Cyt2 increased nuclear β -catenin and TCF-LEF transcriptional activity (Muraoka-Cook et al., 2009).

WNT SIGNALING AND CELL MORPHOLOGIES

Binding of Wnt to Fz leads to activation of pathways involved in planar cell polarity, acting through Dvl, activating RhoA and Ras-related C3 botulinum toxin substrate 1 Rac1 (Gao et al., 2011; Shafer et al., 2011). Rac1 activation then activates c-Jun N-terminal kinase (JNK) downstream of Wnt7b (Rosso et al., 2005). JNK activation has been shown to be crucial for the proper development of axons and dendrites (de Anda et al., 2012; Rosso et al., 2005), and to enhance or inhibit canonical Wnt activation, depending on the Wnt ligand (Billiard et al., 2005). Tao Kinase 2, in the 16p11.2 region, which has CNVs that associate with both autism and schizophrenia (deletion

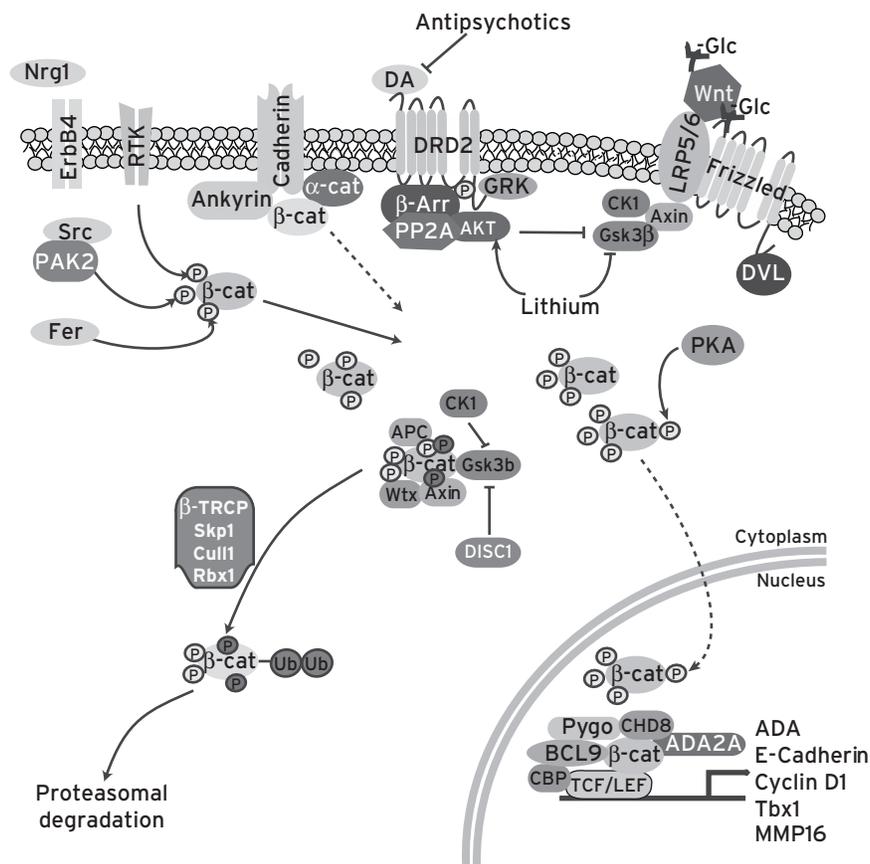

Figure 25.2 Many genes associated with psychiatric disorders regulate or are regulated by the Wnt signaling pathway.

and duplication, respectively), also plays a role in the activation of JNK and affects basal dendrite formation (de Anda et al., 2012; McCarthy et al., 2009).

The proteins in the canonical Wnt pathway also have an effect on postmitotic neurons independent of their effect on β -catenin. One of the alternative β -catenin independent pathways that is downstream of LRP5/6- Frizzled signaling depends on the inhibition of GSK3 β . GSK3 β is known to destabilize microtubules by phosphorylating microtubule proteins such as TAU, MAP1B, and MAP2. Inhibition of GSK3 β stabilizes microtubules, promoting axon growth and growth cone remodeling. The phosphorylation of collapsin response mediator protein 2 (CRMP2) by GSK3 is crucial for neuronal polarity, and CRMP2 has been shown to be involved in determining axon/dendrite fate (Yoshimura et al., 2005). Knockdown of Axin results in the abolishment of axon formation in postmitotic neurons. APC, part of the destruction complex in Wnt signaling, also plays a role in neurite extension and neuronal migration. In this manner, the Wnt pathway is able to exert effects on neuronal morphology.

Binding of Wnt to Ryk has been shown to directly activate the Src pathway, similar to the activation of many other receptor tyrosine kinases. The activation of Src, in turn, has been shown to be crucial for axon guidance. Ryk has also been shown to interact directly to Fz8, as well as Dvl, and to potentiate the canonical Wnt signaling pathway, suggesting that the presence of Ryk in conjunction with Fz may either stabilize the Dvl-Fz interaction, or enhance Axin interaction with Fz (Lu et al., 2004). The convergence of neuropharmacological and genetic evidence makes the Wnt pathway(s), if not a promising target, at least a convenient framework within which the function of psychiatric risk gene polymorphisms and rare variants can be tested.

DISC1, ITS BINDING PARTNERS, AND NEURONAL MIGRATION

Lissencephaly is characterized by a thickened cortex and loss of the organized layers of the brain, which results in a smoothed brain. Because synchronized neuronal migration during embryogenesis is responsible for the laminar structure of the brain, it is thought that this process is disrupted in lissencephaly. The majority of autosomal dominant forms of lissencephaly were found to be due to deletions in chromosome 17, where gene mapping identified LIS1 as the critical gene. Mouse models show Lis1-dosage dependent defects in neuronal migration and cortical lamination (Hirotsume et al., 1998). The centrosome has been shown to play a central role in neuronal migration, which involves the molecular motor dynein. Lis1 regulates microtubule function and dynein activity, both of which are coordinated during neuronal migration. A yeast two-hybrid screen identified Ndel1 as a binding partner of Lis1. It has been shown that Ndel1 allows for the interaction of Lis1 and dynein and is required for dynein function. Ndel1 was also identified in a yeast two-hybrid screen to interact with Disc1. Ndel1 has been shown to be involved in neuronal migration, neuronal localization, and neurite and axon development (Kamiya et al., 2006). Disrupting DISC1/

Ndel1 interaction disrupts neurite outgrowth in PC12 cells (Pletnikov et al., 2007), and also prevents the colocalization of DISC1 and Lis1, which localizes with the dynein heavy chain, indicating that DISC1 plays an important role in the function of Ndel1/Lis1 complex by regulating its localization. In addition, Nde1 has also been associated with DISC1/Ndel1/Lis1 to regulate neuronal proliferation, migration, and neurite extension (Bradshaw et al., 2011) and is found in the 16p13.1 CNV (Ingason et al., 2011).

It has been shown that DISC1 also interacts with this complex via its interaction with DIX domain containing-1 (Dixdc1), the third mammalian gene discovered to contain a Disheveled-Axin (DIX) domain (Dixdc1). DISC1, Dixdc1, and Ndel1 form a tripartite interaction, and the presence of either DISC1 or DIXDC1 seems to be able to properly localize Ndel1, indicating that these two proteins may have redundant effects on neuronal migration (Singh et al., 2010). This also indicates that a partial loss of function of either of these two genes can be offset by the function of the other, potentially explaining why differences in the ability of DISC1 variants to bind to Ndel does not result in an appreciable difference in human disease burden.

A molecular switch between the Wnt signaling and neuronal migration function of DISC1 has been recently uncovered (Ishizuka et al., 2011). DISC1 was found to be a target of PKA-mediated phosphorylation, downstream of cAMP activation. The study identified two putative PKA mediated phosphorylation sites on DISC1, and discovered that one of the sites, at serine 710, is responsible for the differential localization and binding properties observed in neuronal progenitors versus migrating neurons. DISC1 in neuronal progenitors is unphosphorylated at this site, and binds to and inhibits GSK3 β activity: upon phosphorylation at this site, DISC1 increases its affinity for BBS1 and localizes at the centrosome. Crucially, the authors demonstrated that the phospho-dead form of DISC1 (S710A) rescued the proliferative but not the migrational phenotype observed in DISC1 knockdown conditions, while the phospho-mimetic form of DISC1 (S710E) rescued the migrational phenotypes of DISC1 function (Ishizuka et al., 2011). It is becoming clear that DISC1 coordinates multiple signaling cascades.

SYNAPTIC PATHWAYS

Spines are the postsynaptic entity of most excitatory synapses, and their morphological characteristics are important for imparting their functional properties and plasticity. There is recent evidence that has indicated that dendrites and spines are dysregulated in neurological diseases that are accompanied by cognitive impairment, such as autism spectrum disorders and schizophrenia (Pezes et al., 2011). Dysregulation of pathways that regulate the growth, pruning, and maintenance of dendritic spines is a particularly intriguing hypothesis for explaining components of schizophrenia etiology, since the onset is in early adulthood, when there is active synaptic pruning. In addition, analysis of postmortem brain samples show that there is decreased spine number on cortical pyramidal neurons in schizophrenia patients compared to controls (Garey et al., 1998).

DISC1

Discussed earlier was the role of DISC1 in neurogenesis and migration in the developing brain. DISC1 is observed to be present at 40% of synapses in postmortem tissue and primary cultures, and enriched in the postsynaptic density after subcellular fractionation (Brandon and Sawa, 2011). In primary neuron culture, it has been shown that DISC1 knockdown leads to increases in spine size and decreases in spine density, which is also seen in various DISC1 mouse models. In addition to this, there are increases in mini excitatory postsynaptic current frequencies, and knockdown of GluN1 leads to decreases in DISC1 levels. Yeast two-hybrid screens with DISC1 found that its binding partners were enriched for synaptic proteins and proteins associated with NMDA-dependent signaling. It has been subsequently found that binding partners of DISC1 are important for the regulation of spine morphologies, and DISC1 is involved in their regulation.

KALIRIN

A binding partner of DISC1 identified was Kalirin, which is a Rac GTP nucleotide exchange factor. The KALRN gene encodes several isoforms, of which Kalirin-7 is the most abundant form in the rat. It contains a PDZ binding motif and interacts with several other proteins via their PDZ domain. Kalirin-7 is localized to postsynaptic densities of excitatory synapses, and Kalirin-7 clusters are generally positively stained with PSD-95, AMPA, and NMDA receptors in the rat brain (Ma et al., 2008b). Kalirin-7 is known to be crucial for spine morphogenesis and function. *In vitro* overexpression in hippocampal cultures causes increases in spine density, while shRNA-mediated knockdown causes the converse (Ma et al., 2003). KALRN^{-/-} knockout mice have decreases in spine density and dendritic complexity and show impairments in long-term potentiation in the Schaeffer collateral, decreases in spontaneous excitatory postsynaptic currents, and deficits in several animal behaviors associated with schizophrenia (working memory, social interaction, and prepulse inhibition) (Ma et al., 2008a). It has been determined that in the basal state, DISC1 coordinates interaction between Kalirin-7 and PSD-95, which prevents Kalirin-7 activation of Rac1. Upon NMDA receptor activation, a fraction of Kalirin-7 dissociates from DISC1 is able to activate Rac1, whose constitutive activation is known to lead to decreases in spine size. In humans, there are decreased Kalirin mRNA levels in the DLPFC in schizophrenic postmortem brain tissue. In addition, Kalirin has been associated with schizophrenia in a Japanese GWAS and sequencing of its exons has identified rare mutations which also associate with schizophrenia (Brandon and Sawa, 2011; Kushima et al., 2012).

CHANNEL PROPERTIES AND SYNAPTIC TRANSMISSION

In a cross-analysis GWAS between schizophrenia and bipolar disease, ANK3 and CACNA1C were found to be reach genome-wide significance (Ripke et al., 2011). ANK3 encodes for ankyrin 3, a protein found in the axon initial segment which is important for clustering Ca⁺⁺ and Na⁺ channels into electrically active areas of the axon (Pan et al., 2006), while CACNA1C encodes a subunit for an L-type voltage-gated calcium channel. Interestingly,

ankyrin 3 is also known to be a component of the cadherin complex, and disruption of the cadherin complex is known to lead to mislocation of β -catenin (Orsulic et al., 1999), suggesting it may have also have a role in regulating Wnt signaling. Neurogranin, implicated in bipolar disorder and schizophrenia (Stefansson et al., 2009), is a key regulator of the Ca²⁺ binding messenger protein calmodulin, limiting its activity by sequestration. Based on the association of these genes in both schizophrenia and bipolar disorder, channel properties and synaptic transmission may be a shared feature of these two diseases.

There are also intersections of calcium signaling and the Wnt pathway. Wnt activates the G proteins associated with Fz proteins to modulate downstream calcium signaling. The Fz proteins are coupled to the Gai/o G $\beta\gamma$ heterotrimeric G protein complex (Katanaev et al., 2005), and Wnt binding to Fz liberates the G $\beta\gamma$ subunits to activate a calcium-dependent pathway that involves the activation of phospholipase C cascade. The perturbation of these signaling pathways can have consequences beyond this pathway, and can impact the canonical Wnt pathway as well.

MICRORNA PATHWAYS

microRNAs (miRNAs) have been identified as a new regulatory layer that guides synaptic morphologies and functions; they have activity dependent regulation and can have differential subcellular localization (Siegel et al., 2011). Some 30% of humans who have deletion of 22q11.2 develop schizophrenia. Children with this deletion have cognitive dysfunction and similar macroscopic changes to brain structure such as decreased total brain, gray matter, and white matter volumes. Mouse models of this deletion show increased prepulse inhibition and decreased hippocampal dependent learning (Karayiorgou et al., 2010). One intriguing candidate present in 22q11.2 is Dcgr8, a protein important in the miRNA processing machinery. Dcgr8 knockout mice have decreased primary dendrites and spines as well as a decrease in functional glutamatergic synapses.

The strongest association signal in a meta-analysis of a schizophrenia GWAS was found in the putative primary transcript of the microRNA-137 (miR-137) (Ripke et al., 2011). Moreover, four predicted targets of miR-137 reached genome-wide significance and were demonstrated to have sequence-specific downregulation by miR-137 (Kwon et al., 2011), indicating that GWASs may have identified a pathway dysregulated in schizophrenia. miR-137 has been demonstrated to play a role in the dendritic arborization and spine density of adult newborn neurons and on embryonic and adult neurogenesis, although with opposite effects between the two periods (Smrt et al., 2010; Sun et al., 2011; Szulwach et al., 2010). The differential action of miR-137 between embryonic and adult neurogenesis may hold clues to how schizophrenia onset may switch in early adulthood.

