In conclusion, addictions are multistage, chronic, and relapsing diseases with heritabilities that range from 0.39 (hallucinogens) to 0.72 (cocaine). Genes influence each stage of the disease. Because addictions are in parts volitional, inborn, and determined by experience, they pose unique medical and moral challenges. The genetic basis of addictions is largely unknown; however the inheritance of addictions and knowledge of a few specific genes altering vulnerability have established that these are illnesses that can be understood via neuroscience-based chains of causality. Neither heritability of addictions nor the existence of addiction genes establishes that addictions are diseases, because many benign traits are also heritable, but inheritance and gene discoveries point to chains of causality that lead some people and not others to addiction. Many putative addiction genes have been discovered by association studies although few appear are well-validated. Encouragingly, among the small group of genes whose effects appear validated (e.g., *OPRM1*, *ADH1B*, *ALDH2*, *MAOA*, *SLC6A4*, *NPY*, *COMT*, *CHRNA5* and *CYP2A6*) are several that have potential clinical utility, for example to understand alcohol-related flushing and upper GI cancer risk (*ADH1B* and *ALDH2*), variation in nicotine metabolism (*CYP2D6*), and naltrexone treatment response (*OPRM1*). These genes act through a variety of mechanisms: by altering drug metabolism, by altering affinity of receptors for addictive drugs (*CHRNA5*, which may also alter circuitry of reward), and by altering stress response, emotion, and behavioral control, as do genes such as *MAOA*, *NPY*, *HTR2B*, *COMT*, and *HTTLPR*. The genes that influence addiction repeat and enhance broader themes in the neuroscience of addiction.

53 | BRAIN DEVELOPMENT AND THE RISK FOR SUBSTANCE ABUSE

KRISTINA CAUDLE AND B.J. CASEY

An estimated 22.4 million Americans have used illicit drugs in the last month, representing nearly 9% of the population (NSDUH, 2011), and individuals between the ages of 16 to 25 years show the highest rates of illicit substance use. The sharp rise in substance use during adolescence underscores the importance of understanding risk for addiction. Changes in the brain during this developmental period and variation in these changes across individuals may predict who is at risk for substance abuse, enabling the prevention of later dependence. This chapter provides an overview of how the brain circuitry involved in addiction changes across development, and how this may identify who may be most at risk and when they may be most vulnerable.

Addiction is the persistent use of a substance or engagement in a behavior to alter mood despite the adverse consequences of that substance or behavior. Traditionally, addiction research has focused on alcohol, tobacco, and drug use, especially illicit drug use, but recently compulsive behaviors including gambling, gaming, and overeating that are similar in many ways to alcohol and drug dependency have begun to be examined (Gold et al., 2009; Kourosh et al., 2010; Lee, 2012; Reynaud et al., 2010; Weinstein, 2010; Weinstein and Lejoyeux, 2010). At the core of each of these behaviors is an experience of craving and a loss of control that leads to persistence of the behavior, and ultimately addiction.

A theory for why individuals engage in addiction-prone behaviors is for their pleasurable or positive mood-altering effects. According to this hedonic hypothesis, drugs serve as rewards that elicit approach behavior and induce pleasure, increasing the frequency and intensity of consumption. In addiction, it is thought that the behavior becomes pathologically persistent in an attempt to maintain these rewarding effects (Volkow et al., 2011), as well as to avoid the negative outcomes associated with withdrawal symptoms (Robinson and Berridge, 2003). This chapter examines how brain circuitry underlying impulse control and sensitivity to rewards change across development and vary among individuals.

ADDICTION CIRCUITRY

A prominent neurobiological model of addiction is that addictive substances and behaviors act upon the brain's

“reward” circuitry, either directly or indirectly, by flooding the brain with the neurotransmitter dopamine (Volkow et al., 2011). Although several neurotransmitter systems have been implicated in addiction (Fleckenstein et al., 2007; Howell and Kimmel, 2008), increased levels of dopamine are thought to mediate the reinforcing effects (Volkow et al., 2012). Dopamine is released in response to rewards like food, sex, and drugs. Over time, dopamine activity shifts from the rewards themselves to the cues that predict those rewards (Hollerman and Schultz, 1998; Mirenowicz and Schultz, 1994). When a reward is greater than expected, the firing of dopaminergic neurons increases (Schultz et al., 1997), increasing motivation towards the reward via a learning mechanism referred to as prediction error. Prediction error is the difference between an expected reward value and the actual value of that reward (Arias-Carrion and Poppel, 2007). In addiction, cues that come to be associated with the substance of abuse lead to increases in dopamine, rather than the substance itself (Volkow et al., 2011). Unlike healthy individuals, addicts show a blunting of dopamine increases to stimulants, presumably due to their history of prior use and increases in striatal dopamine in response to drug-specific cues. The discrepancy between the expectation of the drug effects and the blunted response in addicts is thought to maintain drug taking in an attempt to achieve the expected reward (Volkow et al., 2011).

The most important brain-reward circuit involved in addiction is comprised of the dopamine-containing neurons in the ventral tegmental area of the midbrain and their target areas in the limbic forebrain, in particular, the ventral striatum and prefrontal cortex (Haber, 2003; Nestler, 2004; Volkow et al., 2011). The majority of studies have focused on the ventral striatum and its role in reinforcing effects in addiction (Breiter et al., 1997; Ito et al., 2002, 2004). This region is an important part of the reward circuit responsible for assigning value to current rewards and learning to predict future events. These value signals are broadcast to prefrontal control regions to help guide future behavior (Knutson et al., 2001; O'Doherty et al., 2002). An imbalance in the communication between regions involved in reinforcement learning and those that underlie cognitive control has been suggested to contribute to addiction. Accordingly, drugs of abuse are thought to “hijack” the systems associated with the rewarding properties of drugs of abuse and lead to less regulation of behavior by prefrontal control regions (Bechara, 2005).

BRAIN DEVELOPMENT

The portrayal of addiction, as an imbalance between brain regions involved in cognitive control and those that are involved in reward processes, parallels aspects of typical behavioral and brain development. Specifically, adolescent brain development has been characterized by a tension between early-emerging bottom-up striatal regions that express exaggerated reactivity to motivational stimuli and later-maturing top-down cortical control regions (Casey et al., 2008; Ernst et al., 2006, 2009; Geier and Luna, 2009; Steinberg, 2008). This bottom-up system that has been associated with reward-seeking and risk-taking behavior gradually loses its competitive edge with the progressive emergence of top-down regulation during development. With age and experience, the connectivity between these regions is strengthened and provides a mechanism for top-down modulation of the subcortically driven reward behavior. Empirical support for this model comes from the differential neurochemical, structural, and functional development in cortical and subcortical regions.

Significant dopaminergic changes occur across development. There is a peak in D1 and D2 receptor density in the striatum during early adolescence (Benes et al., 2000; Brenhouse et al., 2008; Galvan et al., 2005), whereas this peak does not emerge until later in prefrontal cortex (Cunningham et al., 2008; Tseng and O'Donnell, 2007). This differential timeline in the peak of D1 and D2 receptor density in the striatum and cortex may result in an imbalance between these systems.

REGIONAL DIFFERENCES IN BRAIN DEVELOPMENT

Findings from both human and nonhuman primate studies provide evidence for different time courses in regional

postnatal brain development. These changes are illustrated in Figure 53.1. Following cell proliferation, differentiation, and migration there is a rapid overproduction of synapses relative to its adult state (Rakic, 1974). Although this process of synaptogenesis appears to occur concurrently across diverse regions of the non-human primate cerebral cortex (Rakic et al., 1986), the plateau and subsequent decrease in synapses varies by brain regions. The plateau and pruning phases of association cortical regions (e.g. prefrontal cortex) are relatively protracted compared with others (e.g., sensorimotor and subcortical regions; Bourgeois et al., 1994; Huttenlocher and Dabholkar, 1997). Positron emission tomography studies of glucose metabolism show similar patterns of development, with local metabolic rates paralleling the time course of overproduction and subsequent pruning of synapses (Chugani et al., 1987). Human studies using magnetic resonance imaging show a significant decrease in cortical gray matter by approximately 12 years in prefrontal and association cortices that is preceded by earlier maturing development in sensorimotor and subcortical regions (Giedd et al., 1999; Gotgay et al., 2004; Sowell et al., 1999; Sowell et al., 2002). Together these studies support different time courses in the development of brain regions implicated in higher cognitive function relative to those involved in sensorimotor and primitive emotive functions.

Whereas gray matter changes appear to peak during childhood and adolescences, cerebral white matter shows a gradual increase well into adulthood, especially in prefrontal white matter tracts (Klingberg et al., 1999). The protracted development of prefrontal and association cortices, along with white matter fiber tract development in this circuitry, contributes to children's developing capacity for cognitive control (Klingberg et al., 1999; Liston et al., 2006). Variability in the myelination and regularity of prefrontal white matter fibers also contribute

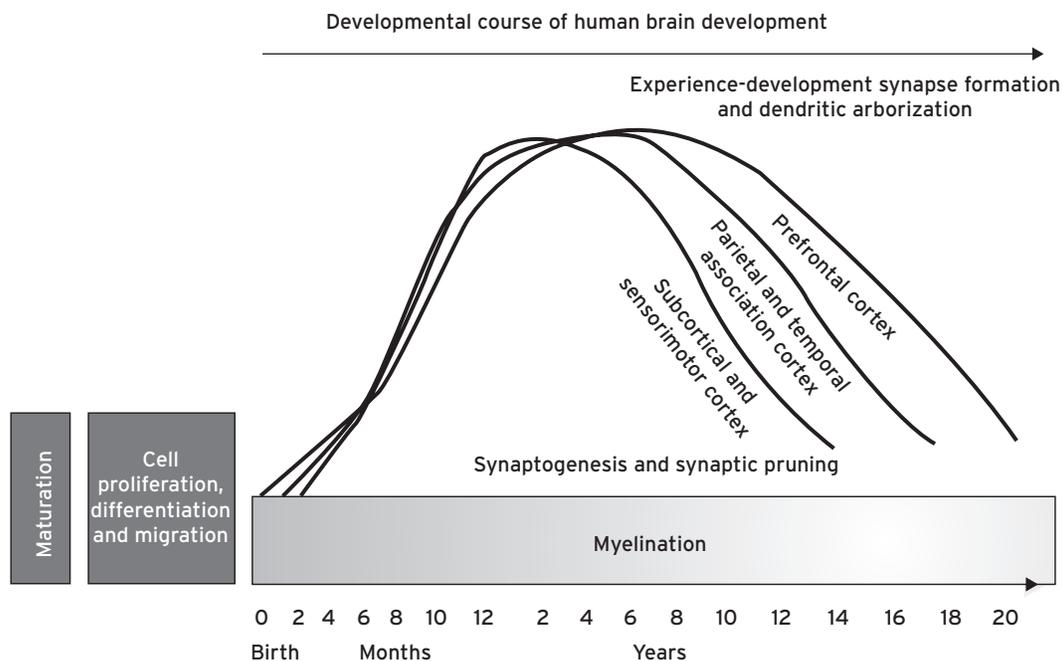

Figure 53.1 Regional brain development. Cell proliferation, differentiation, and migration is followed by rapid formation of synapses that subsequently plateau and decline to adult levels at different time points in development and increases in myelination well into adulthood. (Adapted from Casey et al., 2005. *Imaging the developing brain: what have we learned about cognitive development?* Trends Cogn. Sci., 9(3): 104–110.)

to individual differences in cognitive control and have been linked to disorders of cognitive control like attention deficit hyperactivity disorder (ADHD).

To more directly examine functional neural circuits underlying the development of cognitive control and reward sensitivity across development, a means of assessing, *in vivo*, the developmental physiological course of behavior is needed. Functional magnetic resonance imaging (fMRI) provides this ability (Logothetis et al., 2001). Understanding how brain function changes during adolescence, relative to both childhood and adulthood, and how these changes vary across individuals is essential in predicting risk for later substance abuse and dependence. This chapter reviews recent human imaging work supporting the emerging view of adolescence as characterized by a tension between early-emerging bottom-up subcortical brain regions that express exaggerated reactivity to reward related cues and later-maturing top-down cognitive control regions involved in self-control.

Human functional imaging studies show dramatic changes in corticostriatal circuitry across development. Children recruit distinct but often larger, more diffuse brain regions when performing cognitive control tasks than do adults. The pattern of activity within brain regions central to cognitive control performance, such as prefrontal cortex, becomes more focal or fine-tuned based on cross-sectional (Brown et al., 2004) and longitudinal studies (Durstun et al., 2004). This pattern of activity is suggestive of development within, and refinement of, projections to and from, the prefrontal cortex with maturation. Recent developmental functional connectivity data (Kelly et al., 2009) is consistent with this observation of diffuse correlations among frontal brain regions in children, whereas adults exhibit more focal connections with distal regions. This development of the prefrontal cortex is associated with age-related improvement in cognitive control (Asato et al., 2010; Astle and Scerif, 2009; Casey et al., 2007; Durstun et al., 2006; Forbes and Dahl, 2010; Liston et al., 2006; Luna et al., 2001; Luna et al., 2010; Romeo, 2003).

While the prefrontal cortex shows protracted development, well into adulthood, striatal regions sensitive to novelty and reward appear to develop earlier (Bunge et al., 2002; Liston et al., 2006). One of the first studies to examine reward-related circuitry from early childhood to adulthood (Galvan et al., 2006) used a task previously developed to examine the role of reward magnitude on dopamine firing in nonhuman primates (Cromwell and Schultz, 2003). They found that the ventral striatum was sensitive to varying magnitudes of monetary reward, exhibiting monotonic increases with increasing reward amounts. This response was exaggerated during adolescence, relative to both childhood and adulthood. Moreover, a positive association between ventral striatal activity to large rewards and the likelihood of engaging in risky behavior such as substance use was shown (Galvan et al., 2007). These findings are consistent with the adult imaging literature showing an association between ventral striatal activity and risky choices (Kuhnen and Knutson, 2005; Matthews et al., 2004).

Several groups have shown heightened activation of the ventral striatum in anticipation and/or receipt of rewards in adolescents compared to adults (Ernst et al., 2005; Galvan

et al., 2006; Geier et al., 2010; Van Leijenhorst et al., 2010). This heightened striatal activity and increased reward seeking during adolescence has been associated with heightened dopaminergic prediction error responsivity (Cohen et al., 2010). It should be noted that others report hyporesponsiveness during adolescence in the ventral striatum (e.g., Bjork et al., 2004). Regardless, both hyper- and hyporesponsiveness to rewards and drug-related cues have been implicated in substance use disorders. Heightened responses to drugs potentially increase use, whereas dampened responses to drug-related cues appear to maintain use.

Ventral striatal activity does not appear to be associated with impulse control (Galvan et al., 2007). Instead, impulsivity is negatively correlated with age. Studies of clinical populations characterized by impulsivity problems such as ADHD support these findings. Specifically, individuals with ADHD have reduced activity in prefrontal regions compared to controls when performing impulse control tasks (Casey et al., 2007; Epstein et al., 2007; Vaidya et al., 1998) but do not show heightened responses to incentives in the striatum to rewards (Scheres et al., 2007). Treatment with stimulants that increase the availability of dopamine by blocking the dopamine transporter leads to increases in frontostriatal activity and enhanced impulse control. Together these findings provide support for a dissociation between reward sensitivity and impulsivity both neurally and developmentally, with the former showing a curvilinear developmental pattern and the latter a linear pattern of development.

Only recently have studies begun to examine how rewarding cues can differentially influence impulse control across development. Somerville and colleagues imaged children, adolescents, and adults while they performed an impulse control task with appetitive social cues (happy faces) and neutral cues. The ability to inhibit a response to a rare neutral cue showed steady improvement with age. However, on trials for which the individual had to resist approaching appetitive social cues, adolescents failed to show the expected age-dependent improvement (Fig. 53.2A). Relative to neutral cues, adolescents made more commission errors to these appetitive social cues than did adults or children. This performance decrement during adolescence was paralleled by heightened activity in the ventral striatum (Fig. 53.2B and C). Conversely, activation in the inferior frontal gyrus was associated with overall performance and showed a linear pattern of change with age.

As drug use among teens typically occurs with peers, a number of studies have begun to examine how differential development of cognitive control and motivational systems impact susceptibility to peer influences. These studies find that adolescents relative to adults make riskier decisions when a peer is present as opposed to when alone (Gardner and Steinberg, 2005). This performance is paralleled by heightened activity in the ventral striatum for adolescents relative to adults (Chein et al., 2011). These findings suggest that peers have reinforcing effects on behavior that are represented at the level of the ventral striatum. Moreover, the differential development of reward and cognitive control processes during adolescence suggests that this period of development may be prone to addictive behaviors.

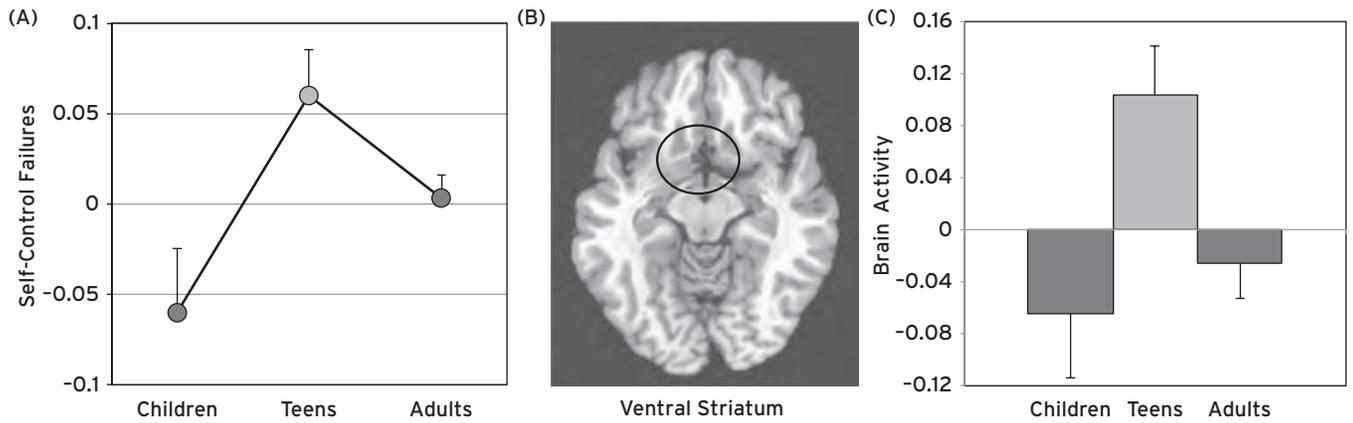

Figure 53.2 Developmental differences in self control. (A) Adolescents have more self control failures (commission errors) when inhibiting responses to appetitive cues than do adults or children. (B) Localization of ventral striatal activity when inhibiting responses to appetitive cues. (C) Adolescents show greater ventral striatal activity when inhibiting responses to appetitive cues. (Adapted from Somerville et al., 2011.)

RISK FACTORS FOR ADDICTION

ADOLESCENCE

Adolescence clearly marks a period of increased experimentation with drugs and alcohol (Hardin and Ernst, 2009) with alcohol being the most abused of illegal substances by teens (Johnston et al., 2009; Windle et al., 2008; Witt, 2010). Early use of these substances, such as alcohol, is a reliable predictor of later dependence and abuse (Grant and Dawson, 1997). Alcohol and substances of abuse, including cocaine and cannabinoids, have been shown to have reinforcing properties. These substances influence mesolimbic dopamine transmission with acute activations of neurons in frontolimbic circuitry rich in dopamine, including the ventral striatum (French et al., 1997; Maldonado and Rodriguez de Fonseca, 2002; Volkow et al., 2002).

The use of these substances may exacerbate enhanced ventral striatum responses resulting in strengthening of reinforcement properties to certain drugs (Hardin and Ernst, 2009). As such, drugs of abuse may “hijack” systems associated with drug incentives like the ventral striatum, and lead to down-regulation of top-down prefrontal control regions (Robinson and Berridge, 1993, 2003, 2008).

Few studies have examined functional brain activity in response to drug or alcohol related stimuli (i.e., pictures of alcohol) in adolescents (Nagel et al., 2005), although this is a growing area of research (Brown and Tapert, 2004). Studies of high-risk populations (e.g., familial load of alcohol dependence) suggest impairments in prefrontal functioning are apparent prior to drug use exposure (e.g., McQueeney et al., 2009; Medina et al., 2008) and predict later substance use (Pulido et al., 2010; Tapert et al., 2003). Poorer top down prefrontal control prior to drug exposure may set up a long-term course of alcohol and drug abuse well beyond adolescence (Monti et al., 2005; Pulido et al., 2010).

A heightened sensitivity to rewarding effects of drugs and alcohol and diminished sensitivity to negative effects has been postulated as a reason for why adolescence may be a specific developmental window of increased risk for addiction. The majority of empirical work on developmental use of drugs and alcohol has been performed in animals, given ethical constraints

on performing such studies in humans. These studies have shown that adolescent rodents, unlike adults, are less sensitive to the negative effects of alcohol like motor impairment, sedation, acute withdrawal, and “hangover effects” of ethanol (Doremus et al., 2003; Pautassi et al., 2008; Spear and Varlinskaya, 2005). These findings are important because they suggest that many of the effects that serve as cues to limit intake in adults are not present in adolescents (Windle et al., 2008). In an early behavioral study of the effects of alcohol in 8- to 15-year-old boys of low and high familial risk (Behar et al., 1983), the most significant finding was little, if any, behavioral change or impairment on tests of intoxication—even after given doses that had been intoxicating in an adult population. In parallel, adolescents seem more sensitive to positive influences of alcohol, such as social facilitation, which may further encourage alcohol and substance use (Varlinskaya and Spear, 2002). Most substance and alcohol use occurs in social situations in adolescents (Steinberg, 2008), potentially pushing them towards greater alcohol and drug use when their peers value this behavior.

INDIVIDUAL TRAITS

One potential risk factor for substance use and abuse is vulnerability in resisting temptation or self-control. Low self-control have been linked to increased sensitivity to stimulant drugs in both humans (Nigg et al., 2006; Tarter et al., 2003) and rats (Yates et al., 2012). Lapses in this ability have been suggested to be at the very core of suboptimal choices (Eigsti et al., 2006; Mischel et al., 1989) including those related to substance use and abuse (Bechara and Van Der Linden, 2005). This ability can be measured in childhood simply by assessing how well the child can resist an immediate reward (e.g., a cookie) in favor of a larger reward later (e.g., two cookies). Although individuals vary in this ability to control one’s impulses or delay gratification, even as adults, developmental studies suggest there are temporal windows in which an individual may be particularly susceptible to temptations.

The ability to wait for reward has been demonstrated to buffer against the development of a variety of dispositional

physical and mental health vulnerabilities in middle age, including higher body mass index and illicit substance use, even when controlling for childhood social environment and child health (Kubzansky et al., 2009; Mischel and Ayduk, 2004; Mischel et al., 1988; Rodriguez et al., 1989). The relative lifetime stability in the capacity to resist temptation or control impulses was recently shown in a 40-year longitudinal study. Specifically, individuals who, as a group, had more difficulty delaying gratification at four years of age continued to show reduced self-control abilities 40 years later. These individuals exhibited more difficulty as adults in suppressing responses to positive social cues during a go/no-go impulse control task (Casey et al., 2011) (Fig. 53.3A). A subset of these high- and low-delaying individuals was imaged during performance of the go/no-go task. Whereas the prefrontal cortex differentiated between no-go and go trials to a greater extent in high delayers, the ventral striatum showed an exaggerated response in low delayers that paralleled their behavioral performance (Fig. 53.3B–C). These findings suggest that sensitivity to rewarding cues can influence an individual’s ability to suppress thoughts and actions and that control systems may be “hijacked” by reward systems, rendering control systems unable to appropriately modulate behavior. Similar analogies of imbalances between these neural systems in the literature suggest that addiction (Bechara, 2005) and adolescence (Chein et al., 2011; Galvan et al., 2006; Somerville et al., 2011) may be contexts during which cognitive control may be particularly vulnerable to salient reward-related cues.

Because addictive substances and behaviors alter mood, the role of positive and negative affect have been examined as risk factors for addiction (Cheetham et al., 2010; Robinson and Berridge, 2003). Individuals who are high in positive affect are more likely to engage in risky behavior, such as drug use, whereas individuals low in positive affect may initially use substances because of a lack of responsiveness to natural positive rewards (Cyders and Smith, 2008). Individuals who are more reactive to negative cues and tend to engage in risky behaviors when distressed are also at high risk for

substance abuse, especially during adolescence (Cyders and Smith, 2008). Individual differences in impulse control and reactivity to affective or emotional states appear to impact different core features of substance use disorders (Dawe and Loxton, 2004). High reactivity and approach behavior predicts the propensity to initiate drug use, whereas high impulsivity predicts the development of persistent and compulsive addiction-like behavior in the face of aversive outcomes (Belin et al., 2008).

PRIOR EXPOSURE

Differential sensitivities to positive and negative properties of substances of abuse have been postulated to underlie risk for addiction. A contributing factor to these sensitivities is the role of prior exposure on the brain and behavior. We focus on two developmental windows of exposure. First, we review the risk of later substance abuse caused by exposure to stimulants (cocaine) during fetal development. Second, we review the effects of stimulant medications during post-natal periods of childhood and adolescence on risk for substance abuse.

EFFECTS OF PRENATAL EXPOSURE ON LATER SUBSTANCE ABUSE

The fetal brain may be especially vulnerable to substances introduced through maternal consumption. Prenatal substance exposure to stimulants has a wide range of possible effects on the developing brain, depending on the dosage and timing in fetal development. Specifically, animal studies show that prenatal exposure to cocaine leads to lasting anatomical alterations in dopamine-rich prefrontal cortical regions (Stanwood et al., 2001a, 2001b). These effects appear to be specific to embryonic days 16–25 in the rabbit when the onset of D1 dopamine receptor expression occurs and there is a peak in corticogenesis (Stanwood et al., 2001a). These changes result in a reduction rather than an increase in reinforcing properties of stimulants and in an increased tolerance for substances of

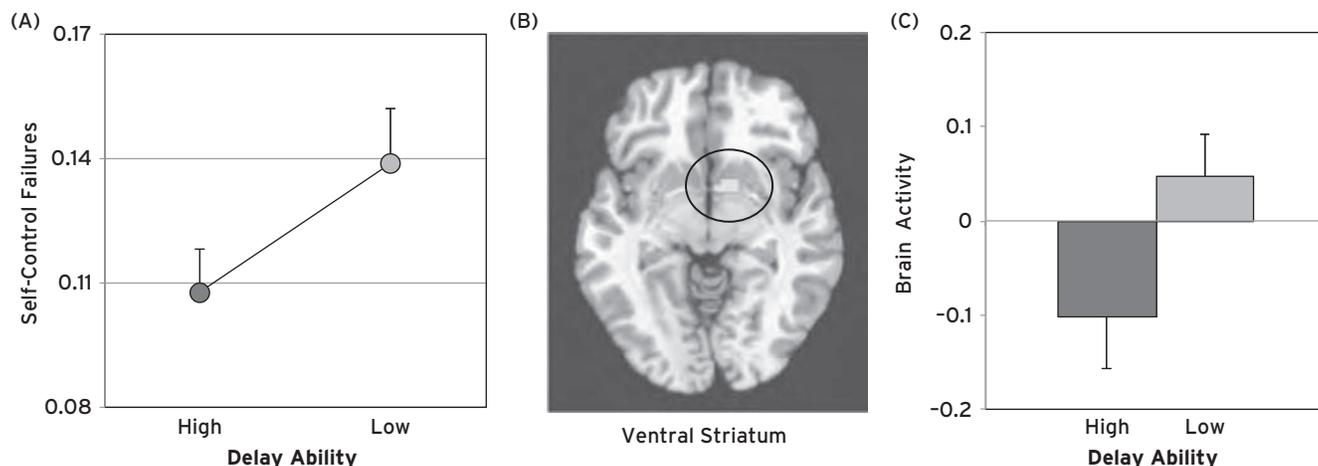

Figure 53.3 Individual differences in self control. (A) Individuals who had difficulty delaying gratification (low delay ability) as 4 year olds have more self control failures when inhibiting responses to appetitive cues 40 years later. (B) Localization of ventral striatal activity when inhibiting responses to appetitive cues. (C) Adults with low delay ability show greater ventral striatal activity when inhibiting responses to appetitive cues than do adults with high delay ability. (Adapted from Casey et al., 2011.)

abuse such as cocaine as adults (Slamberova et al., 2011). These findings suggest one potential pathway to addiction, given that both drug tolerance and hyporeactivity to substances of abuse have been linked to substance use dependence.