CONCLUSION

There is growing evidence that schizophrenia is a neurodevelopmental disorder. The disease progression of schizophrenia is well underway before manifestation; there is cognitive

impairment, decreased connectivity and organization of white matter tracts in DTI studies, and gross anatomical changes that can be detected before onset. Significant progress has been made in understanding the genetics of schizophrenia in the past five years, and there are many emerging lines of evidence networking existing theories of schizophrenia etiology with genes that contribute risk to schizophrenia. Among the various emerging gene candidates from GWAS and CNV studies, several are associated with neurodevelopmental pathways. It is also becoming evident that there are many intersections between neuropsychiatric disorders, such as schizophrenia, bipolar disorder, autism spectrum disorder, and major depressive disorder. Treating the genetics as an aggregate of causative genes with effect sizes, just as the diagnosis of many psychiatric disorders is an aggregate of symptoms with magnitudes, may be useful in parsing their complexity moving forward. At this stage of unraveling the genetics of psychiatric disorders, studying unambiguously associated genes to elucidate pathways that underlie disease may set the framework for appreciating the complexity of gene candidates identified by GWASs. It is also worth noting that these molecular pathways that are important during neurodevelopment are also active throughout adulthood, and that a single protein can have pleiotropic effects; persistent dysregulation/dysfunction of a protein can have lasting effects and affect different pathways depending on developmental time. As geneticists continue genome-wide sequencing studies, such as CNV studies, GWASs, exome sequencing, and whole genome sequencing, and basic biologists uncover functions of identified genes and the effect of the risk alleles on these functions, there is no doubt new discoveries about the etiology of psychiatric disorders will become apparent, and novel therapeutic targets will emerge. In the future, personalized medicine tailored to the unique genetic burden of individual patients may be used to prevent developmental abnormalities that later lead to increased susceptibility to schizophrenia.

DISCLOSURES

26 | NEUROBIOLOGY OF MENTAL ILLNESS PSYCHOSIS PRONENESS

RAQUEL E. GUR

INTRODUCTION

Across medicine, early identification of disorders is recognized as important and at times critical for intervention. A prodrome is an early symptom or set of symptoms, which may be specific (e.g., aura before migraine) or non-specific (e.g., fever, malaise, decreased appetite in infectious illnesses), and is a precursor to a disease. Early detection creates the potential for intervention at a stage where it could disrupt the pathological process or help manage the disorder and ameliorate its course.

The application of the prodrome concept to schizophrenia builds on clinical lore where a prolonged period of two to three years is common before the emergence of psychotic symptoms that meet *Diagnostic and Statistical Manual* (DSM) criteria for schizophrenia or spectrum psychotic disorders. This period is associated with sub-threshold symptoms and some functional decline. A rapidly growing literature since the mid-1990s has examined the clinical course of individuals with prodromal presentation and gauged conversion rates to schizophrenia. Based on the literature and considering potential implications, the DSM-5 work group has examined how “psychosis risk syndrome” or “attenuated psychotic symptoms syndrome,” terms applied to define the prodromal phase of schizophrenia, should be incorporated into the next diagnostic manual (Carpenter and van Os, 2011). As this debate unfolds, it is critical to evaluate systematically concomitant neurobiological processes that can be examined prospectively to elucidate the pathophysiology of vulnerability to psychosis. Complementally, such work can identify markers of resilience by studying those at risk who do not proceed to a more severe form of the syndrome.

Methodological advances in neuroscience have enabled us to probe brain function in schizophrenia. Because it is a neurodevelopmental disorder, understanding the pathophysiology of schizophrenia is central to establishing the neurobiology pertinent to the continuum of psychosis. The study of at risk individuals with quantitative phenotypic measures of brain and behavior can address fundamental questions regarding the presence of abnormalities at an early phase of presentation and their relation to outcome. Importantly, such measures can be integrated with genomics to elucidate underlying mechanisms of vulnerability and resilience. Therefore, this framework of research can help behavioral neuroscience join the genomic effort underway toward precision medicine.

This chapter will summarize current literature on the prodromal state as examined with neurobehavioral and

neuroimaging methods. Findings will be integrated considering the NIMH Research Domain Criteria (RDoC) initiative (<http://www.nimh.nih.gov>).

NEUROBEHAVIOR

Behavioral performance that can be linked to brain function has been examined in neurocognitive measures. More recently, social cognition measures have been included in evaluating those at clinical risk for psychosis, commonly integrating cognitive and social psychology paradigms. A small literature has focused on olfaction.

NEUROCOGNITION

Impaired cognition is prominent in schizophrenia and is associated with disrupted functioning. Whether cognitive deficits are progressive or stable has been debated. Examination of first-episode patients, before initiation of treatment with antipsychotic medications, and their longitudinal follow-up made it possible to determine that the neurocognitive profile in first-episode patients resembles that evident in individuals with schizophrenia with a more chronic course of illness. The pattern of deficits in the executive and memory domains implicates frontotemporal dysfunction. The extension of neurocognitive assessment with tests applied in schizophrenia research to individuals with attenuated psychotic symptoms has been commonly applied in prodromal investigations. Some inconsistencies are noted as studies vary in ascertainment, assessment instruments, tests applied, and the information provided on potential moderators, such as substance use. Previous reviews of this growing literature have been qualitative. Two recent quantitative meta-analyses highlight the emerging findings reported in multiple studies in the literature (Fusar-Poli et al., 2012b; Giuliano et al., 2012).

Giuliano and colleagues (2012) conducted a meta-analysis of fourteen studies that met specified inclusion criteria, published until February 2011, which examined the psychosis risk syndrome. A sample of 1,215 individuals at risk for psychosis was compared to 851 healthy controls on neurocognitive domains derived from multiple tests that are frequently examined in schizophrenia. Tests included measures of general cognitive abilities, language functions, episodic memory, attention, visuospatial abilities, and working memory. Overall,

small to medium effect sizes of neurocognitive impairment were noted in the psychosis risk group, with significant deficits in 9 of the 10 domains examined. The motor skills domain was the only one that did not differ between the groups. Longitudinal follow-up in seven of the studies showed that those in the psychosis risk group, who transitioned to psychosis at follow-up, had medium to large neurocognitive deficits at baseline compared to healthy controls, except for motor speed (Addington et al., 2008; Brewer et al., 2003, 2005; Chung et al., 2008; Dickinson and Gold, 2008; Gschwandtner et al., 2006; Hawkins et al., 2004; Miyake et al., 2000; Pflueger et al., 2007; Pinkham et al., 2007; Reichenberg et al., 2010; Seidman et al., 2010; Smith et al., 2006; Szoke et al., 2008). Given the small samples, the limited period of follow-up, subjects' attrition, and potential treatment effects, the longitudinal results are preliminary and limited.

Fusar-Poli et al. (2012b) have also focused their meta-analysis on cognitive functioning in individuals who were at clinical high risk for psychosis. They examined 19 studies published before January 2011. Specified and carefully delineated inclusion criteria were applied, and only 19 studies of the 78 studies screened were included (Addington et al., 2008; An et al., 2010; Brewer et al., 2005; Broome et al., 2007; Chung et al., 2008; Frommann et al., 2011; Green et al., 2012; Ilonen et al., 2010; Korver et al., 2010; Koutsouleris et al., 2012; Lindgren et al., 2010; Magaud et al., 2010; Pflueger et al., 2007; Seidman et al., 2010; Silverstein et al., 2006; Simon et al., 2007; Szily and Keri, 2009; van Rijn et al., 2011; Woodberry et al., 2010). The sample consisted of 1,188 clinical risk participants and 1,029 controls. Diffuse deficits across several neurocognitive domains were evident in the clinical risk group. Impairments in general intelligence, executive functions, attention, working memory, verbal fluency, verbal and spatial memory, and social cognition characterized the clinical risk group. Processing speed did not distinguish between the groups. Transition to psychosis was examined in 7 studies, with mean longitudinal follow-up of 19 months (Becker et al., 2010; Brewer et al., 2005; Koutsouleris et al., 2012; Pukrop et al., 2007; Riecher-Rossler et al., 2009; Seidman et al., 2010; Woodberry et al., 2010). The group of converters had lower general intelligence at baseline, and more impaired performance in verbal fluency, verbal and visual memory, and working memory, compared to those who did not develop psychosis at follow-up.

To examine the regional distribution of neurocognitive deficits implicated by the test results, we have entered the z-scores of the prodromal group into the "behavioral imaging" algorithm (Gur et al., 1990). This algorithm uses z-scores from neuropsychological tests to create a three-dimensional representation of brain regions that are likely impaired based on the pattern of deficits. We entered the results from the meta-analyses and averaged both when the same measures were included in both analyses (see Table in Fig. 26.1). The algorithm generates three views (Fig. 26.1) of brain cortex, identifying regions of impaired functioning in individuals at clinical risk. As can be seen, the abnormalities seem more pronounced in the left than the right hemisphere, especially in the juncture of frontal, temporal, and parietal lobes.

SOCIAL COGNITION

Relative to the large number of studies that investigated neurocognition in clinical risk groups, as highlighted in the meta-analyses previously summarized, a handful of studies examined processes that relate to the perception, interpretation, and response to other people's behavior. As social cognition is a later addition to studies in schizophrenia and the clinical risk studies are an extension of these efforts, more work is necessary.

Giuliano and colleagues' (2012) qualitative part of the review of the psychosis risk syndrome presents data on social cognition that is insufficiently represented in the literature for quantitative meta-analysis. Three studies are included, and while deficits in emotion processing and theory of mind tasks are noted, the results are too preliminary to be conclusive (Addington et al., 2008; Chung et al., 2008; Pinkham et al., 2007). Fusar-Poli et al. (2012b) meta-analysis noted a significant impairment in 255 clinical risk participants compared to 235 controls in six studies that included measures of the social cognition domain (Addington et al., 2008; An et al., 2010; Chung et al., 2008; Green et al., 2012; Szily and Keri, 2009; van Rijn et al., 2011). While these preliminary studies are encouraging, and ultimately may yield insights into negative symptoms, this effort is in its initial stages.

OLFACTION

The Giuliano et al. review (2012) mentions only two studies on olfactory identification in the psychosis risk syndrome, with medium mean effect size. Similarly, only two studies (Brewer et al., 2003) examined the transition to schizophrenia spectrum disorders at follow-up. These are preliminary data not yet suitable for meta-analysis, and further research is required.

Thus, the pattern of neurobehavioral performance in individuals at clinical risk for psychosis shows diffuse deficits in multiple domains, similar to those evident in first-episode and more chronic patients with schizophrenia. Specifically, deficits in verbal memory and working memory implicating left frontotemporal dysfunction have been extensively documented in schizophrenia. While longitudinal studies are limited, the literature suggests that those individuals who transition to schizophrenia spectrum disorders manifest neurocognitive deficits already at baseline to a greater extent than those who do not transition. This buttresses the importance of examining schizophrenia related disorders neurodevelopmentally and in integration with neuroimaging.

NEUROIMAGING

The application of neuroimaging methodology to the study of schizophrenia, including first-episode presentation, has enabled the examination of brain structure and function and demonstrated key aberrations in the syndrome (Fusar-Poli et al., 2012c). The extension of this line of research to the investigation of vulnerability to psychosis can provide important information on brain changes associated with the emerging psychotic process. Magnetic resonance imaging

(MRI) enables evaluation of brain structure, gray matter and white matter volumes, connectivity, and activity in response to neurobehavioral probes. As the techniques for image acquisition and processing advance rapidly, more refined assessment of brain integrity is feasible.

STRUCTURAL MRI

Detailed morphometric measures can be obtained in individual and group data that provide gray matter, white matter, and CSF whole brain and regional volumes. Parameters commonly scrutinized are highlighted in Figure 26.2.

Structural MRI measures have been tested as endophenotypes in several studies of first-degree family members who are at genetic risk for schizophrenia. Family members show

a similar pattern but diminished extent compared to that observed in probands, with increased ventricular volume and decreased gray matter volume. The literature on clinical risk for psychosis, recently reviewed (Fusar-Poli et al., 2012a), is relatively limited in size of samples and extent of follow-up.

A meta-analysis of voxel-based morphometry studies compared psychosis risk and first-episode schizophrenia patients to healthy controls (Fusar-Poli et al., 2012c). Fourteen studies met specified selection criteria and included participants who were never treated with antipsychotic medications. There were 198 individuals at risk for psychosis compared to 254 healthy controls, and 206 first-episode patients compared to 202 controls. Image acquisition in most studies was on a 1.5 Tesla scanner. Gray matter volume reduction was evident in several regions including the right temporal, limbic prefrontal cortex

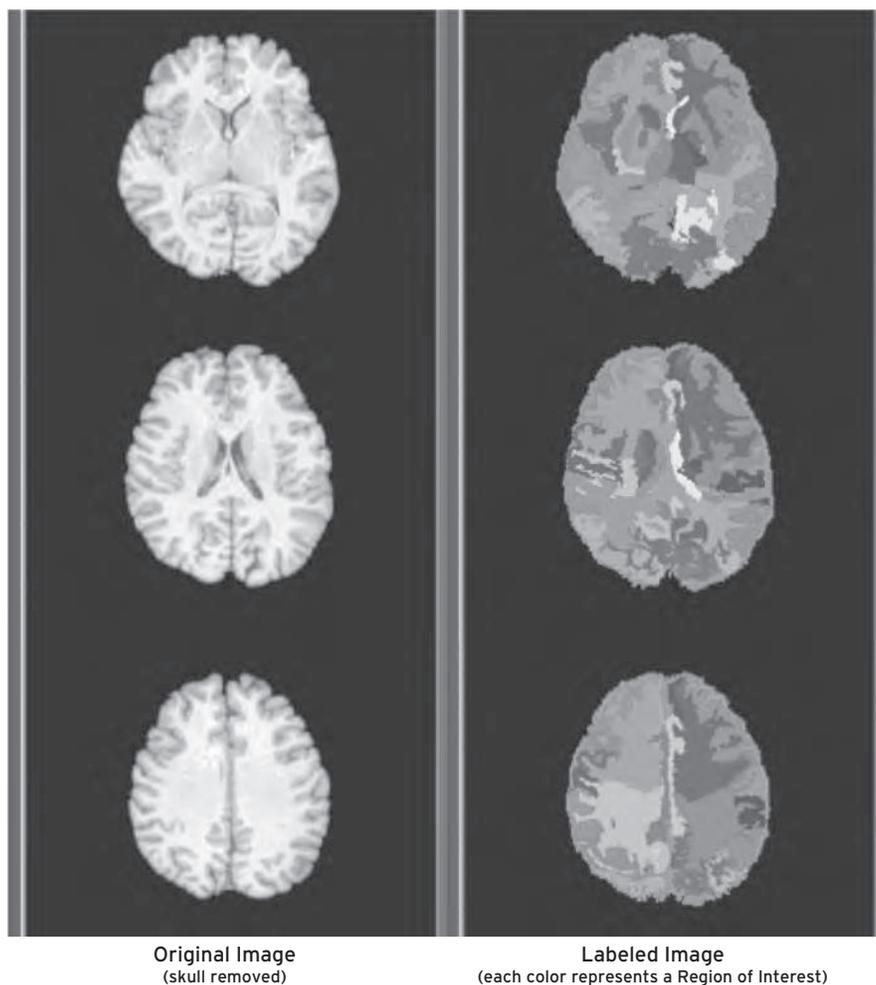

Figure 26.2 MRI template-warping for parcellating regions of interest. A template in which regions are labeled and demarcated is warped into an individual's MRI recording the extent of changes required. As a result, axial slices such as seen on the left are labeled as seen on the right column. Regional volumes can then be calculated for quantitative analysis allowing, for example, comparison between psychosis prone and healthy participants. (See color insert).

in the clinical risk group, and in the temporal insular cortex and cerebellum in the first-episode group. Notably, the onset of psychosis was associated with decreased gray matter volume in temporal, anterior cingulate, cerebellar, and insular regions. In one study, greater severity of psychotic symptoms was related to right superior temporal lobe gyrus volume decrease. These regions have been implicated in multiple studies of schizophrenia and subserve functions that are aberrant in schizophrenia and relate to cognition and emotion processing.