The human literature on prenatal exposure to substances of abuse is less clear. Cognitive and behavioral deficits have been associated with prenatal exposure to cocaine that may put these individuals at risk for later substance abuse. For example, children with prenatal cocaine exposure have problems of inattention and impulsivity (Kable et al., 2008; Li et al., 2009) that are in and of themselves risk factors for substance use. Together the human and animal research suggest that prenatal exposure to stimulants like cocaine alter reward circuitry and function, thus impacting both reactivity to substances and impulse control, both of which increase the risk for later substance abuse.

EFFECTS OF STIMULANT MEDICATION ON LATER SUBSTANCE ABUSE

Given the high comorbidity of addiction with other mental disorders, a clinical concern has been whether treating individuals with medications such as stimulants may enhance their propensity toward substances of abuse, especially in the case of treating developing populations. Some of the most common drugs prescribed in childhood and adolescence are stimulants for ADHD such as methylphenidate. The clinical concerns in using this standard treatment revolve around three major considerations. First, methylphenidate has pharmacological effects similar to drugs of abuse like cocaine, in increasing the availability of dopamine in the ventral striatum (Volkow and Swanson, 2008). Second, this treatment often begins in early adolescence—a period of increased risk for substance use disorders (Casey and Jones, 2010). Third, independent of stimulant treatment, ADHD is a risk factor for substance use dependence (Wilens et al., 2011), which may be attributable to poor impulse control and/or a drive to self-medicate with dopamine-augmenting stimulants. These concerns underscore the need to understand the long-term effects of stimulant medication on the developing brain and on risk for later substance abuse.

The human literature on studies of children with ADHD who were treated with stimulant medications has found no clear evidence for an increase in later substance use disorders. Rather the findings have been mixed, with some studies suggesting sensitization to such substances later (Hartsough and Lambert, 1987; Lambert and Hartsough, 1998; Lambert et al., 2006) and others suggesting protective or no effects of stimulant treatment on later substance use or dependence (Barkley et al., 2003; Biederman et al., 2008; Faraone and Wilens, 2003; Faraone et al., 1997; Katusic et al., 2005; Mannuzza et al., 2003; Mannuzza et al., 2008; Paternite et al., 1999; Wilens et al., 2003). Two recent studies of nonhuman primates, both of which mimic therapeutic methylphenidate administration in human periadolescence, showed no effect in either physical development or proclivity for cocaine self-administration (Gill et al., 2012; Soto et al., 2012). However, recent evidence in humans suggests that age of stimulant treatment onset may be an important factor influencing later substance abuse in treated ADHD patients. Specifically, the earlier the treatment,

the more of a protective effect against later substance abuse, whereas later treatment has little if any effect (Mannuzza et al., 2008).

Animal studies have tried to clarify the mixed clinical findings of methylphenidate treatment effects on later substance abuse. These studies suggest that the potential effects of stimulant exposure on future substance use might be dependent on the timing, dose, and administration of stimulants. For example, administering low doses of methylphenidate that more closely mirror typical plasma levels in therapeutic uses in humans increases cocaine (Brandon et al., 2001) and methamphetamine self-administration (Schindler et al., 2011) whereas high doses do not. Rats administered either intermittent or continuous methylphenidate during adolescence showed a differential effect, wherein intermittent administration increased cocaine sensitivity, and continuous administration decreased cocaine sensitivity (Griggs et al., 2010). Finally, administering stimulants during adolescence to spontaneously hypertensive rats, a proposed animal model of ADHD, results in the rats reaching cocaine self-administration faster than non-spontaneously hypertensive rats and in an increase in cocaine uptake in the prefrontal cortex (Harvey et al., 2011). Thus, a number of variables may moderate how stimulant treatment, such as that seen in methylphenidate treatment of ADHD, may influence later substance abuse and dependence. These variables include the age and duration of methylphenidate treatment, the dosage and type of stimulant treatment (continuous vs. intermittent), and even the presence or absence of ADHD phenotype. Not all children or adolescents who are treated with methylphenidate meet ADHD diagnostic criterion, and clinical status may impact how therapeutic stimulant administration may interact with the dopaminergic system.

CONCLUSIONS

Addiction affects millions each year, with adolescence being a particularly vulnerable period of risk. This chapter has provided an overview of recent human imaging and animal studies of adolescent brain development to help further elucidate who may be most at risk for developing a substance abuse problem and when they may be most vulnerable. Figure 53.4 illustrates how individual, environmental, and developmental factors may enhance the reinforcing effects of drugs in the ventral striatum and decrease self-regulatory capacity of the prefrontal cortex, potentially leading to greater risk for substance abuse and dependence.

Exposure to drugs of abuse is a fundamentally risky proposition. Initial use can represent a gamble with a long-term, highly disruptive, substance use disorder, with immensely high personal and societal costs. Understanding who is most at risk to develop a substance use disorder within a population is valuable, as it may allow earlier interventions and better outcomes. Psychological traits, such as impulsivity and self-control, influence how likely one is to become a substance user or dependent. These traits are closely tied to neural signatures in dopamine rich reward circuitry, especially in the ventral striatum and prefrontal cortex.

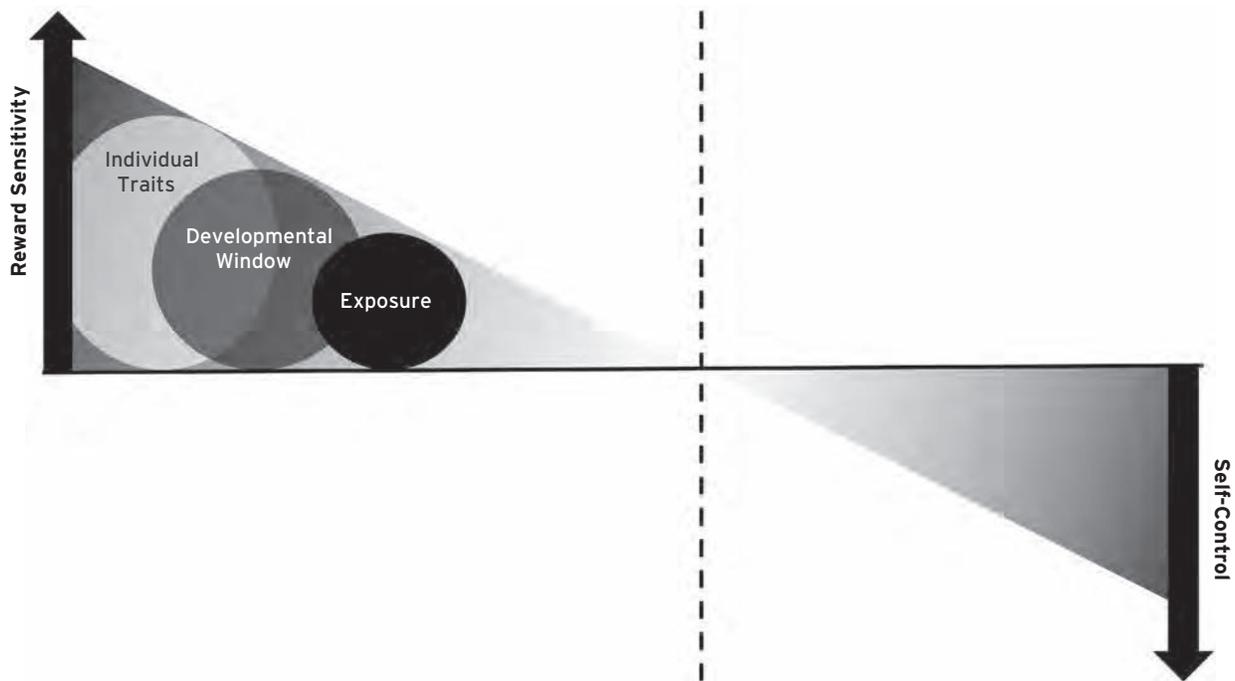

Figure 53.4 Risk factors for addiction. Individual traits, developmental windows, and drug exposure can combine to increase the appetitive response associated with the reinforcing effects of drugs to decrease self-regulatory capacity, potentially leading to greater risk for substance abuse and dependence.

Windows of development enhance vulnerability to substance exposure. These include periods of development when there are significant changes in dopamine receptor expression (fetal development) and peak density (adolescence). Adolescents as a group are also more likely to try drugs for the first time, and may be uniquely susceptible to developing substance dependencies because of an imbalance between structural and functional development of subcortical regions (involved in motivation and reinforcement learning) relative to prefrontal cortical regions (involved in impulse control).

The effects of drug exposure on neurotransmitter systems involved in motivation, reward, and learning are complex, changing both between individuals and across the lifespan. These factors, including brain structure, personal exposure history, and personality traits such as impulse control and reward sensitivity, involved in the response to stimulant exposure combine to form a multifactorial risk profile for substance abuse. The better these risk factors are understood, the more effectively substance use disorders can be managed, treated, and ultimately prevented.

54 | MOLECULAR IMAGING IN ADDICTIVE DISORDERS

CHELSEA L. ROBERTSON, STEVEN M. BERMAN, AND EDYTHE D. LONDON

MOLECULAR IMAGING METHODS AND THEIR APPLICATION IN STUDIES OF ADDICTION

Positron emission tomography (PET) and single photon emission computed tomography (SPECT) are nuclear medicine techniques that allow minimally invasive *in vivo* measurements of biochemical processes and pharmacokinetics. Molecules of interest can be radiolabeled and administered at tracer doses, allowing measurements without perturbing the systems under study. Both techniques can be used to assess functional activity, indexed by global and regional cerebral blood flow and/or metabolism, and how they change with various conditions or treatments. In addition, viability or function in neurotransmitter systems can be evaluated through imaging radiotracer binding to specific neurotransmitter receptors, transporters, and enzymes to assess neurotransmitter turnover. Although PET generally produces images with higher resolution and provides greater flexibility in radiotracer synthesis, SPECT has the advantage of using radiotracers with a longer half-life, reducing the need for onsite radiosynthesis (Cumming et al., 2012).

Molecular imaging of brain function started with the introduction of 2-deoxy-1-[C-14]glucose ([C-14]-2DG) to quantify local cerebral glucose metabolism, relying on the role of glucose as the major substrate for oxidative brain metabolism (Sokoloff et al., 1977). Autoradiographic studies of cerebral glucose metabolism in rodents were extended to human assessments with the development of 2-deoxy-2-[F-18]-fluoro-D-glucose ([F-18]FDG) (Som et al., 1980) to be combined with PET (Phelps et al., 1979; Reivich et al., 1979). Soon thereafter, cerebral blood flow could be measured in humans with PET, using [O-15]-labeled water (Mintun et al., 1984), reflecting the vascular response to energy demand produced by neural activity. Given the two-minute half-life of [O-15], repeated measurements were possible within minutes, offering greater time resolution than the [F-18]-FDG method, which measures glucose metabolism over the first 10–15 minutes after administration of the radiotracer. Cerebral perfusion measurements also were possible with SPECT, using radiolabeled *N*-isopropyl[I-123]-*p*-iodoamphetamine (IMP) (Kuhl et al., 1982); later [Tc-99m]-D,L-hexamethylpropyleneamine oxime (HMPAO) (Nickel et al., 1989) became the most commonly used tracer for SPECT measurements of cerebral blood flow (Mathew and Wilson 1991). Studies using markers of blood flow and glucose metabolism can provide quantitative maps of global and regional cerebral blood flow or metabolic rates for glucose, respectively.

Since 1986, when [C-11]*N*-methylspiperone was introduced as a PET radiotracer for human studies of D2/D3 dopamine receptors (Wong et al., 1986), many other radiotracers have become available for the visualization and quantification of neurotransmitter systems (Table 54.1). Over the last few decades, molecular neuroimaging has extended the knowledge about addiction that had been derived from invasive studies in rodents (Wise and Bozarth, 1987). The human studies using PET and SPECT, which are described later, have provided information about vulnerability to addiction, and brain abnormalities at various stages of the addiction cycle (Fig. 54.1). These findings have contributed to the current view of addiction and potential therapeutic interventions.

VULNERABILITY TO ADDICTIVE DISORDERS

Much attention has focused on why some people become addicts while others do not. This interest was fueled by observations of the fate of Vietnam War veterans who returned home after using heroin and becoming opioid-dependent during their tours of duty. It was estimated that 35–38% of US soldiers used heroin during the Vietnam War (Robins, 1993). Twenty percent of those using heroin reported physical dependence in Vietnam, but only 5% of those remained addicted in the first year after returning home. Because socioeconomic variables or effectiveness of treatment strategy did not explain the differences in outcome (Robins, 1993), the importance of biological factors was apparent. Three decades later, research has included studies of genetic polymorphisms associated with substance dependence, with positive evidence for roles of opioid (Nelson et al., 2012), nicotinic acetylcholine (Hartz et al., 2012), and dopamine receptors (Noble, 2003).