It is notable that while the neuroanatomic studies, when reporting lateralized effects, suggest greater structural abnormalities in the right hemisphere, the neurocognitive studies suggest greater left hemispheric dysfunction. This seeming discrepancy may reflect the lack of emphasis on laterality in neuroimaging studies, which typically examine data on a voxelwise basis within a hemisphere. It could also reflect greater sensitivity of neuropsychological tests to left hemispheric dysfunction. On the other hand, cognitive deficits could reflect compensatory activation, and if these effects are validated in future studies they could thus suggest avenues for remediation.

There are multiple methodological limitations entailed in MRI meta-analytic approaches, and the studies are mostly

cross-sectional and include participants who did not transition to psychosis. However, the results suggest that brain regions that show volume reduction in schizophrenia also show abnormalities in those at risk for psychosis (Fusar-Poli et al., 2012c). Larger samples in a longitudinal design will be important to advance the understanding of underlying neuroanatomical differences between groups. White matter changes have also been reported in schizophrenia, early in the course of illness, as well as in individuals at risk for psychosis (Carletti et al., 2012; Fusar-Poli et al., 2011a).

DIFFUSION TENSOR IMAGING

Diffusion tensor imaging (DTI) quantifies restricted water diffusivity in white matter, enabling non-invasive detection of subtle white matter abnormalities and facilitating the understanding of complex large-scale brain networks. Figure 26.3 illustrates measures obtained in DTI.

Abnormalities in DTI have been reported in schizophrenia, both in chronic patients and in first-episode presentation (Peters et al., 2009), with reduced white matter integrity in frontotemporal tracts. The literature on psychosis risk is limited to several

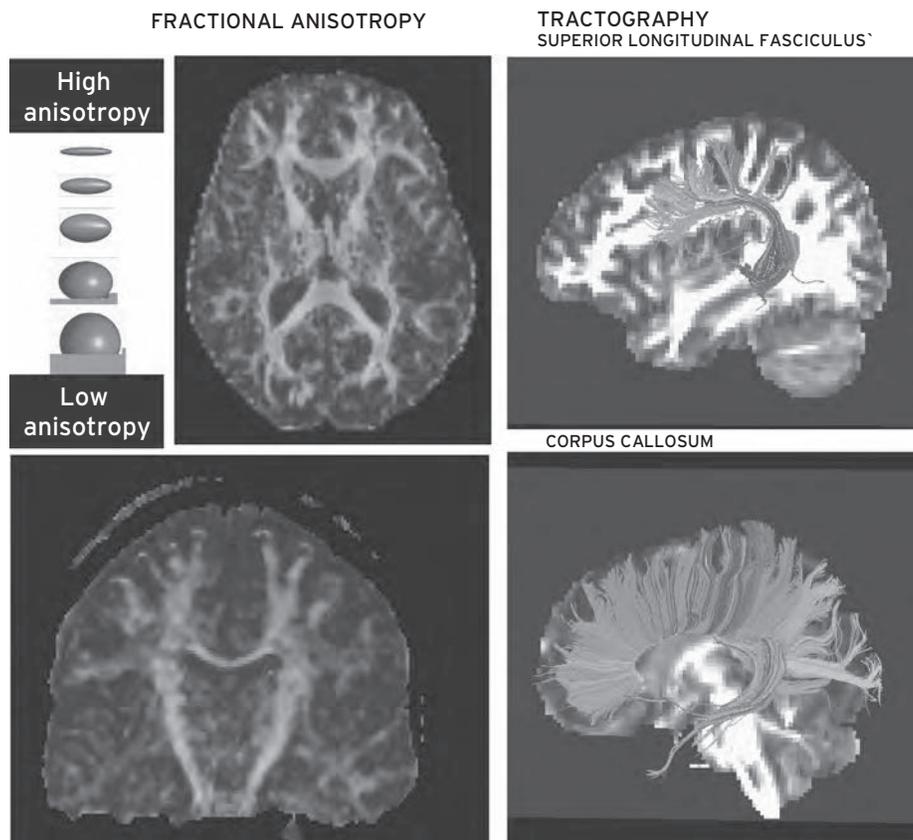

Figure 26.3 Diffusion tensor imaging (DTI) illustrates fractional anisotropy (left) and tractography (right). Fractional anisotropy reveals white matter architecture while tractography depicts the integrity of fiber tracts. (See color insert).

cross-sectional studies, with differing findings including reduced fractional anisotropy in frontal lobe (Bloemen et al., 2010) or in the superior longitudinal fasciculus (Borgwardt et al., 2011). A longitudinal study (Carletti et al., 2012) compared three groups: individuals at risk for psychosis ($n = 32$) healthy controls ($n = 32$), and first-episode schizophrenia ($n = 15$). The psychosis risk and control participants were rescanned on a 1.5 Tesla after 28 months. At baseline, the first-episode group had decreased fractional anisotropy and increased diffusivity relative to controls, and the psychosis risk group was intermediate between the other two groups. At follow-up, further reduction in fractional anisotropy was evident in left frontal region only in those psychosis risk individuals ($n = 8$) who transitioned to psychosis. This suggests that progressive changes occur at disease onset, which has been reported before for gray matter (Borgwardt et al., 2007; Smieskova et al., 2010). Again, however, the available data are meager and must be considered very preliminary.

fMRI

Functional MRI has been applied to individuals at risk for psychosis, commonly in small samples with neurobehavioral probes that have shown differences between schizophrenia patients and controls. Neurobehavioral domains examined include working memory, using the n-back paradigm. Overall, psychosis risk groups show decreased activation in the blood oxygenation level-dependent (BOLD) response in dorsolateral and medial

prefrontal regions (Fusar-Poli et al., 2012c). The pattern of activity is similar to that seen early in the course of schizophrenia, but less pronounced abnormalities are observed. To evaluate activation changes with disease progression, longitudinal designs are necessary. Such designs have been applied in several fMRI studies, reviewed by Smieskova and colleagues (2010). This small literature suggests that individuals who transition to psychosis differ from those who do not, with the latter group showing normalization. Thus, the application of fMRI holds promise as a tool that may facilitate elucidation of the underlying pathophysiology of the psychotic process (Fig. 26.4).

CONNECTIVITY

The resting BOLD signal in fMRI paradigms can provide a measure of connectivity, reflecting “cross-talk” integration among brain regions. It examines the time-series correlations among brain regions, indicating which regions show synchronized activation. Aberrations in schizophrenia in frontotemporal connectivity have been reported and have also been seen in those at clinical risk (Crossley et al., 2009). This literature too is at its infancy.

NEUROTRANSMITTERS

Several neurotransmitters that have been related to the pathophysiology of schizophrenia have been examined in those at psychosis risk. Dopamine dysregulation has been linked to

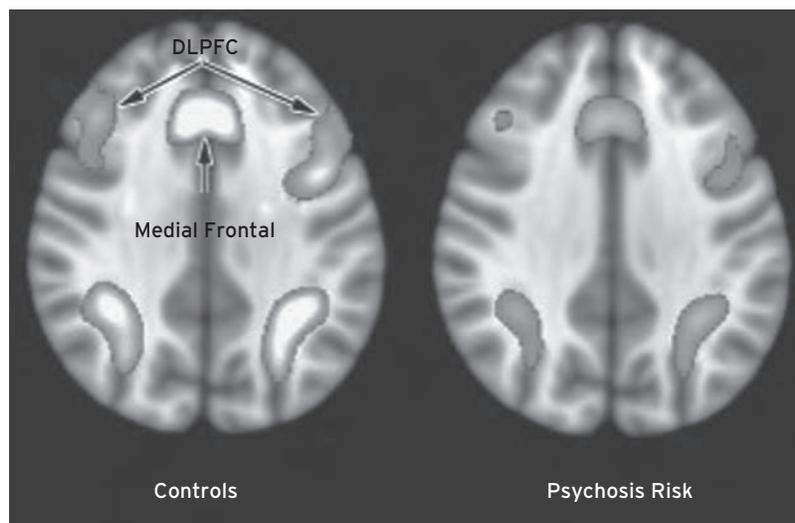

Figure 26.4 Functional MRI (fMRI) BOLD activation in response to a working memory task. A normal pattern of activation (left) and reduced activity in clinical risk for psychosis (right) illustrates the pattern observed in studies applying the *n*-back paradigm.

psychosis, and positron emission tomography (PET) studies have shown increased dopamine striatal activity in schizophrenia (Fusar-Poli and Meyer-Lindenberg, 2013; Howes et al., 2009). Striatal 6-fluoro-L-dopa F18-dopa was also elevated in psychosis risk individuals and related to symptom severity (Tibbo et al., 2004).

Glutamate has also been implicated in the pathophysiology of schizophrenia and studies have examined individuals at genetic risk for psychosis using magnetic resonance spectroscopy (MRS). Increased glutamine/glutamate ratio in medial frontal cortex was reported in adolescents at genetic risk (Tibbo et al., 2004). In a study integrating fMRI and MRS, 24 psychosis risk individuals were compared to 17 healthy controls (Fusar-Poli et al., 2011c). BOLD response to a verbal fluency task showed that the psychosis risk group had greater bilateral activation than controls in midfrontal gyrus. Glutamate levels in the thalamus were lower in psychosis prone individuals. Furthermore, the pattern of correlations with activation suggests that prefrontal, hippocampal, and temporal functioning are related to thalamic glutamate levels and differentiate those at risk from controls.

ELECTROPHYSIOLOGY

As in schizophrenia research, the investigation of brain function has included several studies that have examined brain activity with electrophysiological measures. For example, P300 amplitude was reported to be smaller in a group of 100 clinical risk individuals, early or late in the prodromal state, compared to 40 healthy controls (Frommann et al., 2008). The findings were interpreted as suggesting that selective left temporoparietal amplitude deficits could be a trait abnormality, while deficits at sagittal midline electrodes may relate to changes that underlie the emergence of psychotic symptoms.

A study integrating P300 and volumetric MRI measures (Fusar-Poli et al., 2011b) examined 39 psychosis risk individuals and 41 healthy controls. P300 at intake was lower, and gray

matter was reduced in several regions including the right superior frontal gyrus, left medial frontal gyrus, left inferior frontal gyrus, right orbital gyrus, and right supramarginal gyrus in the psychosis risk group. The longitudinal design made it possible to follow a subgroup, with some subjects transitioning to psychosis. Progressive gray matter alterations in prefrontal and subcortical areas were noted in the psychosis risk group, but no significant changes in P300 amplitude over time were observed.

CHALLENGES AND PROMISES

Advancing the neurobiology of schizophrenia is extremely challenging and requires converging multidisciplinary team science approaches. The bar is even higher when attempting to do what we need to in order to elucidate mechanisms that underlie the pathophysiology early in the course of emerging psychosis. Before turning to the scientific challenges and promises, the context of the debate is important to consider.

Medicine is undergoing a paradigm shift in which “Big Science” is applied to multiple biomarkers in order to permit early identification and targeted interventions that aim at biological processes rather than symptoms. Unfortunately, psychiatry is at risk to stay at the sidelines of the move toward such precision medicine not just because of the complexity of behavior and its organ, the brain, but also because of societal attitudes. Unlike other medical disorders, the burden of stigma and the consequences of false early identification of individuals who may not transition to psychosis weigh heavily when discussing the inclusion of clinical risk in DSM-5. Yet, a shift in research paradigms as envisioned by RDoC provides an opportunity to bypass the stigma by obtaining dimensional data on behavior without emphasis on categorical diagnostic classification. Such a framework can be well integrated into large-scale genomic studies and afford the data essential for addressing fundamental basic and clinical questions that can

fill existing gaps in understanding. Such systematic efforts will help answer questions currently enigmatic or with limited data reflecting an early phase of investigation.

The heterogeneity in clinical features and variability in brain behavior measures necessitate large samples and longitudinal follow-up. Large longitudinal samples are also essential for integration of quantitative phenotypic neurobiological data with genomics. Such efforts are required for progress in advancing the understanding of neurodevelopmental trajectories that underlie the continuum of psychosis.

Several methodological challenges merit consideration and discussion. Some uniformity and standardization in the approach to these issues could ultimately lead to consensus in the next stages of this undertaking.

Ascertainment. The population captured in clinical risk studies is based on help-seeking youths. Some sites develop a referral network that may include community mental health providers, schools, and advertisement in the community at large. Is the pattern of presentation related to the method of ascertainment? Demographics? How does the presentation of help-seekers differ from population-based studies? To enable generalizability and sensitivity of measures, consistent information should be provided, even in the form of supplemental data in journal articles.

Comorbidity. There is inconsistency in the literature in reporting comorbid conditions, such as substance use, despite an extensive literature of psychosis in the context of substance use, such as cannabis. Similarly, the role of environmental stressors that can facilitate or curtail the emergence of psychosis needs attention.

Diagnostic instruments. Several instruments have been applied to assess sub-threshold psychotic symptoms. Adopting a common instrument will be helpful in standardization, and research groups can add other instruments to address further questions. Such standardization will help establish common training across research sites and facilitate clinical training of professionals as the field moves forward. There is also a need to focus on negative symptoms early in the course of psychosis, as the clinical presentation is at times mistakenly diagnosed as depression.

Neurobehavioral measures. Core domains should be included in future studies to enable comparison across samples and pulling data together systematically. Easy access to behavioral measurement procedures is necessary to enable data gathering across diverse settings beyond academic sites.

Neuroimaging measures. For more complex brain indices, such as those obtained in neuroimaging and electrophysiology, further considerations on data acquisition and processing are required. In such studies it is crucial to standardize data analytic approaches, and increasingly multimodal neuroimaging is feasible and could help propel the field. Structural, functional, and

connectivity data can now be obtained in single sessions, and longitudinal follow-up is feasible. Importantly, the neuroimaging data need to be integrated with clinical and neurocognitive data.