Molecular imaging has also provided insight regarding vulnerability to addiction, with a primary focus on the dopamine system. An important observation in this regard was the demonstration that lower levels of striatal dopamine D2/D3 receptor binding than in healthy controls subjects accompanies addictions and is often correlated with severity of the disorder (Martinez and Narendran, 2010; Volkow et al., 2004). Lower than control dopamine D2/D3 receptor availability was found in striata of research subjects dependent on various drugs, including alcohol, cocaine, and opioids. A recent PET study confirmed a previous report that light-smoking men also exhibit lower striatal D2/D3 receptor availability than non-smoking men, but there were no difference between

TABLE 54.1. Radiotracers with potential for use in molecular imaging studies of addiction

RADIOTRACER TARGET	RADIOTRACER COMMON NAME	RADIOTRACER CHEMICAL NAME
D2/D3 dopamine receptor	[C-11]N-methylsprioperidol	[C-11]-8-[4-(4-fluorophenyl)-4-oxo-butyl]-1-phenyl-1,3,8-triazaspiro[4.5]-decan-4-one
	[C-11]raclopride	3,5-dichloro-N-[[[(2S)-1-ethylpyrrolidin-2-yl]methyl]-2-hydroxy-6-[(C-11)methoxy]benzamide
	[F-18]fallypride	(S)-5-(3-[F-18]-fluoropropyl)-2,3-dimethoxy-N-[[[(2S)-(2-propenyl)-2-pyrrolidinyl]methyl]benzamide
	[C-11]FLB457	[C-11](S)-N-((1-ethyl-2-pyrrolidinyl)methyl)-5-bromo-2,3-dimethoxybenzamide
	[F-18]fluoroclebopride ([F-18]FCP)	4-amino-5-chloro-N-[1-(4-[F-18]-fluoranylbenzyl)-4-piperidyl]-2-methoxybenzamide
	[I-123]epidipride	(S)-N-[(1-methyl-2-pyrrolidinyl)methyl 5-[I-123]iodo-2,3-dimethyl benzamide
	[I-123]iodobenzamide ([I-123]BZM)	(S)-(-)-2-hydroxy-3-[I-123]-iodo-6-methoxy-N[(1-ethyl-2-pyrrolidinyl)methyl]-benzamide
Dopamine transporter (DAT)	[C-11]methylphenidate	[C-11]-methyl phenyl(piperidin-2-yl)acetate
	[C-11]cocaine	[C-11]-methyl (1R,2R,3S,5S)-3-(benzoyloxy)-8-methyl-8-azabicyclo[3.2.1]octane-2-carboxylate
	[C-11]WIN35428 ([C-11]CFT)	2-beta-carbomethoxy-3-beta-(4-fluorophenyl)-[N-[C-11]-methyl]tropane
	[I-123]PE2I	N-(3-[I-123]-iodoprop-2E-enyl)-2β-carboxymethoxy-3β-(4-methylphenyl)nortropane
	[I-123]β-CIT	Beta-carbomethoxy-3-beta-4-[I-123]-iodophenyltropane
Vesicular monoamine transporter (VMAT)	[C-11]dihydratetrabenazine ([C-11]DTBZ)	[C-11]2-hydroxy-3-isobutyl-9,10-dimethoxy-1,3,4,6,7-hexahydro-11βH-benzo[a]-quinolizine
Dopamine synthesis capacity	[F-18]FDOPA	6-[F-18]fluoro-L-dihydroxyphenylalanine
D1/D5 dopamine receptor	[C-11]NNC112	[C-11]-chloro-5-(7-benzofuranyl)-7-hydroxy-3-methyl-2,3,4,5-tetra-hydro-1H-3 benzazepine
	[C-11]SCH23390	[C-11]-7-chloro-3-methyl-1-phenyl-1,2,4,5-tetrahydro-3-benzazepin-8-ol
D3 dopamine receptor	[C-11]PHNO	[C-11]-4-propyl-3,4,4a,5,6,10-beta-hexahydro-2H-naphtho[1,2-beta][1,4]oxazin-9-ol
Serotonin transporter (SERT)	[C-11]McN5652	[C-11]-6β-(4-methylthiophenyl)-1,2,3,5,6α,10β-hexahydropyrrolo[2,1-α]isoquinoline
	[C-11]DASB	[C-11]-N,N-dimethyl-2-(2-amino-4-cyanophenylthio)benzylamine
	[C-11]ADAM	[C-11]-2-[2-(dimethylaminomethylphenylthio)]-5-iodophenylamine
	[I-123]β-CIT	2-beta-carbomethoxy-3-beta-(4-[I-123]-iodophenyl)-tropane
Serotonin 1A receptor	[C-11]WAY100635	[C-11]N-[2-[4-(2-methoxyphenyl)-1-piperazinyl]-ethyl]-N-2-pyridinylcyclohexanecarboxamide
	[F-18]MPPF	4-[F-18]-N-[2-[4-(2-methoxyphenyl)piperazin-1-yl]ethyl]-N-pyridin-2-ylbenzamide
Serotonin 2A receptor	[F-18]altanserin	3-[2-[4-(4-[F-18]fluorobenzoyl)piperidin-1-yl]ethyl]-2-sulfanylidene-1H-quinazolin-4-one
Mu-opiate receptor	[C-11]carfentanil	[C-11]-4-((1-oxopropyl)-phenylamino)-1-(2-phenylethyl)-4-piperidinecarboxylic acid methyl
	[F-18]cyclofoxy	6-desoxy-6-beta-[F-18]-fluoronaltraxone

(continued)

TABLE 54.1. (Continued)

RADIOTRACER TARGET	RADIOTRACER COMMON NAME	RADIOTRACER CHEMICAL NAME
Kappa-opiate receptor	[C-11]-GR103545	[C-11]-4-methoxycarbonyl-2-[(1-pyrrolidinylmethyl)-1-[(3,4-dichlorophenyl)-acetyl]-piperidine
Nicotinic acetylcholine receptor (nAChR)	[F-18]-2F-A85380 ([F-18]2FA)	2-[F-18]fluoro-3-(2(S)azetidylmethoxy)pyridine
	[F-18]-6F-A85380 ([F-18]6FA)	6-[F-18]fluoro-3-(2(S)-azetidylmethoxy)pyridine
	[I-123]-5-iodo-A-85380	5-[I-123]-3-(2(S)-azetidylmethoxy)pyridine
MAO(A)	[C-11]-clorgyline	[C-11]N-[3-(2,4-dichlorophenoxy)propyl]-N-methyl-prop-2-yn-1-amine
MAO(B)	[C-11]-deprenyl-d2	[C-11](R)-N-methyl-N-(1-phenylpropan-2-yl)prop-1-yn-3-amine
Type 1 cannabinoid receptor (CB1)	[C-11]-OMAR ([C-11]JHU75528)	1-(2, 4-dichlorophenyl)-4-cyano-5-(4-[C-11]-methoxyphenyl)-N-(piperidin-1-yl)-1H-pyrazole-3-carboxamide
	[F-18]-FMPEP-d2	(3R,5R)-5-(3-[F-18]fluoromethoxy-D2)phenyl)-3-((R)-1-phenyl-ethylamino)-1-(4-trifluoromethyl-phenyl)-pyrrolidin-2-one
GABA(A) receptor	[C-11]-flumazenil	[C-11]-ethyl 8-fluoro-5-methyl-6-oxo-5,6-dihydro-4H-benzo[f]imidazo[1,5-a][1,4]-diazepine-3-carboxylate
	[I-123]-iomazenil	Ethyl 7-[I-123]-iodo-5-methyl-6-oxo-5,6-dihydro-4H-imidazo[1,5-alpha][1,4]-benzodiazepine-3-carboxylate
Cerebral perfusion	[I-123]-iodoamphetamine ([I-123]IMP)	N-isopropyl[I-123]-p-iodoamphetamine
	[Tc-99m]-HMPAO	[Tc-99m]-D,L-hexamethylpropyleneamine oxime
	[O-15]-Water	
Glucose metabolism	[F-18]-fluorodeoxyglucose ([F-18]FDG)	2-deoxy-2-[F-18]fluoro-D-glucose

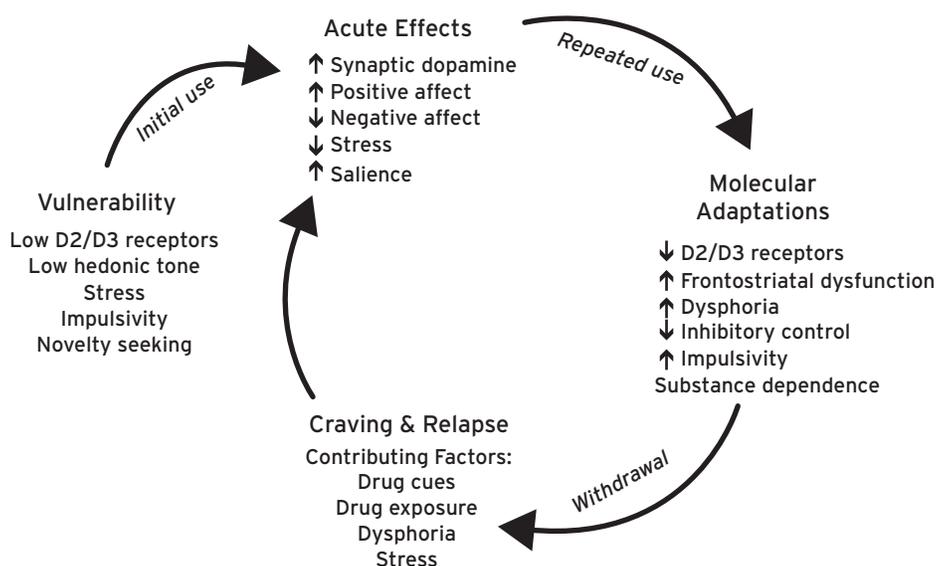

Figure 54.1 Factors that confer vulnerability to addiction increase reward and decrease punishment associated with early use of addictive substances. Acute drug effects increase the saliency of drug-related cues and promote chronic use. Chronic use causes additional adaptations in risk-related biobehavioral systems, favoring continued drug abuse.

smoking and non-smoking women (Brown et al., 2012). In pathologically obese subjects, striatal D2/D3 receptor availability was also below control levels, and inversely related to body mass index (Wang et al., 2004). The extent to which these differences in D2/D3 receptor availability pre-date addiction was not clear, but as indicated in the following, several lines of evidence support a role for dopaminergic dysfunction as a vulnerability factor for substance abuse.

Early PET findings of dopamine D2/D3 receptor deficits in addictive disorders led to the hypothesis that a defect in striatal dopaminergic reward circuits promoted a Reward Deficiency Syndrome characterized by anhedonia and a dysfunctional impulsive-addictive-compulsive trajectory of behaviors (Blum et al., 1995). The premise was that those who suffer from a Reward Deficiency Syndrome engage in behaviors that augment dopaminergic activity, in some cases substituting one reward for another to satisfy a dopaminergic deficit. Such reward substitution is exemplified by unusually high caloric intake by methamphetamine addicts during their first month of drug abstinence, their caloric intake during the initial week being negatively correlated with striatal D2/D3 dopamine receptor availability (Zorick et al., 2012) (see Fig. 54.2).

Molecular imaging studies also have investigated effects of stress, gender, family history of addictive disorders, specific gene variants, and personality traits proposed as intermediate phenotypes associated with vulnerability to substance abuse. Novelty-seeking (Sweitzer et al., 2012), impulsivity (Verdejo-Garcia et al., 2008) and exposure to stress (Cumming

et al., 2011; Dalley et al., 2011; Sinha 2008) have been linked to substance abuse in both humans and animal models; and most relevant investigations support the view that dopaminergic hypofunction, as assessed by amphetamine-induced dopamine release or striatal D2/D3 receptor availability, confers vulnerability for addictive disorders. For example, both impulsivity and lifetime stress were associated with blunted amphetamine-induced dopamine release (Oswald et al., 2005). Although high stress blunted dopamine release at all levels of impulsivity, high impulsivity was associated with rating intravenous amphetamine as being more pleasant, while high stress was associated with ratings of less pleasant responses.

PET findings in humans have supported a link between novelty-seeking and an exaggerated response to amphetamine. Novelty-seeking was inversely related to the availability of D2/D3 dopamine receptors in the midbrain, measured with [F-18]fallypride, as well as a heightened subjective response to amphetamine administration and striatal dopamine release, suggesting an important role of dopamine D2/D3 autoreceptors in the midbrain (Buckholtz et al., 2010; Zald et al., 2008). Novelty-seeking and impulsivity also have been associated with sensitization of amphetamine-induced striatal dopamine release, measured using [C-11]raclopride and PET (Boileau et al., 2006). More recently, a SPECT study found a positive correlation of novelty-seeking with striatal D2/D3 receptor availability (Huang et al., 2010). Extrastriatal dopamine D2/D3 receptors have also been associated with at-risk personality traits. A study using [C-11]FLB457 and PET found that

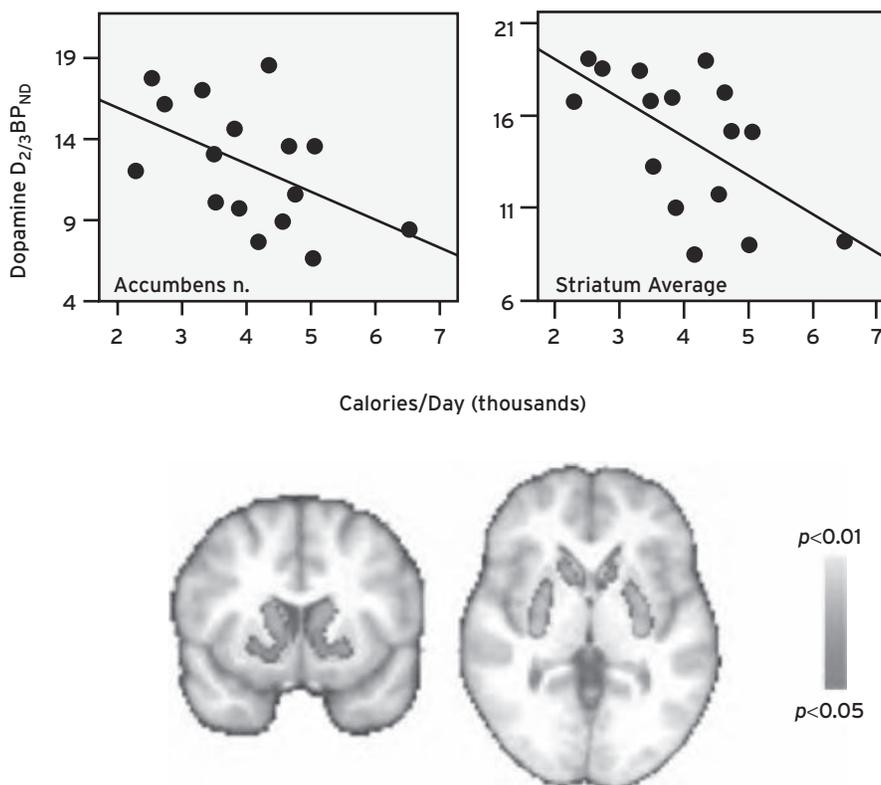

Figure 54.2 Top: Correlations of striatal dopamine D2/D3 receptor availability (BP_{ND}) with daily caloric intake (kcalories/day) in abstinent methamphetamine-dependent participants, $N = 16$. Bottom: Voxelwise regression of D2/D3 BP_{ND} on kcalories/day. Statistical maps are shown with results thresholded at Threshold-Free Cluster Enhancement (TFCE)-corrected $p < 0.05$, and displayed in radiological orientation. Vertical gradient bar indicates p -values.

novelty-seeking was negatively correlated with D2/D3 receptor availability in the insular cortex (Kaasinen et al., 2004).