Sample size. The large volume of data generated in neuroimaging studies underscores the need for large samples. Even larger samples are needed if the aim is to integrate neuroimaging data with genomics. The typical concluding paragraph in neuroimaging papers, which states that “larger samples are required” should become limited.

When genomics is running forward and bioinformatics is keeping up, we have unprecedented opportunities with available and developing technologies to attempt to answer questions that are crucial and critical for early intervention. Such knowledge may help pave the way for novel approaches to ameliorate the impact of illness and enable vulnerable individuals to get back on track as much as possible. Concerns over medicating the young and perhaps those not bound to schizophrenia spectrum disorders is understandable. However, this valid concern should not become a paralyzing fear. As the field is adopting behavioral interventions that show promise, as well as discovering natural substances that can help modulate the disease process, it is up to us to be vigilant as health professionals and do no harm. By educating the public, and free of conflict of interest, we can be in a position to impart knowledge gained, admit our ignorance, and strive to obtain the best data possible in the service of those who need it.

As we gain better understanding of the neurodevelopmental trajectories associated with “deep phenotyping” of brain behavior quantitative measures, and have data on adequately powered samples, we will be in a position to evaluate the degree and extent of departure from the normative growth curve. Implications of symptoms, their duration, persistence, intensification, and impact on functioning can be monitored. Such efforts will lead to better understanding of variability in presentation, vulnerability, resilience, and early intervention.

27 | PSYCHOTIC DISORDERS: NEUROCHEMISTRY AND PHARMACOTHERAPY

CAROL A. TAMMINGA AND ELENA I. IVLEVA

PSYCHOSIS AS AN INDEPENDENT CLINICAL PHENOTYPE

Psychosis is a symptom dimension that appears in multiple brain disorders, most commonly in psychiatric disorders, but occasionally in neurological and other medical diagnoses. Psychotic symptoms include hallucinations, delusions, and thought disorder, as well as thought and behavioral disorganization. These symptoms are experienced by psychotic individuals as actual cognitive or sensory experiences and involve all sensory modalities (auditory, visual, olfactory, gustatory, and tactile). Several first-person accounts written by brilliant and self-perceptive individuals with psychosis record the nature of psychosis and show that there is a profound loss of reality testing around psychotic experiences. John Nash describes the nature of his delusion:

These ideas just keep coming into my head. I can't prevent it. (I) believe that there is a conspiracy among military leaders to take over the world, and that (I) am in charge of the takeover. (I) secretly feel that I am the left foot of God. And that God is walking on the earth. (Nasar, 1998)

Elyn Saks details her experience of psychotic “disorientation”:

Consciousness gradually loses its coherence. The “me” becomes a haze... reality breaks up like a bad radio signal. There is no longer a sturdy vantage point from which to look out, take things in, assess what's happening. No core lens through which to see the world, to make judgments and comprehend risk. Random moments of time follow one another. Sights, sounds, thoughts, and feelings don't go together. No organizing principle takes successive moments in time and puts them together in a coherent way from which sense can be made. And it's all taking place in slow motion. (Saks, 2007).

The clinical manifestations of psychosis as just described, with hallucinations, delusions, thought disorder, and disorganization, are a disturbance of cognition, not a global loss of cognitive capacity as distinct from dementing illnesses. Indeed, psychosis can be thought of as a “gain-of-function” symptom, with increased associational productions, which generate bizarre perceptual experiences, thoughts, and memories with psychotic content; this is in contrast to dementias, which are

“loss-of-function” cognitive disorders. Because the psychotic experiences appear entirely real to the person suffering them, it is easy for the individuals to act on the commands, the psychotic perceptions, or delusional thinking; this can result in bizarre, illogical, or aggressive behavior. Psychosis is a broadly expressed symptom set across diagnoses and thus could be an intermediate phenotype, perhaps a symptom dimension representing a final common pathway of cerebral dysfunction (including limbic cortex, we will argue). It is easy to presume that this symptom set has its own common and distinctive anatomy and pathophysiology, as well as molecular targets and treatments, although this has yet to be fully demonstrated (Fig. 27.1).

Psychotic symptoms in psychiatric diagnosis are highly sensitive to antipsychotic drugs, drugs that block dopamine D2 receptors or diminish dopamine mediated transmission, with limited evidence that serotonin antagonists (MDL100907), muscarinic agonists (xanomiline, Shekhar et al., 2008), or glutamate agonists (LY2140023) (Kinon and Gomez, 2012) can have an effect, albeit partial. It is often debated whether the behavioral state of psychosis can be modeled in a laboratory animal, with the difficulty being the ability to detect symptoms with the actual object dependent on language (behavioral state of psychosis). However, measurable behaviors that have been associated with psychotic human behavior, like altered prepulse inhibition (PPI), declarative memory dysfunction (e.g., fear conditioning correlates), and alterations in intentional bias, and the use of human psychotomimetic drugs can be used to represent psychosis, as putative human correlates of psychosis (Yanagi et al., 2012).

In psychotic diseases, as discussed in several of the earlier chapters, psychosis is not the only symptom set that causes dysfunction. In schizophrenia, which is generally considered to be the most persistent and severe of the psychotic disorders, patients suffer from cognitive dysfunction, negative symptoms, mood symptoms, and anxiety, in addition to psychosis. In psychotic bipolar disorder, it is not only psychosis, but also mood instability with mania, depression, and mixed states, as well as cognitive dysfunction that characterize persons with that diagnosis. The coexisting symptom dimensions (like cognitive dysfunction or negative symptoms) are not treated by antipsychotic drugs; they have their own disease course, with symptom-onset characteristically occurring before the psychosis and their distinctive life course. For these reasons many clinical scientists, exemplified by the NIMH *Measurement and Treatment Research to Improve Cognition in Schizophrenia* (MATRICS) group (Marder and Fenton, 2004), proposed

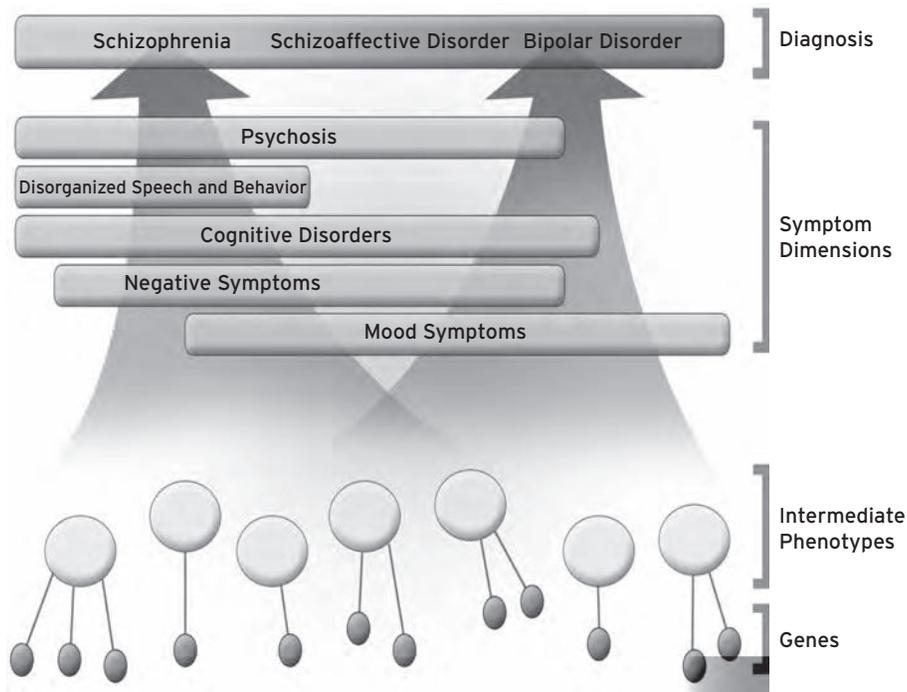

Figure 27.1 The genes, intermediate phenotypes, and symptom dimensions that characterize the categorical diseases that we diagnose have been shown to overlap extensively. Therefore, to deconvolve the biology, we need to focus on disease dimensions and their underlying intermediate phenotypes, which will more directly relate to the genes underlying psychiatric conditions. (Previously published in Ivleva E.I., Tamminga C. 2009. Psychosis as a defining dimension in schizophrenia. In: Sadock, B.J., Sadock, V.A., and Ruiz, P. [Eds.], Kaplan & Sadock's Comprehensive Textbook of Psychiatry, 9th edition. Vol. 1. Philadelphia, PA: Lippincott Williams & Wilkins, schizophrenia. In: Sadock, B. Chapter 12.16, pp. 1594–1605.)

formulating these entities as independent symptom dimensions, each with their own anatomy, molecular determinants, and pharmacology, hence likely to have their own treatments.

Thus, disease dimensions have become the therapeutic target of experimental therapeutics today.

MOLECULAR MECHANISMS OF PSYCHOSIS: MODELS OF THE ILLNESSES

DOPAMINE HYPERFUNCTION

Dopamine hyperfunction was the first molecular hypothesis of schizophrenia (Table 27.1). The only effective treatments discovered so far for psychosis are medications that reduce dopamine-mediated transmission in brain. Their action was identified serendipitously early in 1950 by Delay and Denniker, who used chlorpromazine initially as merely a sedative agent, but were alert enough to notice its selective antipsychotic activity. The use of chlorpromazine spread around the world very quickly for the treatment of psychosis, especially schizophrenia due to extremely high medical need. The identification of the dopaminergic mechanism of chlorpromazine was detected pharmacologically within the next decade by Carlsson and Lindquist (Carlsson and Lindquist, 1963), as dopamine receptor antagonism. Moreover, the subsequent design and development of dopamine receptor antagonists and now of partial dopamine agonists have confirmed the therapeutic action of this family of drugs on psychosis. So, it is well established that drugs which block dopamine receptors in brain improve

psychosis. It was an easy step from this body of knowledge to the idea that schizophrenia itself, and psychosis in particular, are diseases whose mechanisms involve a hyperfunction of the dopamine system. For the last half-century, clinical scientists have examined the “dopamine hypothesis of schizophrenia” using schizophrenia brain tissue, cerebrospinal fluid (CSF), blood, transformed cells, human brain imaging, and anything else available to demonstrate evidence of dopamine hyperactivity. Sadly, these studies as a group have not been able to verify the dopamine hypothesis of schizophrenia (Kendler and Schaffner, 2011). There is no replicable increase in dopamine receptor number, except that associated with chronic antipsychotic use; there is no consistent evidence of altered dopamine metabolites or proteins associated with dopamine signaling in schizophrenia brain tissue; although there is some evidence of increased dopamine release gathered through displacement imaging, this is not a feature unique to schizophrenia. Kendler et al. reviewed this area exhaustively and asked why the hypothesis was not falsified faster, a question important to experimental therapeutics (Kendler and Schaffner, 2011). At the present time, while the hypothesis is often quoted, it is not relied on within the field for the discovery of disease mechanism or for drug development. However, antipsychotic drugs are still identified by their antidopaminergic action, and there is no reconsideration of the well-substantiated observation that dopamine antagonism improves psychotic symptoms. To resurrect the usefulness of the “dopamine hypothesis of schizophrenia” in the field, a new and clear aspect of dopamine pharmacology will have to be identified as altered in schizophrenia.

TABLE 27.1. Molecular models of psychosis

DOPAMINE SIGNALING HYPERFUNCTION
First molecular hypothesis, based on pharmacological data. Postulates have not been confirmed. Yet, all antipsychotic drugs are antidopaminergic.
GLUTAMATE SIGNALING REDUCTION
Based first on the potent psychotomimetic action of phencyclidine. Considerable biochemical evidence has supported this model. There may be regional effects.
GABA SIGNALING REDUCTION IN PREFRONTAL CORTEX
Fast-spiking GABA interneurons show reduced inhibition; may be especially relevant for loss of cortical gamma synchrony and cognitive dysfunction in PFC.
ALTERED CNS NEUROPLASTICITY MECHANISMS
Psychosis could represent the loss of appropriate controls on learning and memory plasticity mechanisms. A still speculative idea.
MODELS BASED ON PSYCHOSIS RISK GENES
These models are interesting but remain tentative until psychosis genetics becomes fully established.
PSYCHOTOMIMETIC DRUG MODELS
These are the classical psychosis models. They have been highly useful for drug development but cannot be used to inform pathophysiology.

GLUTAMATE AND EXCITATORY TRANSMISSION

In the meantime, proteins in the glutamate system have been shown to be altered in schizophrenia tissue, and pharmacological blockade of NMDA glutamate receptors in normal people has been shown to mimic symptoms of schizophrenia, generating the idea that glutamatergic action is reduced in schizophrenia. Pharmacology of the NMDA receptor suggests that a reduction in glutamate signaling at this receptor can mimic some of the psychotic symptoms of schizophrenia (Tamminga, 1999), as well as its cognitive symptoms in normal human volunteers (Krystal et al., 1994a). Molecular alterations in glutamate-related proteins are documented in postmortem tissue and CSF, changes that could impair signaling at this receptor (Gao et al., 2000; Tamminga, 1999; Tsai et al., 1995). Therefore, molecular targets within the NMDA receptor complex have become interesting targets for drug development in both psychosis and cognition (Table 27.1).

Glutamate signaling impinges most neurons in the brain and supports activity-dependent signaling, neuronal growth, and synaptic plasticity (Benarroch, 2011; Lynch and Guttman, 2001; Nikam and Kornberg, 2001). The glutamate system is regionally diverse and complex, with multiple interacting receptors, modulating co-transmitters, and multiple postsynaptic intracellular signaling systems. Presynaptic, postsynaptic, and astrocytic mechanisms all contribute to overall excitatory signaling and to unique plasticity mechanisms that are involved with glutamatergic transmission (Lee et al., 2010; Shepherd and Haganir, 2007; Song and Haganir, 2002); these compartments are all candidate systems for pathology in glutamate-related brain diseases. Regional

characteristics of synapse architecture, local circuitry, and specialized postsynaptic signaling mechanisms, suggest that important aspects of glutamate regulation are local. The roles of many of these synaptic proteins were discussed in Chapter 25. Even within regions, functional specialization occurs on a microcircuit level with the same glutamatergic architecture serving distinct functions (Greer and Greenberg, 2008). It is already known that the hippocampus and its surrounding cortex features glutamate signaling to a greater extent than other neocortical tissue, a characteristic that underlies its learning and memory functions (Franzek and Beckmann, 1996). Moreover, the hippocampus is one of the brain regions functionally altered in schizophrenia, suggesting the potential relevance of glutamate transmission in this structure to psychosis pathophysiology (Tamminga et al., 2010). The evidence for altered glutamate signaling in schizophrenic psychosis, including clinical and pharmacological, data, have been previously reviewed (Tamminga et al., 2010). Since the hippocampus is a prototypical excitatory organ, its signaling, especially in memory function, has been studied for decades, provoked in part by the dramatic demonstration of its essential role in memory by the case of Henry Moliason (HM) (Rempel-Clower et al., 1996). Thus there exists a rich understanding around the role of glutamate and excitatory transmission in declarative memory. There exists evidence and plausible models that psychosis is due to reduced glutamatergic transmission at the NMDA-sensitive receptor and several hypotheses have been proposed to account for this (Olney and Farber, 1995; Tsai and Coyle, 2002). While no definitive mechanisms have yet been demonstrated, the idea that psychosis in schizophrenia may involve inadequate glutamatergic transmission at the NMDA receptor is widely acknowledged and remains plausible. In addition, evidence implicates the hippocampus, in particular in psychosis, involving its unique cortical anatomy and its subfield-specific functions (Tamminga et al., 2010)

GABA AND INHIBITORY TRANSMISSION

As detailed in Chapter 24, considerable evidence implicates alterations in GABAergic transmission in the manifestations of schizophrenia, based on very early and simple ideas of neocortical function, dependent on controlled excitation extensively modulated by GABA-mediated inhibition. Modern postmortem research has shown cell-specific GABA reductions in neocortex, most precisely worked out in prefrontal cortex (PFC) (Krystal et al., 1994b). In PFC schizophrenia tissue, reduced concentrations of GAD67, one of the synthetic enzymes for GABA, occur and are especially prominent in CCK- and parvalbumin-containing inhibitory interneurons. Upregulated postsynaptic GABA receptors have been found (Krystal et al., 1994b), which have been interpreted to reflect reduced synaptic levels of GABA in the specific synapses in PFC. Speculations have connected this GABA reduction with PFC regional cerebral activation reductions, with reduced cognitive function possibly mediated by the loss of gamma synchrony already associated with schizophrenia. Some (Wang et al., 2011) but not all (Kegeles et al., 2000) data implicate GABA reduction

in other areas of PFC and in hippocampus, leaving the role of GABA in hippocampal function less clear.