Rats that were bred for high levels of impulsivity self-administered greater amounts of intravenous cocaine and nicotine than rats with low levels of impulsivity. PET revealed lower levels of ventral striatal D2/D3 receptor availability in high-impulsive rats, and the dopaminergic receptor deficit was correlated with the degree of impulsivity (Dalley et al., 2011). These findings are concordant with a human study in which self-reported impulsivity was negatively correlated with striatal D2/D3 receptor availability in healthy control subjects as well as methamphetamine-dependent subjects, with a more robust effect in the addict sample (Lee et al., 2009).

PET studies have provided evidence that high levels of striatal D2/D3 dopamine receptors may protect against drug abuse. For example, when methylphenidate, a stimulant with a mechanism of action similar to that of cocaine, was administered to healthy control subjects, an inverse relationship was found between D2/D3 receptor availability and subjective drug experience. Individuals with high D2/D3 receptor availability reported more unpleasant effects, suggesting a lower risk of drug self-administration (Volkow et al., 2002). This idea was supported by work using animal models (Cumming et al., 2011; Gould et al., 2012), showing that striatal D2/D3 receptor availability, quantified in drug-naïve rhesus monkeys with PET and [F-18]FCP, was negatively correlated with cocaine self-administration. Furthermore, adenoviral-mediated increased expression of striatal D2 receptors decreased alcohol self-administration in rats (Thanos et al., 2001).

The identification of high striatal D2/D3 dopamine receptor availability as a protective factor was further supported by observations that despite association of alcoholism with low striatal D2/D3 receptors, non-alcoholics with a strong family history of alcoholism have higher striatal D2/D3 receptors than non-alcoholics from low-risk families (Volkow et al., 2006a), suggesting that this neurochemical phenotype may protect against alcohol dependence. This view is consistent with results from a PET study with [F-18]FDG examining the hedonic effects of drinking ethanol versus placebo beverages in non-alcoholic men with and without a genetic allele conferring reduced D2/D3 receptor availability (London et al., 2009). Ethanol decreased anxiety and fatigue in men with the allele, but increased these measures in men without it. Reduction of anxiety and fatigue in men carrying the allele was associated with greater glucose metabolism in the orbitofrontal cortex and less activity in subcortical structures implicated in anxiety, fatigue and craving. Hedonic changes in men without the allele were unrelated to metabolic activity.

Animal studies of dominance hierarchies have provided insight into other factors, particularly environmental stressors, that contribute to drug abuse vulnerability. Social dominance and subordination in animals are considered forms of environmental enrichment and stress, respectively (reviewed in Cumming et al., 2011; Gould et al., 2012). Dominant social status was associated with higher [C-11]raclopride binding than subordinate social status in animals. After a stressful encounter with a stranger, [F-18]FDG and PET revealed a greater increase in mesocorticolimbic glucose metabolism in

dominant than in subordinate monkeys. After the encounter, dominant monkeys chose fewer cocaine injections and more food rewards than subordinate monkeys (Gould et al., 2012). The development of social dominance in group cages increased dopamine D2/D3 receptor availability by approximately 20%, with no change in the subordinates. Dominant male monkeys subsequently self-administered less cocaine than subordinates, suggesting protection against the reinforcing properties of cocaine. In contrast, dominant female monkeys chose more cocaine injections than female subordinate monkeys (Gould et al., 2012).

These results link impulsivity and novelty-seeking in non-addicted subjects to both pleasant subjective effects and striatal dopamine release elicited by addictive drugs. Sensitivity to drug-induced reward may increase vulnerability for initiation and early abuse of addictive substances. Ethical considerations limit the extent to which vulnerability may be manipulated in humans, but animal findings, in combination with demonstrations of drug-induced response as a function of genotype and inferences from genetic association studies, suggest that preexisting levels of dopaminergic signaling combine with personality traits and environmental conditions or stress to influence risk for substance abuse disorders.

ACUTE EFFECTS OF ADDICTIVE DRUGS: REWARD AND REINFORCEMENT

Although drugs of abuse from different chemical classes differ in some of their effects on mood and feeling state, they all produce positive subjective effects that reinforce drug-taking, and thereby promote addiction. These effects involve multiple neural systems, but a large body of evidence, primarily derived from animal studies, supported the idea that drug-related reinforcement requires dopaminergic neurotransmission (Di Chiara and Imperato, 1988; Everitt and Robbins, 2005; Koob, 1992). Molecular brain imaging has demonstrated that an increase in intrasynaptic dopamine within the striatum is also important in human drug abuse.

Fluctuations in synaptic dopamine and other neurotransmitters can be measured using PET and SPECT, based on the principle that endogenous neurotransmitters compete with radiotracers for receptor binding (Laruelle, 2000; Martinez and Narendran, 2010). With respect to dopamine dynamics, [C-11]raclopride and [F-18]fallypride have been used with PET and [I-123]IBZM was used with SPECT to measure extracellular dopamine dynamics as a function of physiological and/or pharmacological state (Laruelle, 2000; Riccardi et al., 2006). Molecular imaging has been combined with microdialysis in nonhuman primates to show that changes in radiotracer binding mostly reflect changes in extracellular dopamine levels (Laruelle et al., 1997b), but that the sensitivity of PET is lower than that of microdialysis, a 1% decrease in [C-11]raclopride binding potential corresponding to a 44% change measured with microdialysis (Breier et al., 1997). With an intravenous amphetamine challenge, [C-11]raclopride and PET revealed up to a 40% decrease in receptor binding potential indexed by the ratio B_{max}/K_d (Laruelle et al., 1997a, 1997b)

despite evidence that intravenous amphetamine (1.5 mg/kg) increases extracellular dopamine concentrations more than 100-fold (Laruelle et al., 1997b). Notably, many factors contribute to insensitivity and problems in collecting reproducible and accurate measurements of intrasynaptic dopamine concentrations using radiotracers. These include D2/D3 receptor affinity state (Laruelle 2000), receptor internalization (Skinbjerg et al., 2010), receptor polymerization (Logan et al., 2001), and timing of dopamine release and radiotracer equilibration. Also important are methodological details, such as the time window for data collection and the kinetic modeling approach.

Despite these caveats, molecular imaging has shown that all classes of abused drugs increase intrasynaptic dopamine concentrations in the ventral striatum of human subjects. These findings were obtained with PET using amphetamine (Drevets et al., 2001), cocaine (Schlaepfer et al., 1997), cigarette smoking (Brody et al., 2004), alcohol (Boileau et al., 2003), and opiates (Spreckelmeyer et al., 2011). PET studies with [C-11]raclopride have provided mixed findings regarding ventral striatal dopamine release by $\Delta 9$ -tetrahydrocannabinol (THC) (Bossong et al., 2009; Stokes et al., 2009). Such molecular imaging studies allow for the linking of acute biochemical effects of drugs with simultaneous changes in mood and feeling state. In this way, it has been used to directly relate change in intrasynaptic dopamine with feelings of drug-liking and euphoria after exposure to intravenous amphetamine (Drevets et al., 2001), intravenous methylphenidate (Volkow et al., 2001c), and cigarette smoking (Barrett et al., 2004).

The effects of various drugs and treatments on striatal dopamine dynamics are under genetic control. Examples of such effects have been derived from studies of cigarette smoking. In one study, dopamine release from smoking a cigarette, inferred from decreases in the binding of [C-11]raclopride, was influenced by polymorphisms in genes that influence dopamine function and metabolism (Brody et al., 2006b). In another study, using similar methodology, striatal dopamine release after cigarette smoking was modulated by the mu opioid receptor A118G polymorphism, carriers of the G allele showed a stronger response to cigarette smoking than those homozygous for the more common A allele (Domino et al., 2012).

Similar methodology has been used to detect increased release of endogenous opioids from PET studies showing reductions in the binding of [C-11]carfentanil after administration of various drugs of abuse. This has been observed after the administration of oral amphetamine (Colasanti et al., 2012), oral alcohol (Mitchell et al., 2012), and smoked cigarettes (Scott et al., 2007), highlighting the importance of opiate signaling in the effects of these drugs. In this regard, direct interactions between opioid and dopaminergic neurotransmission in rats have shown that nicotine-induced dopamine release in the nucleus accumbens depends on activation of mu-opioid receptors in the ventral tegmental area (Tanda and Di Chiara, 1998).

Pharmacokinetic profile and route of administration can have substantial effects on subjective experience and dopamine dynamics. For example, a PET study of dopamine transporter occupancy, measured using [C-11]cocaine, found that at the time of peak plasma levels after unlabeled cocaine administration,

DAT occupancy was comparable after intravenous, smoked and intranasal administration, but that self-ratings of “high” were greater after smoking than after administration by the other routes (Volkow et al., 2000). This suggested that the speed of drug delivery to the brain influences the subjective response to cocaine. These results are corroborated by the relationship between the rate of uptake of cocaine analogs into the brain and their reinforcing properties in a self-administration paradigm in non-human primates, such that the drugs with faster brain uptake produced greater levels of responding relative to the drugs with slower brain uptake (cited in Howell and Murnane, 2011). Collectively, these studies show how the route of administration and pharmacokinetic properties of drugs are key elements mediating the subjective, reinforcing, and behavioral effects of abused drugs, and thus their addictive potential.

In addition to measuring drug-induced changes in specific neurotransmission, PET and SPECT can measure changes in cerebral blood flow and glucose metabolism. Quantitative global measures as well as values normalized to global or other (e.g., activity in the slice) values have been used. As measures of glucose metabolism and perfusion are positively linked (Roy and Sherrington, 1890), they provide indices of neural activity that require oxidative metabolism. Glucose is the primary metabolic substrate in the adult brain, and perfusion follows metabolic activity to deliver glucose and oxygen. Similar to fMRI, these methods do not resolve the contributions of different neurotransmitter systems to the signal, nor do they separate the effects in afferents from those in intrinsic neurons or dendrites of receptive neurons.

Some of the earliest assessments of acute changes in cerebral function involved [F-18]FDG PET studies of changes in cerebral glucose metabolism produced by euphorogenic doses of morphine (30 mg, intramuscularly) and cocaine (40 mg, intravenously), administered to research participants reporting recent use of heroin or cocaine (London et al., 1990a, 1990b). Self-reports of positive subjective effects of morphine coincided with a 10% decrease in global cerebral glucose metabolism, not unexpected given the sedative effects of opiates. Decreases in telencephalic regions were significant, and the decrement was greater in the frontal than occipital cortex, consistent with the distribution of mu-opioid receptors observed with [C-11]carfentanil in humans (Frost et al., 1990); however, the reductions in glucose metabolism were not correlated with subjective responses.

Cocaine also produced a global decrease in glucose metabolism (London et al., 1990b), which initially seemed incompatible with the behavioral stimulant effects. However, global decreases in glucose utilization and/or cerebral blood flow after administration of most drugs of abuse, including ethanol (de Wit et al., 1990; Volkow et al., 1988b), opiates (London et al., 1990a), benzodiazepines (de Wit et al., 1991), and nicotine (Domino et al., 2000b; Stapleton et al., 2003; Zubieta et al., 2001), were subsequently revealed by PET. SPECT studies with [Tc-99m]HMPAO showed an acute effect of cocaine to reduce global perfusion (Wallace et al., 1996), which was related to ratings of subjective experience (Pearlson et al., 1993). The mechanism by which abused drugs reduce global glucose metabolism and blood flow is unknown.

These effects observed in humans were inconsistent with observations from earlier animal studies, potentially reflecting species differences or poor matching of doses or drug histories. Cocaine reduced cerebral glucose metabolism in human subjects with substantial drug experience, but produced dose-related increases in glucose metabolism in dopaminergic brain regions and the cerebellar vermis of naïve rats studied using the autoradiographic [C-14]2DG method (London et al., 1986; Porrino et al., 1988). Acute cocaine administration to cynomolgus monkeys decreased glucose utilization in a discrete set of cortical and subcortical limbic structures (Lyons et al., 1996), resembling decrements found in humans (London et al., 1990b). Subsequent PET studies of rhesus monkeys trained to self-administer cocaine employed the [F-18]FDG method (cited in Howell and Murnane, 2011). Absolute quantification was not reported, but normalized voxelwise analyses revealed that the initial dose of cocaine produced relative increases in glucose metabolism in the prefrontal cortex. With increasing cocaine exposure, relative effects extended throughout frontal cortex and striatum, demonstrating the importance of prior drug history and identifying brain regions that are progressively affected by increasing drug exposure. Normalized blood flow maps in nonhuman primates after cocaine administration also showed relative increases in the dorsolateral prefrontal cortex (cited in Howell and Murnane, 2011), indicating selective activation of regions with dopaminergic innervation, and suggesting that dopaminergic transmission may underlie cocaine-induced increases in neuronal activity.

Similar to observation with cocaine, nicotine administration shows marked species differences in its effect on local cerebral glucose metabolism. In rats, dose-related increases in nicotine-induced local cerebral glucose metabolism (London et al., 1988) were observed in a pattern that generally followed the distribution of high-affinity nAChRs reported by earlier studies using autoradiographic ligand binding sites with [H-3]nicotine (London et al., 1985) thus linking the nicotine binding sites to nicotine-induced changes in neuronal function. Noninvasive imaging of nAChRs in the human brain *in vivo* is important for elucidating the role of these receptors in response to nicotine administration. Development of specific radioligands targeting nAChRs (β 2-containing) for use with SPECT (Fujita et al., 2003) and PET (Kimes et al., 2003) in humans were used to show high levels of binding in the thalamus, cerebellum, putamen, pons, and cerebral cortices, indicating that species differences in nAChR distribution may underlie the differential response to nicotine.