LEARNING AND MEMORY PLASTICITY DYSFUNCTION

Observations drawn from *in vivo* imaging studies in schizophrenia (which show *increased* perfusion in the hippocampus; Heckers et al., 1998; Medoff et al., 2001; Schobel et al., 2009) and from postmortem schizophrenia tissue studies (which show *decreased* GluN1 expression in hippocampal subfields, especially dentate gyrus [DG]; Deicken et al., 1999; Gao et al., 2000) converge to suggest that homeostatic plasticity mechanisms might be altered in the hippocampus in patients (Eichenbaum, 2000; McClelland et al., 1995; Preston and Wagner, 2007). We have proposed a speculative and testable model of psychosis, based on evidence of altered hippocampal learning and memory, and suggest that altered glutamate-mediated functions in hippocampal subfields are involved in psychotic and deficient declarative memory manifestations of schizophrenia (Tamminga et al., 2010).

It is the functional effect secondary to this reduced glutamate signaling in DG in CA3 that could be of interest for psychosis. DG projects to CA3 in the mossy fiber pathway, a link within the trisynaptic circuit. We suspect that this decrease in activity-dependent signaling from DG sensitizes its target tissue (CA3) to incoming stimuli and generates a lower LTP threshold and increased cellular sensitivity; this could generate higher levels of neuronal activity in CA3, to be projected onto CA1. We suggest that this results in an increase in synaptic strength in CA3, accompanied by increased associational memory function. The ability of homeostatic plasticity phenomena to support this kind of model is included in data generated in the Malenka, Bear, and Malinow laboratories, among others (Tamminga et al., 2010). It is a speculation that increases in CA3 associational function could generate false associations, some with psychotic content, which could then get laid down in memory as psychotic thoughts and memories. This idea is consistent with the reduction in glutamate signaling in DG (indicated by a decrease in GluR1 protein), as well as the increase in hippocampal perfusion that we detect with rCBF measures (Tamminga et al., 2010) and the finding that BDNF is increased regionally in CA3 in schizophrenia tissue (Ghose et al., 2006). Dysfunction of associational memory with changes localized to CA3 would lead to the assumption that occasional and fleeting mistakes in CA3 could be responsible for the psychosis-like phenomena in normal and in “prodromal” individuals. Persistent and high increases in CA3 activity could stimulate psychosis thinking and generate manifestations that would resemble schizophrenia.

GENETIC ASSOCIATIONS AS MODELS

Modern genetic outcomes have contributed to the realization that schizophrenia and psychosis are complex genetic illnesses. Whereas there was early evidence for specific risk genes, the problems with replication and power soon suggested that many

genes generate risk for schizophrenia and psychosis. Recent genome-wide association studies suggest that there may be more than 1,000 risk genes, each of small effect, for psychosis syndromes (Wellcome Trust Case Control Consortium, 2007). Although the majority of the candidate genes were first implicated in schizophrenia, recent reports have suggested an overlap in genetic susceptibility across the traditional diagnostic categories. GWAS, candidate genes, family, and twin genetic studies all indicate overlap across diagnostic categories, as outlined in Chapter 19. This implicates the potential for common genetic risk across the whole psychosis spectrum. It also suggests that simpler behaviors, like intermediate phenotypes for psychosis, may be useful in genotyping to develop a more precise understanding of the basis of psychotic illness (Fig. 27.1). Understanding the genes associated with intermediate phenotypes of psychosis will surely inform genetic mouse models for psychosis, as soon as the relationship between genes and intermediate phenotypes becomes clarified.

ANIMAL MODELS OF PSYCHOSIS

Animal models of human brain diseases, which are stringently based on disease features having strong construct validity, are critical for testing disease pathophysiology and novel treatment development (Young et al., 2009, 2010). However, because the mechanistic basis of schizophrenia remains obscure, our ability to develop verified animal models has been critically challenged (Nestler and Hyman, 2010). Current preclinical models of schizophrenia are primitive and mechanistically speculative, with no forward vision of how to verify the models; there is often insufficient indication that these models are related to disease pathophysiology in human constructs. Nonetheless, developments in the conceptualization of complex diseases like schizophrenia will allow more kinds of animal models to be relevant and their verification more direct (Hyman and Fenton, 2003).

The *Schizophrenia Research Forum* lists 87 putative rodent models for aspects of schizophrenia. These models can be organized into three main categories and model not only psychosis in schizophrenia but also cognitive dysfunction and negative symptoms, all dimensions of illness in schizophrenia. These animal models are based on psychotomimetic drug stimulation, early adversity and lesion models, and schizophrenia risk gene models.

Psychotomimetic agents include amphetamine, phencyclidine and their congeners. These are drugs that cause psychosis in humans, often including schizophrenia-like symptoms, and tend to exacerbate the psychotic manifestations in schizophrenia. It has been assumed that an understanding of the mechanism(s) of these psychosis-inducing actions might contribute to our fundamental understanding of psychosis, although this has not yet been the case. Psychotomimetic drugs have been administered to animals both for psychosis pathophysiology studies and in order to model pharmacological antagonist approaches as treatments.

The approach of introducing environmental adversity to animals early in development to model schizophrenia grew out of observations and epidemiological data showing that early

childhood adversity, including prenatal, perinatal, and developmental adverse events, predispose individuals to schizophrenia in adulthood (Akbarian, 2010; Brown, 2011). How these childhood adversities predispose individuals to develop illness in adulthood is not known but could be associated with epigenetic alterations that develop in childhood to pose risks during adulthood. The idea that early changes in brain structure or function, or in epigenetic signaling, contribute to an adult onset illness has been a generative concept in the field of schizophrenia pathophysiology.

Closest to a study of disease mechanism has been the study of genetically modified animals at schizophrenia-risk loci. These animal models are reviewed in Chapter 9, and provide critical evidence of specific molecular lesions which can be associated with illness. It is unfortunate that these risk genes are not strong enough to be comprehensive, but will become increasingly useful as the molecular bases of psychosis is defined.

ESTABLISHED AND EXPERIMENTAL PSYCHOSIS TREATMENTS

HISTORY OF ANTIPSYCHOTIC DRUG DEVELOPMENT

Discovery of the antipsychotic action of chlorpromazine in the mid-1950s identified the first therapeutic agent for schizophrenia and it happened serendipitously. Its selective antipsychotic properties were noticed with its first application, and its use spread around the world within a few years, signaling the overwhelming medical need for psychosis treatments. In the decade following this clinical discovery, not only was the probable mechanism of antipsychotic drug action articulated as monoamine (especially dopamine) receptor blockade (Carlsson and Lindquist, 1963) but also many additional antipsychotic compounds were generated, based on the clear molecular target being the dopamine receptor. These dopamine antagonists have formed the exclusive effective, but incomplete, antipsychotic armamentarium for psychiatrists throughout the past half-century. Each of the traditional and newer antipsychotics is associated with a distinctive side effect profile but with the same primary antipsychotic effects (Davis, 1969).

TRADITIONAL ANTIPSYCHOTIC DRUGS

There are many primary and review papers in this area (Gallego et al., 2012; Leucht et al., 2012), allowing the emphasis here to highlight the trajectory of drug development and special features important to the clinical use of antipsychotic drugs.

Chlorpromazine, after its serendipitous discovery, was evaluated in the early 1950s in multicenter trials (Davis, 1969). The trials inevitably included drug-naïve individuals, because this was the first effective drug for psychosis. Patient response was brisk and extensive; improvement occurred incrementally over several weeks. Remarkable reductions of 80% or more in psychotic symptoms were reported, including resolution of hallucinations, delusions, and thought disorder. The drug

was broadly applied and the development of additional compounds strongly encouraged because of the long awaited efficacy of a drug treatment for florid psychosis. Side effects of chlorpromazine include parkinsonism and akathisia, and also hypotension, sedation, and amenorrhea. Hepatotoxicity and electrocardiographic changes were less frequent but more serious side effects. Tardive dyskinesia occurred as well. Today the use of chlorpromazine has gradually diminished, based mostly on its sedative and cardiovascular side effects, and still significant parkinsonism.

Haloperidol was introduced in the late 1950s, and until recently, was the most widely prescribed antipsychotic for schizophrenia and psychosis in general. Its potent antipsychotic action with little sedation, despite acute chronic motor side effects, sustained its widespread recommendation as an antipsychotic. It remains to be seen if new drugs will offer side-effect advantages over haloperidol to increase compliance and reduce relapse sufficiently to balance their increased cost. The pharmacology of haloperidol is broadly documented because the drug is often used as the prototypical control antipsychotic for animal and human studies. Functional imaging studies of humans have addressed the question of where in the brain haloperidol exerts its actions, relating its extensive pharmacology to its clinical actions. In this regard it is interesting to note that haloperidol increases neuronal activity throughout the basal ganglia, in both dorsal and ventral regions, and in the thalamus, while it decreases neuronal activity in the PFC and in the anterior cingulate cortex (ACC) (Holcomb et al., 1996). We presume that activations in dorsal basal ganglia relate to motor side effects, while functional alterations in PFC and ACC may underlie therapeutic actions, although this interpretation is still speculative. The antipsychotic efficacy of haloperidol was initially established in controlled clinical trials in the early 1960s (Davis, 1969). But it was not until recently that a dose-response study was conducted across the apparent dose-sensitive range for haloperidol, showing a highly potent action without a linear relationship between dose and antipsychotic action (Zimbardo et al., 1997). Haloperidol produced significant parkinsonism and akathisia across all doses used, even at the lowest dose tested (4 mg/day).

Clozapine is an antipsychotic drug, which, although it has led the “new drug” era, is not itself new. Clozapine has a uniquely superior antipsychotic action, demonstrated in treatment-resistant individuals and in partial treatment responders (Kane et al., 1988). While it is the only superior antipsychotic, the molecular mechanism(s) associated with this action are unknown, although often suggested to be associated with its broad but low affinity for many monoamine receptors; its pharmacology is consistent with these characteristics (Coward, 1992). Clozapine has several active metabolites, two abundant examples of which are norclozapine and desmethylclozapine. Clozapine’s neurochemical profile showing reduced dopamine receptor occupancy in striatum and increased serotonin receptor occupancy in cortex (Farde et al., 1992) is characteristic of the second generation of antipsychotics (Kapur et al., 1999). Functional imaging results are consistent with those for haloperidol, although the striatal activations are only in limited ventral regions, not broadly throughout the

basal ganglia, compared with extensive actions by haloperidol (Lahti et al., 2002). Moreover, clozapine differs from haloperidol in that it increases neuronal activity in the ACC and PFC, areas that are important to core cognitive functions like attention and working memory. Acute motor side effects are not often seen with clozapine including parkinsonism and akathisia. In addition, clozapine appears by all estimates to have an extremely low (if any) incidence of tardive dyskinesia. With respect to other side effects, however, clozapine is at the top of the list. It causes agranulocytosis with an incidence of 0.5–1%, a condition which has a 3–15% mortality. The risk for agranulocytosis is highest in the second and third months after beginning treatment; risk is reduced after the first six months and remains flat and relatively low after the first twelve treatment months of treatment. In addition, the drug can induce seizures, increase heart rate, and stimulate cardiac arrhythmias. The drug causes substantial weight gain, and alters carbohydrate metabolism while it affects plasma lipids, a symptom complex called the metabolic syndrome (Allison et al., 1999; Henderson et al., 2000; Wirshing et al., 1999). It also causes other less medically significant, but bothersome side effects like sedation and drooling. It is surprising that, with this serious side effect profile, clozapine is used at all; however, the value of its added benefit in psychosis weighs successfully against all of these side effects, particularly for the seriously ill schizophrenic person.

One of the active metabolites of clozapine is *N-desmethylclozapine* (NDMC); it has similar pharmacological properties to clozapine with the exception of demonstrating M_1/M_5 agonist actions instead of the M_1/M_5 antagonist actions of clozapine (Burstein et al., 2005; Weiner et al., 2004). This distinction suggests that NDMC will have an improved action on cognitive dysfunction in schizophrenia along with the superior clozapine-like antipsychotic action. Indirect evidence supports this prediction with the observation that among clozapine treated patients, a linear correlation exists between cognitive performance and the ratio of NDMC/clozapine (Davies et al., 2005).

SECOND-GENERATION ANTIPSYCHOTIC DRUGS

Risperidone is a benzisoxazol derivative with high affinity for the $5HT_{2A}$ and D_2 receptors. Its *in-vitro* affinity for serotonin $5HT_{2A}$ is 20 times higher than for dopamine D_2 receptors. Risperidone efficacy has been evaluated in schizophrenia across a broad dose range (2–16 mg/day) in several large multicenter trials showing a reduction in positive and negative symptoms; positive symptoms responded to risperidone in a similar fashion as to haloperidol; negative symptom response may be greater (Marder and Meibach, 1994). A risperidone dose of 3–6 mg/day produces the most desired outcome in the usual patients (Love et al., 1999). Risperidone has been extensively used as an antipsychotic in the elderly, in part because of its favorable motor side effect profile with limited sedation. A long-acting injectable preparation of risperidone is available, made up of active medication encapsulated in a Medisorb polymer, generating microspheres. After a single injection of a recommended dose of 25–50 mg, the microspheres will generate a slow and steady release of risperidone

between three and seven weeks after injection. Steady state plasma levels occur after four injections. Clinical actions begin three weeks after the injection and will extend 4–6 weeks after that. This long-acting risperidone has shown full antipsychotic efficacy in several large multicenter clinical trials. Its primary actions and side effects are similar to the parent drug. Its recommended dose is 25 mg every two weeks, with an increase to 37.5 mg or 50 mg where necessary. This is the first long-acting preparation of any second-generation drug and has the potential to improve medication compliance in persons with psychosis. Motor side effects are relatively low with risperidone at doses below 4 mg/day. At doses above 10 mg/day, parkinsonism and akathisia are similar to haloperidol. Hyperprolactinemia is common and frank galactorrhea regularly seen with risperidone. Weight gain occurs, but to a mild degree. The metabolic syndrome, although apparent with risperidone, is not as frequent as with clozapine or olanzapine (Allison et al., 1999).

Olanzapine is a structural congener of clozapine and has many of the same pharmacologic characteristics as clozapine, with significant exceptions in side effects (i.e., no agranulocytosis) and in efficacy (i.e. equal, but not superior efficacy). Olanzapine efficacy was established based on four large placebo- and haloperidol-controlled multicenter registration trials (Tamminga and Kane, 1997; Tollefson et al., 1997b). Consistently, olanzapine showed a clear antipsychotic response in actively psychotic schizophrenic patients, significantly greater than placebo and equivalent to haloperidol on positive symptoms. There was a suggestion that olanzapine could be more effective for negative symptoms than haloperidol (Tollefson et al., 1997a). Motor side effects with olanzapine treatment are remarkably diminished compared to traditional drugs. Whereas at high doses, mild akathisia can be seen, anticholinergic drug use for motor side effects is low. Weight gain can be substantial. Metabolic syndrome with abnormal carbohydrate metabolism, frank diabetes, and elevated plasma lipid measures is reported, thus increasing metabolic and cardiovascular burden (Bettinger et al., 2000; Osser et al., 1999). No blood dyscrasias are associated with olanzapine use, a side effect closely evaluated because of the structural similarity between olanzapine and clozapine.

The other second-generation antipsychotic drugs include *quetiapine ziprasidone, and aripiprazole*. Each of the second-generation drugs has demonstrated antipsychotic activity and moderate, if any, motor side effects. Quetiapine is distinguished by its sleep action (prolongs sleep without inducing it) and it is often administered before bed but it still retains the metabolic side effects of clozapine-like drugs. Ziprasidone and aripiprazole both have low levels of metabolic side effects and are antipsychotic drugs that avoid gross weight gain. Additional drugs with antipsychotic activity have continued to be marketed, including lurazidone (Kane, 2011), asenipine (Potkin, 2011), paliperidone (Richelson, 2010), and iloperidone (Weiden, 2012), and others are under development. All of the new drug actions include antidopaminergic activity, so success at novel drug development for psychosis outside of the dopaminergic modulation class has not achieved full success. It remains unclear why the effective pharmacotherapy of psychosis is so focused.

GLUTAMATERGIC DRUGS

Drugs that block the NMDA receptor generate robust psychotic manifestations in normal people, as well as psychosis exacerbation in patients, and generate psychotic-like behaviors in animals. Moreover, analysis of human tissue from schizophrenia cases shows alterations in NMDA receptor and signaling proteins. Therefore, glutamate enhancers, especially those acting at the NMDA receptor, have been put forward as rational hypothetical antipsychotics. In 2006, when Schoeppe et al. reported the efficacy of LY2140023, an agonist at the mGluR2/3 metabotropic receptor which is thought to augment glutamate release through a presynaptic mechanism, there was considerable excitement (Kinon and Gomez, 2012). However, the promise has not been born out, and public summaries of two follow-up studies have both been negative. Several additional glutamatergic drugs are still in development, both as stand-alone antipsychotics and as co-treatments with standard drugs for cognitive dysfunction (Kinon, 2011). Results from additional glutamate enhancing strategies will inform this area further as they become available. It is widely speculated that these drugs may act effectively in subgroups of individuals with glutamate-mediated lesions accounting for their psychosis.

MUSCARINIC AGONISTS

An interesting antipsychotic candidate, xanomiline, was originally developed as a cognition-enhancing drug for Alzheimer's disease, and now has shown surprising effects in a single-site schizophrenia trial (Shekhar et al., 2008). Xanomiline showed both a significant (although not large) antipsychotic action in schizophrenia as well as an advantage for cognition. Whether or not these manifestations can be demonstrated in a large multisite trial is an unanswered question. Cholinesterase inhibitors are not effective antipsychotic agents but have a much lower potency as cholinergic drugs than direct-acting cholinergic agonists. There are additional cholinergic agents available to test (Sellin et al., 2008) and considerable activity in the development of allosteric modulators of selected muscarinic receptors subtypes. It may be possible within the next few years to follow up on this original clever finding.

COGNITIVE DYSFUNCTION IN PSYCHOSIS AND EXPERIMENTAL TREATMENTS

Cognitive dysfunction in schizophrenia is often associated with poor psychosocial outcome, correlating significantly with aspects of poor psychosocial outcomes, therefore effective treatment is important (Green, 1996). This motivated the NIMH to open up the area of cognition treatments in schizophrenia, in part by spearheading the NIMH Measurement and Treatment Research to Improve Cognition in Schizophrenia (MATRICS) project (Marder and Fenton, 2004). The literature supports the presence of several, but not all, cognitive dimensions as abnormal in schizophrenia, including "speed of processing," "attention and vigilance," "working memory," "verbal

learning and memory," "visual learning and memory," "reasoning and problem solving" and "social cognition." Animal research suggests that each cognitive domain could be distinctive in its anatomy, pharmacology, and likely in its molecular treatment. Many studies are ongoing to identify treatments for cognitive dysfunction.

MOLECULAR TARGETS FOR COGNITION IN SCHIZOPHRENIA

No treatments currently exist for cognitive dysfunction in psychosis. No human targets are apparent, and no understanding of the molecular basis exists. However, abundant animal literature exists to support interest in several different molecular targets in schizophrenia.

The role of the hippocampal alpha-7 nicotinic receptor in sensory gating and attention, and its alteration in schizophrenia provide the basis for strategies augmenting alpha-7 nicotinic signaling in schizophrenia (Martin et al., 2004). In addition, the delineation of selective deficits in GABA receptor subunits within subpopulations of GABA-containing neurons in the prefrontal cortex have led to the strategy of augmenting GABA signaling in prefrontal cortex pharmacologically (Lewis et al., 2004). These strategies are currently being tested in humans with pharmacologic probes.

With non-human primate models of working memory, Goldman-Rakic elegantly established the importance of D₁ dopamine signaling for working memory, a key area of cognition dysfunction in schizophrenia. Diverse experiments suggest that dopamine signaling at the D₁ receptor could be insufficient in persons with schizophrenia (Akil et al., 2003; Karlsson et al., 2002; Okubo et al., 1997; Potkin et al., 2003; Selemon et al., 1995). In animals, D₁ but not D₂ antagonists disrupt working memory and D₁ agonists promote cognition (Goldman-Rakic et al., 2004). Therefore, the augmentation of D₁ signaling in schizophrenia is one of the most viable approaches for improving cognition, especially for augmenting working memory.

Serotonin, as a neurotransmitter, uses different CNS receptors for its signaling pathways. Evidence supports a role for the 5-HT_{1a}, 5-HT_{2a}, 5-HT₄, and 5-HT₆ receptor systems as potential targets for schizophrenia cognition (Roth et al., 2004). The 5-HT_{1a} receptors are located in regions of brain that subserve learning and memory, including the hippocampus and neocortex. Considerable animal evidence suggests that 5-HT_{1a} active drugs could be cognitively enhancing in humans; clinical evidence also supports this idea, but without being clear if it is a 5-HT_{1a} partial agonist or a 5-HT_{1a} full antagonist that would have the best cognition-enhancing action (Roth et al., 2004). Modest, but indirect evidence, supports the role of the 5-HT₂, 5-HT₄, and 5-HT₆ receptors in cognition enhancement. Studies are currently being carried out in humans with cognitive disorders testing candidates from each of these families.

Additional data (mostly preclinical) exist to support several other molecular targets for cognitive enhancements in schizophrenia, including the muscarinic cholinergic receptors (Friedman, 2004), the metabotropic glutamate receptor (Moghaddam, 2004), and adrenergic receptors (Arnsten, 2004).

It is an era of discovery for schizophrenia therapeutics (Insel, 2012). The possibility that multiple, dimension-specific co-treatments could be necessary for full response in the illness will be tested.

DISCLOSURES

Dr. Tamminga has the following conflict of interest, disclosures, and financial support. To my knowledge, all of my possible conflicts of interest and those of my coauthors, financial or otherwise, including direct or indirect financial or personal relationships, interests, and affiliations, whether or not directly related to the subject of the chapter, are listed here.

- American Psychiatric Association—Deputy Editor >\$10,000
- Astellas—Ad Hoc Consultant <\$10,000
- The Brain & Behavior Foundation—Council Member; Unpaid Volunteer
- Eli Lilly Pharmaceuticals—Ad Hoc Consultant <\$10,000

28 | THE NEUROBIOLOGY OF BIPOLAR DISORDER

KATHERINE E. BURDICK, STEPHEN J. HAGGARTY, AND ROY PERLIS

INTRODUCTION

Efforts to understand the fundamental neurobiology of bipolar disorder, as with other psychiatric illnesses, have been hindered by the inability to directly access the primary organ of interest in living patients, as well as a lack of valid cellular and animal models of disease. As a result, the majority of data to date comes either from postmortem studies, from peripheral cells, and from investigations of the effects of known therapeutic agents in bipolar disorder, particularly lithium. New technologies are emerging that may inform these studies; these include new kinds of cellular models (Brennan et al., 2011; Sheridan et al., 2011), including models that will be informed by the genetic studies described elsewhere (Chapter 19), as well as new ways of characterizing those models. As such, any summary of relevant neurobiology is undoubtedly incomplete and likely to have a short half-life.

The genetics of bipolar disorder were extensively covered in an earlier chapter in view of substantial overlaps with schizophrenia. However, topics that are relatively more specific to bipolar disorder are the focus of the current chapter. Several areas will be covered. First, the temporal development of bipolar disorder from high-risk to prodromal to first-episode symptoms will be discussed. Second, evidence that bipolar disorder has well-documented, measurable cognitive abnormalities, in contrast with older views, is explored. Third, the disruption in circadian biology in bipolar disorder patients is discussed. Fourth, we describe the current, existing model systems that have implicated a number of signaling pathways, processes, and animal models that are likely to be relevant to bipolar disorder itself and/or therapeutic mechanisms. These include circadian abnormalities, epigenetic processes including histone modification, Wnt/GSK3 signaling, other modulators of neuroplasticity, and mitochondrial function. The evidence for each of these is summarized in the following.

HIGH-RISK STUDIES IN BIPOLAR DISORDER

As discussed in Chapter 19, the heritability of bipolar disorder is high, and substantial evidence indicates that the illness runs in families. Specifically, first-degree relatives of patients with bipolar illness are at about a 10-fold increased risk of developing bipolar disorder as compared with individuals who do not have a family history. These data suggest that one useful approach to understanding the risk factors associated with

bipolar disorder, as well as the longitudinal development of the illness, is to study high-risk offspring of bipolar parents. Unlike studies focused on prodromal or chronic patient cohorts, high-risk offspring samples are not as likely to be confounded by existing symptoms, medications, and other comorbid conditions such as substance use disorders.

Children with at least one parent who is diagnosed with bipolar disorder are at a fourfold increased risk of developing a mood disorder over their lifetime (Lapalme et al., 1997). The rate of diagnosis of bipolar disorder in high-risk offspring ranges broadly from 3% to 50% but is consistently higher than in the general population (1–2%) (Kessler et al., 2005). Most high-risk studies are limited by very small sample sizes and are descriptive in nature, making it difficult to identify specific risk factors for conversion to the full-blown illness. Very few studies have systematically assessed clinical or environmental risk factors; however, certain personality traits such as behavioral disinhibition are more commonly seen in high-risk offspring than in those without enhanced risk (Hirshfeld-Becker et al., 2006) and significant negative life events during childhood increase the likelihood of developing a subsequent mood disorder (Hillegers et al., 2004). There is also some evidence that high-risk children and adolescents have neurocognitive impairments across several domains including processing speed, working memory, executive functions, and response inhibition (Salvadore et al., 2008), but these deficits are milder than those noted in first-episode and more chronic patients with bipolar disorder and are rather non-specific.

Neurobiological risk factors for bipolar disorder have also been identified in high-risk offspring including stress-vulnerability associated with hypothalamic-pituitary-adrenal (HPA)-axis dysfunction and increased inflammatory/immune response; however, again data are limited by small cohorts. Most studies assessing biomarkers in offspring of bipolar parents include individuals who are themselves diagnosed with either depression or another psychiatric disorder, confounding the interpretation of these findings. Nevertheless, early evidence indicates subtle abnormalities in HPA-axis functioning in high-risk offspring such as elevated salivary cortisol levels upon waking when compared with children with no family history (Ellenbogen et al., 2004). Likewise, at least one study has identified markers of an activated immune system in offspring of bipolar parents prior to the development of overt affective symptoms as evidenced by altered expression in genes that are involved in the inflammatory process (Padmos et al., 2008).

Despite the increased risk for illness that is associated with being born to a bipolar parent, most offspring do not go on

to develop bipolar disorder, making high-risk studies time-consuming and expensive with inherently small sample sizes. Other approaches have been implemented to increase the likelihood of studying individuals who will develop the full-blown illness, including studies focusing on the clinical prodrome and the early phase of the illness.

THE PRODROME

The bipolar prodrome constitutes a period of disturbance characterized by distinct features/symptoms that lead up to the onset of the full-blown disorder. The schizophrenia prodrome has been well characterized and has been researched for decades, yielding significant findings that point toward clinical and cognitive predictors as was discussed in Chapter 27. Large consortia have been formed, such as the North American Prodrome Longitudinal Study (NAPLS; Addington et al., 2007), in order to collect sample sizes that are sufficient for obtaining maximal predictive power. However, the field of bipolar disorder has yet to firmly establish the presence of a prodrome or to identify clear, replicated clinical/cognitive predictors for the disorder. Data from retrospective studies suggest that there are attenuated forms of symptoms seen in the disorder as well as less specific psychiatric features that precede the onset of the illness; however, there are very few prospective studies confirming these findings.

CLINICAL PREDICTORS

According to retrospective reports, between 45% and 96% of bipolar disorder patients reported prodromal symptoms at least one month prior to the full onset of bipolar disorder (Correll et al., 2007; Conus et al., 2010). Depressive symptoms are typically reported as the first prodromal signs, however some manic symptoms were also reported, including sleep disturbance/decreased need for sleep and increased energy/activity. Psychotic symptoms have also been identified as a prodromal symptom (Jackson et al., 2003), although they tend to occur later in the prodrome and have low specificity.