Intravenous or intranasal (spray) nicotine administration in human subjects, like other stimulants, decreased global glucose metabolism (Domino et al., 2000b; Stapleton et al., 2003) and perfusion (Zubieta et al., 2001). Normalized data have revealed relative increases in glucose metabolism (Domino et al., 2000b) and blood flow (Domino et al., 2000a; Zubieta et al., 2001) in thalamus and other regions with high nAChR binding (Fujita et al., 2003; Kimes et al., 2003), suggesting that regional nicotine-induced changes in glucose metabolism are mediated by nAChRs. Increases in normalized regional cerebral blood flow, measured with [O-15]water and PET, in the

left frontal cortex, anterior cingulate (Rose et al., 2003) dorsolateral prefrontal cortex, orbitofrontal cortex, and striatum after nicotine administration (Domino et al., 2000a) further support the role of nAChRs in nicotine-induced neuronal activation. One to two puffs of a cigarette result in over 50% occupancy of brain nAChRs in smokers studied using PET and [F-18]2FA (Brody et al., 2006a), and this occupancy lasts for over three hours. In combination with data showing that secondhand smoke produces 20% occupancy of nAChRs (Brody et al., 2011), these findings demonstrate that low doses of nicotine occupy a substantial proportion of brain nAChRs, and thereby can influence brain function.

In summary, molecular imaging studies of acute administration of abused drugs have confirmed the importance of striatal dopamine release in the rewarding properties of these drugs. Molecular imaging studies of the time course of drug effects have shown the importance of rapid actions with respect to striatal dopamine and drug-induced euphoria. In the case of cigarette smoking, PET has been used to reveal a mismatch between duration of nAChR receptor occupancy and smoking behavior, presenting questions regarding the molecular basis for the frequency of smoking among nicotine-dependent smokers. In addition, studies on the effects of secondhand smoke have shown how PET may be useful in guiding policy decisions regarding smoking.

MOLECULAR ADAPTATIONS TO CHRONIC DRUG EXPOSURE

Over the course of the past two decades, the focus of human drug abuse research have moved from the acute effects of drugs of abuse to persistent neurochemical alterations that promote the maintenance of addiction. Mounting evidence indicates that drug abuse produces adaptations within neural circuits that process reward, react to stress, and mediate executive functions (Broft and Martinez, 2012; Koob and Volkow, 2010). Drug-induced increases in synaptic dopamine cannot fully explain the changes observed during the shift from drug use to addiction in vulnerable individuals (Volkow et al., 2011), or the sequential neuroadaptations that follow repeated drug exposure (Everitt and Robbins, 2005). These transitions involve dopaminergic, serotonergic, nicotinic cholinergic, and endogenous opioid systems (Table 54.2).

A consistent finding relates to lower levels of striatal D2/D3 dopamine receptors in research participants who had abused drugs compared to controls (Broft and Martinez, 2012). Chronic users of cocaine (Volkow et al., 1990), methamphetamine (Lee et al., 2009), alcohol (Volkow et al., 1996), opiates (Wang et al., 1997), or nicotine (Brown et al., 2012; Fehr et al., 2008) all display deficits in striatal D2/D3 dopamine receptor availability. Similar observations have been made in behavioral addictive disorders, such as pathological obesity (Wang et al., 2004). This commonality across several addictive disorders raises questions regarding the extent to which low D2/D3 receptor availability predates drug abuse, or is an effect of chronic drug exposure.

Whereas ethical restrictions limit direct evaluation of this question in humans, molecular imaging studies of nonhuman

TABLE 54.2. Findings from molecular imaging studies of human substance abuse: adaptations and/or preexisting differences

primates have provided useful information. Vervet monkeys exposed to a methamphetamine dosing regimen designed to mimic human consumption of the drug showed significant decreases in striatal D2/D3 receptor availability using [F-18] fallypride and PET after two weeks of methamphetamine exposure. These deficits persisted for at least seven weeks after cessation of treatment (Groman et al., 2012), indicating deleterious effects that are long-lasting. In another study, baseline striatal D2/D3 receptor availability, measured using [F-18]FCP, in rhesus monkeys was inversely related to rates of subsequent cocaine self-administration, but irrespective of baseline levels, chronic exposure to cocaine significantly reduced D2/D3 receptor availability (cited in Howell and Murnane, 2011). Taken together, these findings indicate that the apparent D2/D3 receptor deficiencies in human research participants who abuse addictive drugs reflect both a vulnerability to drug abuse and a consequence of chronic drug use.

Although abnormalities in D2/D3 dopamine receptor binding in addiction are well documented, findings regarding

the dopamine transporter (DAT) have been less consistent. One report showed low levels of DAT binding using [C-11] WIN35428 in methamphetamine-dependent individuals (McCann et al., 1998). In another study, DAT binding recovered with at least one year of abstinence (Volkow et al., 2001a). A direct relationship between the recovery of DAT and duration of abstinence (Sekine et al., 2001) suggested that reductions in striatal DAT associated with methamphetamine dependence may reflect short-term, drug-induced neuroadaptations.

SPECT studies of recently detoxified alcoholics using [I-123]PE2I found lower striatal DAT binding compared to control subjects (Repo et al., 1999). In a study using [I-123]β-CIT, DAT binding availability returned to control levels after four weeks if participants abstained from drinking (Laine et al., 1999). In contrast, a small PET study using [C-11] D-threo-methylphenidate (N = 5) showed no differences in striatal DAT binding between alcohol-dependent and healthy subjects (Volkow et al., 1996). That study reported a lower D2/D3 receptor to DAT binding ratio in the alcohol-dependent

group, suggesting that chronic alcohol abuse may disrupt the balance between pre- and postsynaptic dopaminergic function. Changes in DAT levels in alcoholism may be transient adaptations that typically recover with abstinence.

Striatal DAT has also been studied with respect to nicotine dependence and heroin abuse. A SPECT study using [I-123]β-CIT revealed no differences in DAT availability between smokers and nonsmokers (Staley et al., 2001). However, a PET study examining DAT using [C-11]PE2I binding in cannabis and tobacco smokers showed significantly less striatal DAT binding availability in participants who smoked both substances compared to subjects who smoked neither. Furthermore, tobacco-only smokers showed a trend towards lower striatal DAT binding than the control group (Leroy et al., 2011). SPECT studies using [I-123]β-CIT showed no differences in striatal DAT binding between heroin addicts and controls (Cosgrove et al., 2010), but higher binding in cocaine-dependent subjects than controls (Malison et al., 1998). A later PET study using [C-11]CFT found lower striatal DAT availability in opiate-dependent subjects than in control subjects, even after an abstinence period of six months (Shi et al., 2008).

Sample sizes and differences in tracers and techniques must be considered when interpreting DAT findings, but variation in the abstinence period may be particularly important. As DAT is subject to regulation by drugs that alter synaptic dopamine concentrations (Vander Borgh et al., 1995), the length of abstinence from dopamine-modulating drugs may substantially influence measures of DAT. This issue has encouraged the use of other markers of dopaminergic terminal integrity, such as the vesicular monoamine transporter (VMAT2), which are less sensitive than DAT to pharmacological alterations (Narendran et al., 2012; Vander Borgh et al., 1995). VMAT2 is present in all monoaminergic neurons and has been assessed in substance-dependent groups.

Lower striatal VMAT2 was seen postmortem in former methamphetamine abusers (Wilson et al., 1996), and PET studies using [C-11]dihydrotrabenazine to assess striatal VMAT2 *in vivo* showed lower levels in participants with severe alcohol-dependence (Gilman et al., 1998), cocaine-dependence (Narendran et al., 2012) and methamphetamine-dependence even after three months of abstinence (Johanson et al., 2006). In another study, however, the same tracer showed that recently abstinent methamphetamine-dependent individuals had greater VMAT2 binding availability than controls (Boileau et al., 2008). As drugs such as alpha-methylparatyrosine and d-amphetamine, which affect endogenous vesicular dopamine, modulate striatal VMAT2 binding in rats (Tong et al., 2008), a paradoxical increase in VMAT2 in early abstinence from methamphetamine (Boileau et al., 2008) may result from transient methamphetamine-induced alterations in vesicular dopamine concentration (Tong et al., 2008). Indeed, consideration of time since last drug use revealed VMAT2 increases relative to control subjects only in those who had most recently used methamphetamine (<12 days) (Boileau et al., 2008). Collectively, these findings suggest that increased VMAT2 may be a transient response to drug exposure and the reduction in VMAT2 binding observed after longer abstinence may indicate lasting damage to neuronal terminals as a consequence of drug use.

Quantification of endogenous vesicular dopamine pools can be inferred from molecular imaging studies of drug-induced dopamine release and depletion. Levels of endogenous dopamine in the brain can be reduced by alpha-methyl-*para*-tyrosine (AMPT), which inhibits tyrosine hydroxylase, the rate-limiting enzyme in the dopamine biosynthesis pathway (Brogden et al., 1981). PET and SPECT studies have estimated endogenous dopamine levels inferred from changes in D2/D3 receptor availability before and after AMPT treatment (Laruelle et al., 1997a). Using PET and [C-11]raclopride, the AMPT paradigm was used to examine endogenous dopamine levels in cocaine-dependent and healthy participants (Martinez et al., 2009a). Cocaine-dependent subjects had lower levels of endogenous dopamine, reflected in a 6% increase in D2/D3 receptor availability in the cocaine-dependent group as compared to an 11% increase in the control group. Therefore, group differences in D2/D3 receptor binding reported using [C-11]raclopride in cocaine-dependent participants (Martinez et al., 2004; Volkow et al., 1993) may have been underestimated because of interference by endogenous dopamine (more so in control than in cocaine-dependent subjects).

PET studies also have suggested that cocaine dependence is associated with diminished activity of the presynaptic element of dopaminergic neurons. A PET and [C-11]raclopride study of the effect of methylphenidate, which blocks reuptake of released dopamine, showed smaller changes in D2/D3 receptor availability in cocaine-dependent than in healthy subjects (Volkow et al., 1997). Similar findings were obtained in studies of heroin- (Martinez et al., 2012), methamphetamine dependence (Wang et al., 2011) and alcohol dependence (Martinez et al., 2005). In light of the findings from studies with AMPT, a smaller response to a methylphenidate challenge in substance-dependent groups may reflect low endogenous dopamine (Martinez et al., 2009a) in addition to reduced presynaptic activity. This view is consistent with lower rates of striatal dopamine synthesis, as measured by [F-18]DOPA uptake, in recently abstinent cocaine-dependent (Baxter et al., 1988; Wu et al., 1997) and alcohol-dependent subjects (Salokangas et al., 2000) relative to controls.

Alterations to the dopaminergic signaling system in substance dependence also occur via neurotransmitter metabolism. Monoamine oxidase A (MAOA) and monoamine oxidase B (MAOB), are both involved in dopamine degradation (Riederer et al., 1987). In cigarette smokers, levels of each are reduced between 30 and 40% (Fowler et al., 1996a, 1996b), as measured with PET using [C-11]clorgyline (MAOA) and [C-11]deprenyl-D2 (MAOB). Inhibition of MAOA and B by cigarette smoking results in enhanced dopaminergic activity and may represent an additional mechanism by which nicotine provides reinforcement. MAO inhibition by smoking is temporary because normalization of enzymatic activity occurred after approximately four weeks of abstinence (Rose et al., 2001). Because MAOA also regulates central serotonergic activity, impaired MAOA activity in smokers may contribute to antidepressant effects of cigarette smoking, and depressive symptoms during nicotine withdrawal. Because MAOA breaks down monoamines linked to mood, and persons with major depression are more likely both to smoke and to have difficulty

stopping (Covey et al., 1998), MAOA inhibition should be considered as a link between smoking and depression (Fowler et al., 1996b).

Although dopaminergic markers generally show deficits across addictive disorders, findings regarding other neurotransmitter systems are more variable. Alcohol abuse has been studied with molecular probes for the GABA and serotonin systems. Alcohol-dependent subjects had lower GABA_A receptor binding than controls, as shown using [I-123]iomazenil and SPECT (Abi-Dargham et al., 1998; Lingford-Hughes et al., 1998) and [C-11]flumazenil and PET (Gilman et al., 1996). Alcohol-dependent subjects showed less serotonin transporter availability using [I-123]βCIT and SPECT (Heinz et al., 1998). In a separate PET study, alcohol-dependent subjects showed no differences relative to control subjects in serotonin transporter availability, using the tracer [C-11]DASB or 5-HT1A receptor availability using [C-11]WAY100635 (Martinez et al., 2009b).

Deficits in serotonin transporter (SERT) availability, assessed with PET and [C-11]McN5652, were seen in subcortical brain regions of methamphetamine- (Sekine et al., 2006) and alcohol-dependent subjects (Heinz et al., 1998). In rhesus monkeys, SERT binding was studied with PET and [C-11]DASB after chronic self-administration of cocaine (cited in Howell and Murnane, 2011). SERT availability differed as a function of cocaine self-administration where monkeys with a history of cocaine exposure showed higher levels of striatal SERT than drug-naive monkeys. This result resembled findings in cocaine-dependent humans (Jacobsen et al., 2000), indicating that chronic cocaine exposure may increase striatal SERT binding.

Few human molecular imaging studies have examined endogenous opioid systems in addiction, and most of the relevant information has come from studies of mu-opiate receptors. Using PET and [C-11]carfentanil, it was shown that one- to four-day abstinent cocaine-dependent subjects had higher mu-receptor binding than controls in the cingulate, frontal cortex, caudate, and thalamus, persisting up to 12 weeks of abstinence (Gorelick et al., 2005; Zubieta et al., 1996). PET studies using [C-11]carfentanil have shown greater mu-receptor binding availability in the ventral striatum of alcohol-dependent subjects (Heinz et al., 2005a), with deficits also observed in cortical mu-receptor availability (Bencherif et al., 2004). Heroin-dependent subjects had higher mu-receptor availability in the anterior cingulate and inferior frontal cortex relative to control subjects (Zubieta et al., 2000). Endogenous opiate-receptor signaling represents an important facet of substance dependence because many studies show relationships between mu-receptor levels and drug craving (Gorelick et al., 2005; Zubieta et al., 1996) and substance abuse treatment outcomes (Ghitza et al., 2010). An increasing body of literature supports a role of dynorphin and kappa-opioid receptors in addiction (Shippenberg et al., 2001), but further investigations of abuse-related plastic changes within the endogenous opiate signaling system are needed to draw conclusions that can improve addiction treatment strategies. Development and application of specific radiotracers, such as [C-11]GR103545 to image kappa-opiate receptors (Schoultz et al., 2010), may yield valuable new information.