Prospective accounts of prodromal symptoms support mood lability (Angst et al., 2003) and attenuated positive symptoms as putative prodromal symptoms in bipolar disorder (Thompson et al., 2003). Data indicating attenuated positive symptoms as prodromal to bipolar disorder are limited by the fact that most of these samples were being collected in the context of a schizophrenia high-risk study; therefore, those who went on to develop bipolar disorder may not be representative of the general at-risk population. During the prodromal phase, these patients presented with similar clinical and neurocognitive profiles compared to individuals who ultimately developed a schizophrenia spectrum disorder.

COGNITIVE PREDICTORS

Global and specific neurocognitive impairments are prominent during the prodrome for schizophrenia (Davidson et al., 1999). In contrast, global measures of cognitive function, such

as IQ, do not appear to be viable cognitive predictors of bipolar disorder. Most studies agree that there is no significant IQ deficit in individuals before they develop bipolar disorder (Meyer et al., 2004; Reichenberg et al., 2002; Zammit et al., 2004) if they are at high risk for the disorder based on family history (Frangou et al., 2005), or if they are in the early stages of the disorder (Hill et al., 2009; Zanelli et al., 2010). There is even some evidence to suggest that an *increased* IQ may be predictive of bipolar disorder (MacCabe et al., 2010). This is in stark contrast with the schizophrenia literature, which consistently finds IQ deficits in those at increased risk and in the early stages of the disorder.

Although global measures are not useful in predicting impending onset of bipolar disorder, some specific neurocognitive domains, such as declarative memory and executive function, remain promising. Deficits in these domains have been reported in unaffected siblings (Christensen et al., 2006), in offspring from bipolar parents (Klimes-Dougan et al., 2006; Maziade et al., 2009), and in first-episode patients (Hill et al., 2009; Zanelli et al., 2010), and are consistent with deficits reported in chronic patients with bipolar disorder. Cognitive deficits in memory and executive function are noted during acute episodes, as well as during euthymic periods (Martinez-Aran et al., 2004). In fact, convergent and meta-analytic data suggest that verbal memory, in particular, may be the most valuable cognitive phenotype for bipolar disorder (Glahn et al., 2004).

FIRST EPISODE

The onset of bipolar disorder is marked by the first affective episode of either polarity; however, the diagnosis itself is not made until the first manic episode occurs. In up to 2/3 of cases, the first episode of mania is preceded by a major depressive episode (Daban et al., 2006) but most studies of first-episode bipolar disorder focus on patients who are experiencing their first hospitalization or their first mania.

Given the relative preservation of premorbid functioning in bipolar disorder, the period surrounding the first mania is of particular importance. At the time of first episode, frank symptoms of psychosis present in approximately 60% of subjects; neurocognitive deficits are significant, and functional abilities are disrupted. Onset of first episode typically occurs during adolescence; however, many patients will have been suffering undiagnosed, or misdiagnosed, for months or even years prior to initial treatment (Weller et al., 1995). With adequate treatment, first-episode bipolar subjects show relatively high rates of remission from mania within six months, ranging from 80% to 100% in most studies; however, relapse rates within the first year are also high (35–52%). Moreover, syndromic recovery rates, defined by no longer meeting DSM criteria for an acute episode, are considerably higher than symptomatic recovery rates, suggesting a persistent clinical course marked by sub-syndromal symptoms in most patients (Tohen et al., 1992). Of particular concern are the consistently replicated findings of social, occupational, and general functional recovery rates falling far below remission rates (Conus et al., 2006; Tohen et al., 2003).

Neurocognitive functioning at the time of first episode also tends to decline significantly as compared with premorbid functioning; although the deficits are generally less severe than those noted in first episode schizophrenia samples (Hill et al., 2009). Overall there is substantial evidence documenting poor outcomes in first-episode bipolar disorder. Certain illness features such as earlier age at onset and comorbid drug and alcohol abuse (McGorry et al., 1996) can exacerbate these poor outcomes and should be the focus of future early intervention efforts.

CIRCADIAN ABNORMALITIES

It has long been understood that changes in sleep, daytime activity, and energy levels are cardinal features of acute mania and depression, with more recent data suggesting that these symptoms may represent trait-related risk factors for BPD (Plante and Winkelman, 2008). Changes in the sleep-wake cycle and other circadian rhythms represent core features of bipolar disorder, with sleep abnormalities reported in ~90% of patients during acute episodes. Even when euthymic, many BPD patients continue to demonstrate circadian disruptions, including diminished sleep efficiency and lower daytime activity levels. These trait-like circadian disruptions are of particular clinical relevance as changes in sleep are highly predictive of impending affective instability, and BPD patients with poor sleep quality report diminished quality of life (Gruber et al., 2009).

The exact nature of the circadian abnormality in BPD is unknown; theories posit a potential uncoupling of the biological clock from external variables that entrain circadian rhythms (e.g., light) versus the desynchronization of the sleep-wake cycle such that it falls out of phase with other biological rhythms (Dallaspezia and Benedetti, 2009). Euthymic BPD patients are commonly characterized by an “eveningness” chronotype, such that their time-to-sleep preference is phase-shifted to a later than average hour, one that is not typically aligned with the 24-hour light-dark cycle (Plante and Winkelman, 2008). Harvey et al. reported that 70% of remitted BPD patients had diminished sleep efficiency and decreased daytime activity levels (Harvey et al., 2005). More recently, Ritter et al. found that patients with BPD demonstrated increased sleep latency compared to healthy controls as determined by actigraphy. In addition, patients with BPD self-reported a persistent pattern of increased insomnia and hypersomnia, as well as sensitivity to shifts in circadian rhythm (Ritter et al., 2012). Interestingly, participants at increased risk for BPD reported a similar pattern, suggesting that circadian abnormalities may represent a core illness feature that precedes the onset of frank mood episodes.

Along these lines, a decreased *need* for sleep (the ability to maintain energy without adequate sleep) has been shown to be present prior to the illness onset and during the prodrome (Skjelstad et al., 2010). Unaffected offspring of BPD patients demonstrate disrupted sleep and activity levels versus healthy subjects without a family history (Ankers and Jones, 2009), suggesting that circadian abnormalities may be a genetically

mediated, central feature of the disorder. In order to provide support for this hypothesis, molecular genetic studies have tested candidate genes that are known to regulate circadian functions (e.g., *CLOCK*, *PERIOD*) for association to BPD (Dallaspezia and Benedetti, 2009). Some evidence for modest level of association has been found. For example, a *CLOCK* gene polymorphism was found to be nominally associated with moderate features of the illness such as diurnal preference (Katzenberg et al., 1998), levels of evening activity, and delayed sleep onset in BPD (Benedetti et al., 2007). In general, studies of circadian genes are limited by (1) the small sample sizes available in which relevant phenotypes can be tested, and thus (2) the lack of appropriate replication samples, which are critical to establish valid genetic association. Information on circadian abnormalities is not routinely available in samples that have been used in genome-wide association studies. Thus the data are intriguing, but extensive further studies will be necessary to ensure relevance to the etiology of bipolar disorder.

The nature of the circadian abnormality in BPD is not known; however, a recent review by Dallaspezia and Benedetti (2009) described two related hypotheses: (1) patients with BPD have a biological clock that is detached from environmental variables that act to regulate circadian rhythms; and/or (2) the normal sleep-wake cycle in BPD is not in phase with other biological rhythms (e.g., melatonin release). As noted, data in BPD support a high rate of an “eveningness” chronotype, a preference for later bedtimes/wake-times, and for carrying out mental and physical activity in the evening as opposed to the morning (Giglio et al., 2010). Eveningness is associated with a circadian phase delay, a shift in the normal temperature reduction and melatonin secretion that triggers onset of the circadian-based sleep cycle, as well as waking times that are misaligned to circadian phase (Duffy et al., 1999). Such circadian desynchronization results in elevated melatonin, a sleep-promoting hormone, early in the day thereby impairing wakefulness and vigilance (Benca et al., 2009). Importantly, these data suggest that impaired sleep quality in BPD is associated with reduced quality of life. Animal models of circadian abnormalities are discussed in what follows.

EPIGENETICS

Epigenetic mechanisms, including methylation of DNA and DNA-associated proteins, represent key means of regulating gene expression. Histone proteins “package” DNA in units called nucleosomes, and thereby regulate access of transcription factors and other proteins to that DNA. The nucleosomes are regulated by histone-modifying complexes and ATP-dependent remodeling complexes (Gardner et al., 2011; Racki and Narlikar, 2008), and these groups of proteins either modify histones directly or alter the position of nucleosomes, to influence the accessibility of DNA itself. Two groups of enzymes of particular importance to these epigenetic mechanisms are the histone acetyltransferases (HATs), which tend to alter chromatin in a manner that makes DNA more accessible for transcription, and the histone deacetylases, which tend to

have opposing effects and repress transcription (Berndsen and Denu, 2008; Selvi et al., 2010). Other enzymes modify DNA itself, primarily through addition or removal of methyl groups (Guo et al., 2011; Mikaelsson and Miller, 2011).

Evidence implicating histone deacetylases (HDACs) in mood and psychotic disorders, including bipolar disorder, comes from two major sources: animal data in disease models, and known HDAC effects of existing therapeutics. Preliminary human studies also suggest some role for epigenetic effects in bipolar disorder.

ANIMAL MODELS: MEMORY AND STRESS RESPONSE

The link between epigenetics and psychiatric illness began with evidence that chromatin plays a key role in memory formation and in learning (Guan et al., 2002; Korzus et al., 2004; Levenson et al., 2004). Work in *Aplysia* from the Kandel lab demonstrated the effects of excitatory and inhibitory neurotransmitters on transcription were mediated by HATs and HDACs, respectively (Guan et al., 2002). Later work in mutant mice heterozygous for the specific HAT identified in that system, CREB-binding protein (CBP), indicated deficits in synaptic plasticity as well as long-term potentiation in hippocampus, which was associated with reduced histone acetylation. Notably, an inhibitor of HDACs was able to reduce both the molecular and cellular effects of reduced CBP function suggesting a potential novel approach to therapeutic development for cognitive disorders (Alarcon et al., 2004; Wood et al., 2005).

A particularly relevant form of memory for psychiatric disorders amenable to investigation in animal models is fear conditioning, in which a neutral stimulus is paired with a noxious stimulus resulting in anxiety and fear in the presence of what was previously a neutral stimulus. While anxiety is not a core feature of bipolar disorder, it is highly comorbid with a prevalence of 50% or more in clinical samples. Initial investigations found conditioned fear to be associated with acetylation of histone H3 in hippocampus; fear conditioning could be enhanced with administration of an HDAC inhibitor (Levenson et al., 2004). At a cellular level, administration of the HDAC inhibitor enhanced hippocampal long-term potentiation in area CA1. Subsequent investigations suggest that HDAC inhibitors may potentiate memory even in mouse models of neurodegeneration (Graff et al., 2012), and find consistent effects with modulation of HDAC function. In particular, increased expression of Hdac2 appears to suppress memory formation and reduce synapse number, while reduced Hdac2 expression has opposing effects (Guan et al., 2009).

Multiple pharmacologic treatments for mood disorders can modulate chromatin structure or DNA methylation. The monoamine oxidase inhibitor antidepressant tranylcypromine also acts as a direct inhibitor of lysine histone demethylase 1 (*LSD1*) (Lee et al., 2006). Antidepressants from other classes, including the tricyclic imipramine and the selective serotonin reuptake inhibitors (SSRI), indirectly inhibit DNA methyltransferase (*DNMT1*) in primary cortical culture (Zimmermann et al., 2012). Finally, the antimanic drug

valproic acid is known to inhibit one class of HDACs (Phiel et al., 2001), including HDAC2 described in the preceding to play a key role in cognition.

Non-pharmacologic interventions have been shown to influence chromatin modification as well. In a rat study, electroconvulsive seizures (analogous to human electroconvulsive therapy) elicited increases in histone acetylation (Tsankova et al., 2004). Among the genes influenced by an increase in open chromatin was the promoter region of brain-derived neurotrophic factor (*Bdnf*), whose expression is known to be increased following electroconvulsive seizures. Additional chromatin changes were observed following chronic administration of electroconvulsive seizures.

Animal models of the stress response may also be important for understanding bipolar disorder. Stressful life events such as early adversity have been shown to increase risk for development of mood disorders, including bipolar disorder (Gilman et al., 2012; Horesh et al., 2011; Post et al., 2001), while acute stress may be associated with onset of mood episodes.

One of the most direct links between epigenetics and behavior comes from studies that demonstrated in rats that maternal behavior influenced histone acetylation as well as DNA methylation in offspring observed one week after and persisting at ninety days after birth (Weaver et al., 2004). Most notably, these offspring exhibited hyperactivity of the hypothalamic-pituitary-adrenal axis when exposed to acute restraint stress. Conversely, when pups were fostered by mothers exhibiting higher levels of grooming and licking behavior, these changes were reversed—an infusion of an HDAC inhibitor, trichostatin A, could also normalize stress response.

Importantly, the changes in histone acetylation may exhibit a complex kinetic relationship with stress response. For example, following a similar restraint stress paradigm (Hunter et al., 2009), some chromatin marks decreased while others increased at seven days, with opposing changes observed following twenty one days, which may represent an attempt to maintain homeostasis following acute stress exposure.

Additional animal models of stress response also support a role for epigenetic effects. For example, forced swim tests increase histone phosphorylation as well as other chromatin marks (Chandramohan et al., 2008), which can be blocked by antagonism of *N*-methyl-D-aspartate (NMDA) receptors or downstream signaling pathways. Similarly, chronic social defeat, in which mice are exposed to an aggressive male mouse for a brief period daily, yields increase in histone methylation in the defeated mouse up to one month after exposure (Tsankova et al., 2006). Work with this latter model has also yielded important insight into epigenetic mechanisms of antidepressant effect, discussed further in the following.

ANIMAL MODELS OF MOOD AND PSYCHOSIS

Epigenetic effects in animal models of mood and psychosis have been investigated in two main ways. First, initial studies have characterized changes in chromatin or DNA methylation among animals following exposure to specific stressors known to produce mood disorder-like phenotypes. Second, some

studies have directly examined the effects of perturbing function of HDACs or other enzymes important in chromatin modification and remodeling. An example of the former is studies in the mouse social defeat model, indicating increased histone methylation a month after stress exposure (Tsankova et al., 2006). Specific changes in nucleus accumbens were observed in histone methylation (Wilkinson et al., 2009).

Several studies investigated the perturbing effects of known HDAC inhibitors in mouse models. Results with a lower-potency HDAC inhibitor, sodium butyrate, have been inconsistent. One study suggested augmentation of fluoxetine effect in the tail suspension tests (Schroeder et al., 2007), and another showed antidepressant-like effects on both tail suspension and forced swim tests (Yamawaki et al., 2012). On the other hand, a 21-day treatment study using sodium butyrate failed to show change in forced swim test behavior, even though changes in histone acetylation were observed (Gundersen and Blendy, 2009). More potent HDAC inhibitors yielded consistent effects. In the forced swim test, a model of acute stress, the nonselective HDAC inhibitor SAHA diminishes depression-like behaviors (Uchida et al., 2011). A more selective HDAC inhibitor, MS275, can reverse depression-like effects in the mouse social defeat model (Covington et al., 2009). The antidepressant imipramine also reduces the depression phenotype in this model, and is associated with increase in other marks associated with the more active form of chromatin. In addition to the drug-induced manipulation of HDACs, mouse investigations that directly manipulate HDAC expression have yielded convergent results in certain cases. For example, increased expression of Hdac5 in mouse hippocampus, previously shown to be reduced by imipramine treatment, yielded antidepressant effects (Tsankova et al., 2006).

One of the most intriguing links between histone modification and bipolar disorder comes from investigations of the *CLOCK* gene (Doi et al., 2006), which itself codes for a histone acetyltransferase. This gene interacts with HDACs and other histone-modifying enzymes (Etchegaray et al., 2006; Katada and Sassone-Corsi, 2010; Nakahata et al., 2008) that may be involved in generating circadian rhythms. A direct role for *CLOCK* in interacting with a small network of genes including *BMAL1*, *PER1-3*, and *CRY1* and *2* has been demonstrated to be central for generation of circadian rhythms (Brown et al., 2012). A dominant-negative mutation in *CLOCK* has been demonstrated to elicit mania-like increases in activity and disruption of sleep-wake cycle in mouse models (Roybal et al., 2007). Such phenotypic changes have high face validity given the prominence of disruption of circadian rhythms in many bipolar patients (Milhiet et al., 2011).

The dominant-negative mutation *CLOCK* mouse model (King et al., 1997) has also provided an opportunity to investigate the effects of known bipolar therapies. For example, chronic lithium treatment appears to normalize anxiety and depressive behaviors in these models (Roybal et al., 2007), while an inhibitor of GSK3 β , a putative lithium target, reduces another mania-like phenotype in these mouse models, referred to as novelty-induced hyperactivity (Kozikowski et al., 2011). This last finding may provide an important link between

investigation of histone modification and the GSK3 β /Wnt pathway discussed in more detail in what follows.

Another mouse model of a manic-like phenotype likewise supports a role for epigenetic effects of known antimanic therapies. The HDAC inhibitor sodium butyrate, like valproic acid, reduces the hyperactivity induced by psychostimulants in mice (Arent et al., 2011; Kim et al., 2008). The mechanism of this effect has not been directly demonstrated, though other lines of evidence indicate that valproic acid, like certain antipsychotic treatments, does demonstrate epigenetic effects (Tremolizzo et al., 2005).

Psychosis is a prominent feature of bipolar disorder that may occur during both manic and depressive episodes and some antipsychotic medications have demonstrated efficacy in treating psychosis as well as preventing mania depression. Here too, antipsychotic mechanism of action has been linked to epigenetic effects. In mice, chronic administration of the antipsychotic clozapine yields increased expression of Hdac2 in frontal cortex, coupled with decreased expression of the metabotropic glutamate receptor 2 (*mGluR2*), a transcriptional target of Hdac2 (Kurita et al., 2012). Other atypical antipsychotics exerted similar effects, which were dependent on antagonism of serotonin receptor 2A. Conversely, injection of the HDAC inhibitor SAHA increased mGluR2 expression, and chronic SAHA administration prevented some psychotic-like phenotypes such as deficits in prepulse inhibition induced by an NMDA receptor antagonist, MK801.

HUMAN STUDIES

A small but expanding set of studies suggests that individuals with mood disorders may exhibit changes in chromatin. Such studies are challenging because chromatin modification is highly time-, experience-, and tissue-specific. Absent a way to directly measure chromatin modification *in vivo* without directly sampling brain tissue, these studies rely either on post-mortem tissue or on peripheral cells such as lymphocytes.

A number of studies find mood disorders to be associated with changes in expression of chromatin-modifying enzymes, using either lymphocytes or postmortem brain tissue (Abe et al., 2011; Covington et al., 2011; Hobara et al., 2010; Iga et al., 2007). One comprehensive examination of 11 different HDACs in lymphocytes from mood disorder patients found multiple changes, some of which appeared to be state-dependent. That is, among individuals with major depressive disorder, *HDAC2* and *HDAC5* expression was reduced only during the depressive episodes, while individuals with BPD exhibited an increase in *HDAC4* (Hobara et al., 2010). Conversely, BPD subjects demonstrated reduced expression of *HDAC6* and *HDAC8* regardless of mood state. While those changes appeared to be independent of medication treatment, work in postmortem brain samples from individuals with schizophrenia (Kurita et al., 2012) has suggested that chronic antipsychotic use increased expression of *HDAC2*.

Two studies have directly demonstrated modification in levels of acetylation for a particular histone, H3, among individuals with bipolar disorder. The first compared blood-derived

lymphocytes in BPD patients and healthy controls (Gavin et al., 2009); notably, H3 acetylation was increased in lymphocytes from valproate-treated patients (Sharma et al., 2006). A post-mortem brain study found consistent results among individuals with major depression, with H3 methylation levels reduced (Covington et al., 2011).

GLYCOGEN SYNTHASE KINASE 3 (GSK3) PATHWAY

Several lines of evidence implicate the Wnt/GSK3 pathway in the etiology of neuropsychiatric disorders. First, the Wnt pathway is known to play a crucial role in neurodevelopment. The peak age of emergence of both bipolar disorder and schizophrenia is known to correspond to critical periods in brain development (Chapter 26). Second, this pathway is targeted by pharmacological agents used to treat these disorders, most notably lithium (Gould and Manji, 2005; Klein and Melton, 1996). Finally, and most directly, the Wnt/GSK3 pathway has been implicated by the demonstration that at least two psychotic disorder liability genes influence this pathway: inhibition of GSK3 by the protein encoded by the schizophrenia-associated gene *Disrupted-in-Schizophrenia 1 (DISC1)* (Mao et al., 2009), and *TCF4*, which is a known target gene of β -catenin (David et al., 2010).

GSK3 β has become a focus of investigation in bipolar disorder in large part because of its position as one target of lithium (Klein and Melton, 1996). In particular, the antidepressant properties of lithium preparations are thought at least in part to occur as a result of inhibition of GSK3 β (Beaulieu et al., 2007; Beaulieu et al., 2004; Pan et al., 2011), although the downstream mechanisms remain poorly understood (Bachmann et al., 2005; Chen et al., 2000; Gould and Manji, 2002). At the cellular level, with inhibition of GSK3 β by lithium (Beaulieu et al., 2008; Klein and Melton, 1996), the degradation of β -catenin is blocked, resulting in its accumulation in the cytoplasm and translocation to the nucleus, where it acts as an activator of transcription of TCF/LEF-dependent genes, such as *CCND1*, *AXIN2*, which can play a key role in cell cycle progression and neuroplasticity (Harris and Peifer, 2005).

NEUROGENESIS AND NEUROPLASTICITY

The discovery that neurogenesis occurs in adult brains, first in mouse and subsequently in human brains, prompted great excitement about the potential therapeutic implications. The observation of subtle abnormalities of histopathology, and in magnetic resonance spectroscopy studies, suggests that abnormalities in neuronal or glial proliferation or differentiation may contribute to the pathophysiology of bipolar disorder.

In particular, one postmortem study in mood disorder patients suggested a region-specific reduction in glial cell counts (Ongur et al., 1998), while another found normal glial density but reduction in neuronal size (Cotter et al.,

2005). Other studies fail to find any consistent differences in cytoarchitecture in bipolar disorder (Beasley et al., 2009). Complicating the interpretation of these studies are differences in region assessed, general methodology, and medication exposure. Taken together, however, at least some evidence exists for cellular abnormalities in bipolar disorder.

One possible indicator of synapse integrity *in vivo* is N-acetyl aspartate (NAA). Considered a marker of neuronal metabolism (see next section), NAA appears to increase along with synapse formation and reductions may be associated with axon dysfunction (Baslow, 2003). A recent review examined nearly 150 studies utilizing magnetic resonance spectroscopy in schizophrenia and bipolar disorder (Kraguljac et al., 2012). In those studies, among the most consistent findings were diminished levels of NAA in basal ganglia in individuals with bipolar disorder. A subset of studies have also found reductions in NAA in prefrontal cortex, including among children and adolescents diagnosed with bipolar disorder (Caetano et al., 2011). Notably, a recent study found reduced prefrontal NAA levels compared to controls in lithium-nonexposed bipolar patients, but normal levels in patients treated chronically with lithium (Hajek et al., 2012), consistent with a prior investigation of NAA and lithium in older adults (Forester et al., 2008), though another study did not observe such changes in adolescents (Patel et al., 2008).

Multiple studies have demonstrated that lithium promotes neurogenesis in adult rodent brain in hippocampus (Chen, et al., 2000; Hanson et al., 2011), an effect dependent on Wnt pathway integrity (Wexler et al., 2008). Anticonvulsants also demonstrate effects on neuronal proliferation and differentiation (Boku et al., 2011; Laeng et al., 2004). Studies in rodent models also suggest that lithium may oppose the antiproliferative effects of glucocorticoids, and further link lithium's proneurogenic effects to Wnt/GSK3 β , discussed in the preceding (Boku et al., 2009).

Beyond neuronal proliferation and differentiation, bipolar disorder may impact maturation and remodeling of synapses, so-called neuroplasticity. Here again indirect evidence comes from lithium's effects in model systems. For example, lithium augments long-term potentiation in the rat dentate (Son et al., 2003). Convergent effects of lithium and valproate have been observed in postsynaptic density gene expression (Nanavati et al., 2011).

An interesting proof-of-principle of lithium's effects on synapse function comes from models of Fragile X syndrome, which exhibit synaptic dysfunction that includes increases in glutamate-dependent long-term depression in hippocampus. Chronic lithium treatment in the mouse model normalizes these deficits, suggesting yet another mechanism by which lithium impacts synapse formation and maintenance (Choi et al., 2011).

MITOCHONDRIAL DYSFUNCTION

Another hypothesis about the pathophysiology of bipolar disorder relates to abnormalities in mitochondrial function. Evidence for such abnormalities comes from multiple lines of

investigation, ranging from studies of peripheral lymphocytes to magnetic resonance imaging. Complicating the investigation of mitochondria is the breadth of effects associated with them: in addition to their centrality in cellular metabolism, they play key roles in buffering calcium and regulating cell death (apoptosis).

A small number of studies have investigated the role of mitochondrial function in producing depressive- or manic-like phenotypes. In one study, manipulation of the mitochondrial polymerase gene *POLG* produced disruption of circadian rhythms (Kasahara et al., 2006), effects that could be eliminated with lithium administration or electroconvulsive shock (Kasahara et al., 2008). From a therapeutic perspective, a mouse study of creatine supplementation, a putative enhancer of mitochondrial function, suggested an antidepressant-like response among female but not male rats (Allen et al., 2010).

In humans, some studies of peripheral cells suggest abnormalities both of mitochondrial structure and function. An investigation of fibroblasts and lymphoblastoid cell lines from patients with bipolar disorder found abnormal cellular location of mitochondria (Cataldo et al., 2010). Deprived of glucose, peripheral monocytes from bipolar patients failed to exhibit the upregulation in genes related to electron transport observed in healthy control subjects (Naydenov et al., 2007). Abnormalities in calcium buffering and homeostasis have also been observed in peripheral cells from bipolar patients. These include elevated basal levels of calcium and elevated calcium peaks after stimulation of peripheral blood cell lines (Dubovsky et al., 1992; Kato et al., 2003; Kusumi et al., 1992). *In vitro* studies suggest that lithium protects mitochondria exposed to excessive calcium (Shalbuyeva et al., 2007) and improves oxidative stress tolerance (Allagui et al., 2009).

Direct evidence that genetic abnormalities cause mitochondrial dysfunction in bipolar disorder is limited (Clay et al., 2011; Conus et al., 2006). Neither parent of origin studies nor single nucleotide association studies have arrived at consistent conclusions. These studies are technically difficult due to high levels of heteroplasmy as well as high levels of ancestral variation in mtDNA. Notably, however, the 22q11 deletion syndrome, or velo-cardio-facial syndrome, has been associated with both psychotic and manic-like presentations in up to one-third of patients (Baker and Vorstman, 2012). While they have received less attention than other candidates, the deleted locus includes multiple genes important in mitochondrial function (Maynard et al., 2008). Likewise, Mendelian mitochondrial disorders are sometimes associated with mood or psychotic symptoms (Anglin et al., 2012).

Human imaging studies also suggest the potential role for mitochondrial dysfunction in bipolar disorder; magnetic resonance spectroscopy (MRS), which allows direct imaging of ATP and phosphocreatine, has been particularly relevant here. Two early studies suggested changes in frontal lobe metabolism (Kato et al., 1993, 1998) in a state-dependent fashion; whether these represent cause or effect cannot be determined. In general, multiple investigators have suggested that a key aspect of pathophysiology in bipolar disorder is the shift of neuronal metabolism from oxidative phosphorylation to glycolysis (Kato and Kato, 2000; Stork and Renshaw, 2005). Consistent

with this hypothesis, an investigation of bipolar depression using proton-MRS found elevated lactate levels compared to healthy subjects.

Bipolar pharmacotherapies may moderate these abnormalities observed by MRS. One report found lithium-associated changes in an aggregate measure of glutamate, glutamine, and GABA (Friedman et al., 2004). A study of quetiapine in rapid-cycling bipolar disorder patients correlated clinical improvement in manic symptoms with reduction in lactate levels (Kim et al., 2007). Other mood disorder studies incorporating MRS have similarly suggested that efficacious depression treatments act in part by modulating brain metabolism (Iosifescu et al., 2008).

SUMMARY

The neurobiology of bipolar disorder is still in a phenomenological and descriptive phase. The temporal pattern of development of bipolar disorder includes high-risk, prodromal, and first-episode symptoms, but does not have either the prominent prodrome, or the cognitive abnormalities observed in schizophrenia. A disruption in circadian biology in bipolar disorder patients is a consistent finding, and several intriguing animal models are being investigated. There is substantial evidence for neurobiological abnormalities in aspects of epigenetic regulation of several pathways and in the mitochondria. As yet the progress in genetics largely has not converged with the existing neurobiological abnormalities and will be an important part of future research.

DISCLOSURES

Dr. Burdick has no conflicts of interest to disclose.

Dr. Haggarty has no conflicts of interest to disclose.

Over the past 12 months, Dr. Perlis received fees for consulting or scientific advisory board membership from Bristol Myers-Squibb, Genomind, Healthrageous, Proteus Biomedical, PamLab, and RIDVentures. He received royalties/patent fees from UBC/Medco.