Motivated by the high prevalence of cigarette smoking worldwide, much attention has been paid to adaptations of nicotinic acetylcholine receptors (nAChRs) in the brains of cigarette smokers (Sharma and Brody, 2009). These receptors modulate the release of transmitter from presynaptic terminals on several types of neurons (Wonnacott, 1997). Nicotine-induced stimulation of nAChRs on dopaminergic neurons increases extracellular dopamine levels in the nucleus accumbens (Nisell et al., 1994). Alterations in nAChRs observed using molecular imaging techniques have been important in development of nicotine-cessation therapies. Chronic nicotine administration upregulates nAChRs in rodents (Koylu et al., 1997), as has been shown in human postmortem studies (Benwell et al., 1988) and *in vivo* with the tracer 2-[F-18]fluoro-A-85380 (Mukhin et al., 2008). [I-123]5-iodo-A-85380 was used with SPECT to show that β2* nAChR availability was elevated in the striatum and cerebral cortex of one-week abstinent smokers, relative to nonsmokers, and was correlated with the days since last cigarette (Staley et al., 2006). A SPECT study using the same tracer, showed that β2* nAChR availability returned to baseline after 21 days of abstinence (Mamede et al., 2007). These findings indicate that when smokers quit smoking, upregulation of the receptors normally activated by nicotine persists for several weeks. Greater β2* nAChR availability during this period may impact the ability of smokers to maintain abstinence.

SPECT imaging, using [I-123]5-iodo-A-85380, showed higher β2* nAChR binding in the striatum and cerebellum of male smokers, compared to nonsmokers, but no detectable difference between female smokers and nonsmokers (Cosgrove et al., 2012). This study corroborated the observation that nAChRs were upregulated in male but not female rats (Koylu et al., 1997). Notably, men and women show differences in the smoking-induced upregulation of nAChRs, which may be useful in treating nicotine dependence. The lack of nAChR upregulation suggests that females may respond better to medications that do not target nAChRs than to nicotine replacement or varenicline (Cosgrove et al., 2012).

Molecular adaptations to substance abuse have also been evaluated using PET and SPECT measurements of blood flow and glucose metabolism. An early PET study of blood flow measured with [O-15]water showed large focal deficits in the prefrontal cortex of cocaine-dependent relative to control subjects (Volkow et al., 1988a). A SPECT study using [Tc-99m]HMPAO found focal decreases in perfusion of the frontal cortex and basal ganglia (Holman et al., 1991). Glucose metabolism, measured with [F-18]FDG and PET, showed deficits in frontal cortical regions, relative to control subjects, with no recovery after three–four months of cocaine abstinence (Volkow et al., 1992). Similar deficits in global and relative glucose metabolism were noted in three-week abstinent alcohol-dependent men (Volkow et al., 1994). Although relative metabolism in the basal ganglia recovered somewhat during abstinence, it was still abnormal after detoxification. A repeat study in women showed no differences from controls in cerebral glucose metabolism associated with alcohol dependence (Wang et al., 1998). The women, however, had markedly lower rates of alcohol use than the men in the previous study (Volkow et al., 1994), which may contribute to the apparent sex difference.

Regional cerebral glucose metabolism in fourteen-day abstinent intravenous cocaine users with histories of polysubstance abuse was lower than in control subjects. The polysubstance abusers showed lower absolute metabolic rates for glucose in lateral occipital gyrus and higher normalized metabolic rates in temporal and frontal cortices, including orbitofrontal cortex (Stapleton et al., 1995). Cocaine-dependent subjects had higher rates of orbitofrontal cortex glucose metabolism than controls after one week of abstinence, but metabolism normalized after four weeks (Volkow et al., 1991). Compared to control subjects, methamphetamine-dependent participants (4–7 days abstinent) had lower glucose metabolism in the anterior cingulate and insular cortices, and higher glucose metabolism in the lateral orbitofrontal cortex, middle and posterior cingulate, amygdala, ventral striatum, and cerebellum (London et al., 2004). In both cocaine-dependent and methamphetamine-dependent subjects, orbitofrontal glucose metabolism was negatively correlated with striatal D2/D3 receptor availability (Volkow et al., 1993, 2001b), suggesting a mechanistic link between orbitofrontal function and striatal dopaminergic transmission in stimulant dependence. These findings support a model in which dysfunction of frontal circuits that inhibit the striatal dopaminergic reward system, combined with deficient striatal dopaminergic transmission, may promote behaviors that perpetuate the cycle of addictive disorders (Volkow and Fowler, 2000).

PET and SPECT studies of molecular adaptations in substance use disorders have extended preclinical findings to humans. Most studies have focused on the dopamine system. Dopaminergic deficits are consistently reported in substance dependence, suggesting that they contribute to initiation and/or maintenance of the addictive process. Imaging of serotonin, nicotinic, and opiate receptor signaling have not yet yielded as consistent a picture.

PERSISTENT STATES: FACTORS CONTRIBUTING TO RELAPSE

Drug addiction is associated with intense craving or desire to consume the relevant drug, and reduced motivation to seek other forms of reinforcement (Parvaz et al., 2011). Even after prolonged periods of abstinence, craving triggered by reminders of substance abuse, such as relevant people, places, or things, can overcome attempts to maintain sobriety. Studies in animals have revealed an important role of striatal dopamine in the conditioned responses that model craving (Everitt and Robbins, 2005), and molecular neuroimaging has been used to extend this work to delineate the circuits and neurotransmitter systems that mediate drug craving in humans.

SPONTANEOUS CRAVING DURING ABSTINENCE

The period of early abstinence has been a focus of study because most treatment for addiction begins at this time (Huber et al., 1997). PET with [F-18]FDG showed elevated glucose metabolism in the basal ganglia and orbitofrontal cortex during the first week of abstinence from chronic cocaine, and orbitofrontal

cortical metabolism was correlated with self-rated cocaine craving (Volkow et al., 1991). Newly abstinent cocaine abusers had higher mu-opioid receptor binding than control subjects in the dorsal striatum, thalamus, anterior cingulate, and frontotemporal cortices, as assessed with PET and [C-11]carfentanil (Zubieta et al., 1996). Craving was correlated with binding of the radiotracer in amygdala, anterior cingulate, and frontotemporal cortices. In a later study, craving on the first day of cocaine abstinence was correlated with mu-opioid receptor binding in the anterior cingulate, prefrontal, temporal, and parietal cortices (Gorelick et al., 2005). Correlations were significant between craving and mu-opioid receptor binding in the left frontal and right temporal/parietal cortex for up to six days. These findings contrasted with a report that mu-opioid receptor binding in the right dorsolateral prefrontal cortex, right anterior frontal cortex, and right parietal cortex in alcohol dependent subjects was lower than control values, and that the deficit was associated with alcohol craving (Bencherif et al., 2004). The literature points to involvement of frontostriatal regions as well as more extended corticolimbic circuitry in spontaneous craving for cocaine as well as upregulation of the mu-opioid system.

Other studies have focused on striatal dopamine D2/D3 receptors. In abstinent alcoholics, alcohol craving was inversely related to striatal D2/D3 receptor availability, measured using [F-18]fallypride, and to dopamine synthesis capacity in the putamen, as indexed by [F-18]FDOPA uptake (Heinz et al., 2005b). In contrast, an [F-18]fallypride PET study of 24-hour abstinent, heavy cigarette smokers found no relationship of cigarette craving to D2/D3 receptor availability, but when the participants were tested without forced abstinence from smoking, craving was positively correlated with D2/D3 receptor availability in the ventral striatum, but negatively with D2/D3 receptor availability in the anterior cingulate and inferior temporal cortices (cited in Parvaz et al., 2011), suggesting that cigarette craving may be maintained by region-specific shifts in D2/D3 receptor availabilities.

CUE-ELICITED CRAVING

The first imaging study of cue-elicited drug craving used [F-18]FDG and PET, and showed increased glucose metabolism in a network of corticolimbic regions implicated in memory when abstinent cocaine-abusing participants viewed videotapes of drug-related objects, compared to a session in which they viewed a neutral videotape (Grant et al., 1996). The cue-related increase in craving was correlated with a metabolic increase in dorsolateral prefrontal cortex, amygdala, and cerebellum. Expansion of this work (Bonson et al., 2002) showed that cocaine cues elicited a higher degree of craving than previously reported and resulted in activation of lateral amygdala, lateral orbitofrontal cortex, dorsolateral prefrontal cortex, and cerebellum. Activation in these regions and the insular cortex was correlated with self-reported craving, suggesting that activity within a network that integrates emotional and cognitive aspects of memory links environmental cues with cocaine craving. Similar methodology was used in a study of cue-induced craving for cigarettes (Brody et al., 2002). In the active-cue video condition, smokers had greater increases

in relative glucose metabolism than nonsmokers in the perigenual anterior cingulate cortex. Craving was correlated with glucose metabolism in the orbitofrontal, dorsolateral, anterior insular, and right sensorimotor cortices, suggesting potential therapeutic targets for treatments designed to reduce cigarette craving.

Studies of cue-induced craving have also used [O-15]water and PET to measure cerebral blood flow. In the first of these studies, cocaine abusers exhibited greater activation, indexed by blood flow in the amygdala and anterior cingulate cortex, but lower blood flow in the caudate nucleus and globus pallidus when they viewed a cocaine-related video than when viewing a neutral video (Childress et al., 1999). In another study, script-guided imagery of autobiographical memories was used to generate cocaine craving and was compared to a control condition of neutral memory recall during PET data acquisition (Kilts et al., 2001). Compared with the neutral condition, drug craving activated the bilateral (right greater than left) amygdala, left insula and anterior cingulate gyrus, and right subcallosal gyrus and nucleus accumbens. A subsequent study of cue-induced craving in opiate-dependent subjects who listened to autobiographical scripts of an episode of craving and a neutral episode while undergoing a PET scan with the tracer [O-15]water revealed cue-induced activation in the left medial prefrontal and left anterior cingulate cortices, and activation of the orbitofrontal cortex was correlated with craving ratings (Daglish et al., 2001). When similar methods were used to study heroin addicts, the “urge-to-use” heroin after viewing heroin-related as compared with neutral videotapes was correlated with blood flow increases in portions of the inferior frontal/orbitofrontal cortices, precuneus, and insula (cited in Parvaz et al., 2011). These findings show the involvement of a corticolimbic network, including brain regions important for decision-making, in generating or experiencing craving in response to relevant environmental cues.

Dopaminergic modulation of cue-elicited craving was revealed in a study using [C-11]raclopride and PET to measure change in intrasynaptic dopamine concentrations, inferred from changes in [C-11]raclopride binding, in cocaine-dependent subjects viewing cocaine-related videotapes. Subjects who reported craving for cocaine had larger cue-induced decreases in dopamine D2/D3 receptor availability than those who did not report craving. Furthermore, the magnitude of change in intrasynaptic dopamine concentrations in the putamen was positively correlated with the intensity of cocaine craving (Wong et al., 2006). Comparable results were found in a similar study (Volkow et al., 2006b) wherein cue-induced decreases in [C-11]raclopride binding in the dorsal striatum were largest in the most severely addicted participants. Similar heroin-related videotapes elicited greater dopamine release in the right putamen of opiate-dependent subjects, relative to controls, with dopamine release being correlated with chronic craving and anhedonia, in a SPECT study of D2/D3 receptor availability (Zijlstra et al., 2008). Evidence of cue-elicited dopamine release in the dorsal striatum, a region implicated in habit learning, suggests that dopaminergic transmission in this region is a fundamental component of how craving maintains addiction.

DRUG-ELICITED CRAVING

An early SPECT study used [Tc-99m]HMPAO to examine blood flow in alcoholics after craving was elicited by a low non-pharmacological dose of alcohol (cited in Hommer, 1999). An increase in blood flow in the right caudate was correlated with the increase in craving for alcohol. Similarly, in a study of hospitalized patients who had chronically abused cocaine, methylphenidate increased glucose metabolism measured with [F-18]FDG and PET in frontal cortex, thalamus, and cerebellum, with the increases in right orbitofrontal cortex and caudate metabolism positively correlated with increased craving (cited in Hommer, 1999). These correlations add to substantial literature on the link between orbitofrontal cortex and striatal function in evaluating and responding to potential rewards.

In a novel PET study on the effects of secondhand smoke, the tracer [F-18]2FA was used to label the β_2 subtype of nicotinic acetylcholine receptors (nAChRs) (Brody et al., 2011). After one hour of moderate exposure to second-hand smoke, smokers reported increased craving, and the specific binding volume of distribution of the radiotracer was reduced by ~19%, corresponding to occupancy of β_2 nAChRs by nicotine. The thalamic nAChR occupancy in smokers by secondhand smoke was correlated with the alleviation of craving by subsequent smoking. This link between the amount of nicotine delivered and the response to subsequent smoking suggested that secondhand smoke primes a smoker to receive greater negative reinforcement from smoking.

Finally, a PET study using [C-11]raclopride showed that reducing serotonin transmission via acute tryptophan depletion increased cocaine-elicited craving and cocaine-induced striatal dopamine release in non-dependent intranasal cocaine users (Cox et al., 2011). Neither craving nor striatal dopamine release were altered by tryptophan depletion prior to placebo administration. These observations suggested that low serotonergic transmission may increase craving and dopaminergic responses to cocaine, indicating a possible mechanism by which individuals with low serotonergic transmission may be at elevated risk for substance use disorders.

Generally, the findings presented here suggest that craving, whether it is spontaneous, cue-induced, or drug-induced, involves corticostriatal and more generally corticolimbic circuitry. These data suggest that the orbitofrontal cortex is involved in the induction of craving in several substance-dependence disorders. As the orbitofrontal cortex and other regions of the prefrontal cortex are involved in salience attribution, inhibitory control, emotion regulation, and decision-making (London et al., 2000), dysregulation in the frontal cortex may enhance the motivational value of the drug of abuse and may lead to loss of control over drug intake (Goldstein and Volkow, 2002). Notably, deficits in D2/D3 receptor availability in stimulant-dependent subjects are related to low rates of glucose metabolism in the orbitofrontal cortex (Volkow et al., 1993, 2001b), suggesting a mechanistic link between striatal dopaminergic dysfunction and frontal metabolism.

A study highlighting the importance of frontostriatal dysfunction and inhibition studied cocaine-dependent subjects

that were instructed to inhibit craving actively while viewing a cocaine-related video (cited in Parvaz et al., 2011). Successful inhibition of craving was associated with decreased glucose metabolism in the right nucleus accumbens and increased metabolism in right inferior frontal cortex, suggesting that strengthening frontostriatal regulation could be a useful goal and biomarker of therapeutic interventions.

CONCLUSIONS

Animal models of substance dependence have helped to elucidate the neurobiological mechanisms involved in the reinforcing effects of addictive drugs in human subjects and have provided a foundation for studying the biological basis of drug addiction. However, there remains a degree of uncertainty regarding the extent to which these observations coincide with relevant addiction-related processes in humans. Molecular imaging approaches can be instrumental in providing direct evidence of the analogous biological processes and behaviors in humans.

The progress of the molecular imaging field in addiction is principally driven by the development of novel radiotracers to image integral components of neurochemistry, with the goal of developing targeted interventions for substance abuse disorders. Within the dopaminergic system, agonist-based tracers targeting D2/D3 dopamine receptors designed to distinguish between high- and low-affinity receptor configurations will be instrumental in elucidating dopamine receptor dynamics as a mechanism of functional state of the receptor. New tracers targeting the glutamate, cannabinoid, and kappa-opioid systems in humans will allow for the expansion of concepts surrounding the integral role for these neurotransmitters in addiction that were constructed using evidence from animal models.

Finally, molecular imaging tools enable the examination of biological processes as a function of genotype, which is essential for understanding the processes by which genes affect the vulnerability or resilience of an individual to addiction. Furthermore, effectiveness of future treatment interventions designed to strengthen and restore brain areas affected by chronic drug use can be assessed using molecular imaging to track progressive changes in the relevant brain systems during the course of treatment and recovery.

DISCLOSURES

Dr. Robertson, Dr. Berman, and Dr. London have no conflicts to disclose. Their work is funded by NIDA and the Friends Research Institute only.

VANI PARIYADATH, MARTIN P. PAULUS, AND ELLIOT A. STEIN

Substance abuse and dependence have an enormous impact on society. For example, according to the Substance Abuse and Mental Health Services Administration (SAMHSA; <http://www.samhsa.gov/>), in the United States, the lifetime prevalence of substance abuse or dependence in adults is over 15%. Estimates of the overall costs of drug and alcohol abuse in the United States exceed \$600 billion annually (National Institute on Drug Abuse, 2011). In 2006, an estimated 20.4 million Americans aged 12 or older used illicit drugs over the past month, which represents 8.3% of the population aged 12 years or older (SAMHSA). According to another SAMHSA report, 14.8 million individuals reported using marijuana in the past month, with an additional 9.6 million persons who used illicit drugs other than marijuana.

Addiction occurs rarely as an isolated disease entity. Instead, there is significant comorbidity between substance dependence with most mood disorders and anxiety disorders (Reske and Paulus, 2008). Interestingly, only a minority of individuals with substance use disorders seek treatment (Reske and Paulus, 2008). Psychiatric comorbidity has a profound influence on course and outcome. Individuals with substance use disorders and posttraumatic stress disorder, relative to those with substance use disorders only, are more impaired, have greater psychosocial problems, and show a more severe course (Reske and Paulus, 2008). Similarly, comorbid antisocial personality disorder results in earlier onset of substance use disorders, greater multisubstance use, poorer outcomes, more severe course, and other psychosocial dysfunctions (Reske and Paulus, 2008). The complex neural basis of addiction is complicated by three major factors. First, addiction is a highly dynamic disorder that undergoes frequent transition from intense use to sobriety. Second, psychiatric comorbidity has profound influences on the course and neurobiology of drug addiction. Finally, and of particular relevance here, both reward-related processes as well as negative reinforcement processes are thought to contribute to the various stages of drug addiction.

Reward is a complex construct that entails a feeling and an action. Components of reward include the hedonic aspects, that is, the degree to which a stimulus is associated with pleasure, and the incentive motivational aspects, that is, the degree to which a stimulus induces an action towards obtaining it (Berridge and Robinson, 2003). Typically, the feeling is described as pleasurable or positive and the actions comprise behavior aimed to approach the stimulus that is associated with reward. However, importantly, both feeling and action are highly dependent on the homeostatic state of the individual

(Craig, 2002). Few other topics in neuroscience have received as much attention in the last 60 years as the brain's reward system, and yet much of its function remains poorly understood. With more sophisticated technology and tools for studying brain reward circuitry, an increasingly complex yet still ambiguous picture has emerged. A more thorough understanding of this intricate system may yield a better appreciation of the challenges facing addiction research and treatment outcome improvement. We thus begin with a brief introduction of the reward system before reviewing the current literature on addiction neuroimaging.

REPRESENTATION OF REWARD IN THE BRAIN

Since the seminal study from Olds and Milner (1954) establishing that rats would move to a specific place in an open field to obtain electrical stimulation of certain brain areas, it has been established that there exists a neural system, which were originally conceptualized as centers, whose activation appears to signal positive rewarding effects. In the intervening decades, pharmacological, electrophysiological, and neuroimaging studies have helped delineate an extensive reward circuit that spans striatal, midbrain and prefrontal regions (Fig. 55.1A).

Research on the reward circuit has revolved around midbrain dopaminergic neurons, along with the structures they enervate (Haber and Knutson, 2010). This includes the mesolimbic pathway or the dopaminergic nerve bundle that originates mostly in the ventral tegmental area in the midbrain and projects to multiple limbic structures, the mesocortical pathway that projects to frontal cortical regions, and the nigrostriatal pathway that extends primarily between the substantia nigra and the dorsal striatum. Although we have a limited understanding of their specific roles, other subcortical regions have now been identified as being central to reward processing including the lateral habenula and the amygdala (Haber and Knutson, 2010). When probing the reward circuit in humans on a systems level, functional magnetic resonance imaging (fMRI) studies have highlighted the orbitofrontal cortex, amygdala, nucleus accumbens, ventral tegmental area, and hypothalamus as responding to abused drugs and other positive reinforcing stimuli (Haber and Knutson, 2010). Extracting the specific roles of these nodes within the reward circuit is made complicated by the extensive forward and backward projections between them (Ikemoto, 2010; Fig. 55.1B), as

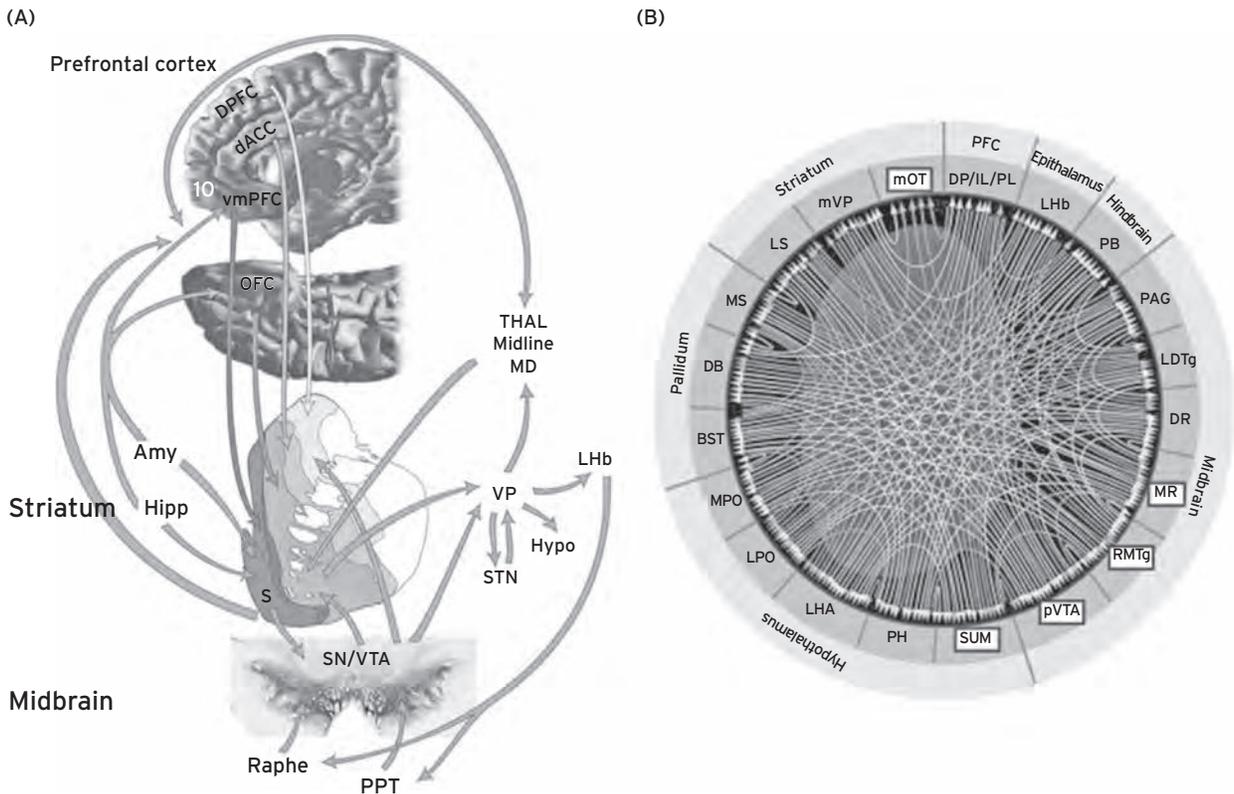

Figure 55.1 The reward circuit and its complexity. (A) Brain regions identified as being key players in the reward circuit, including striatal, midbrain, and prefrontal regions and, more recently, the amygdala, hippocampus, lateral habenula, and brainstem structures. (B) The connectivity between proposed brain reward regions is incredibly complex and has rendered identifying the roles of individual components difficult. Orange lines indicate unidirectional connection and yellow lines reciprocal connections. Purple area represents the medial forebrain bundle, the stimulation of which results in rewarding brain stimulation. (A from Haber S.N., Knutson B. (2010). Brain reward circuitry beyond the mesolimbic dopamine system: a neurobiological theory. *Neurosci Biobehav Rev* 35:129–150.) (See color insert.)

well as the complexity introduced by the interaction of different neurotransmitter systems and their associated receptor machinery.

NEUROTRANSMITTER SYSTEMS INVOLVED IN REWARD PROCESSING

THE DOPAMINE HYPOTHESIS OF REWARD

Arguably, the most influential model for dopamine function has stemmed from the anhedonia hypothesis, which suggested that dopamine signals the pleasure experienced from food and other natural and artificial rewards (Wise, 2008). However, dopamine receptor antagonists do not diminish the appetitive value of rewards, as would be expected from the anhedonia model, but instead affects the animal’s ability to act upon these value computations (Berridge, 2007). In the last 30 years, the anhedonia hypothesis has faced severe opposition and undergone revisions, but there is no denying the impact it has had on successive theories of motivation and dopamine function (Wise, 2008).

A second school of thought posits that dopaminergic neurons in the ventral tegmental area (VTA) reflect a reward prediction error: These neurons fire phasically in response to an unexpected reward, and, after learning has taken place, in

response to the omission of an expected reward, but not to an expected reward itself. Curiously, after multiple presentations of a paired cue and reward, these neurons shift their time of firing from the onset of the reward to that of the cue predicting the reward (Schultz et al., 1997). Reinforcement learning models have emphasized the difference between the encoding of the reward itself and the reward prediction error, and have provided the field with quantitative tools for understanding dopaminergic function. For example, temporal difference learning models have contributed a precise basis for the temporal evolution of the dopamine signal as learning of cue-reward associations takes place (Niv et al., 2005).

An alternative viewpoint holds that there are two components to the response to reward: one is “liking,” which corresponds to the pleasure experienced from a reward, and the other is “wanting” or incentive salience that relates to the attractiveness of the reward (Berridge, 2007). To assay the former, researchers have focused on facial palatability responses to appetitive (e.g., sweet tasting) and aversive (e.g., bitter tasting) stimuli (Steiner et al., 2001). Humans and a wide range of animals display a distinct, reproducible facial response to both types of stimuli, for example, gaping in response to bitter tasting stimuli and tongue protrusions in response to sweet tasting ones. Importantly, these liking responses are not influenced by dopamine modulations (Berridge, 2007). Instead, dopamine

seems to play a role in the wanting of rewarding stimuli, such that elevated dopamine levels in the synapse (e.g., in hyperdopaminergic mutant mice) bring about increased wanting of the reward, measured by the willingness to work for it (Berridge, 2007). In this sense, the wanting component of the reward signal corresponds to the reward prediction error, whereas the liking component resembles the hedonic aspect of reward described in early models of dopamine function.

MOVING BEYOND THE DOPAMINE HYPOTHESIS OF REWARD AND PREDICTION ERROR

Although much effort has been spent on elucidating the precise function of dopamine, many important questions about reward processing remain unanswered. While the role of this neurotransmitter, especially within the basal ganglia, carries important implications for the effects of drugs of abuse, it is clearly far from a simple mediator of reward in the brain, as was once presumed. Perhaps only by deemphasizing the role of dopamine can further progress on reward-related disorders like addiction be made. To this end, this chapter offers a brief exploration of the research linking other major neurotransmitters to reward learning.

The neurotransmitter system best positioned to enhance addiction research is probably glutamate, an excitatory neurotransmitter localized within over half of all synapses in the brain. Within the reward circuit, glutamate-dopamine interactions appear to play an important role in synaptic plasticity in the striatum (Wang et al., 2012), and in frontostriatal communication (Taber and Fibiger, 1995). Some view such interactions as a promising new avenue of research, especially in the context of such psychiatric disorders as drug addiction (Wang et al., 2012).

There is also emerging evidence to suggest that dopamine and serotonin work in opposition to each other (Cools et al., 2011). Although earlier models proposed a symmetric relationship for dopamine and serotonin centered around reward and punishment learning, a more nuanced framework has emerged wherein the two neurotransmitters control the interaction between reward/punishment and behavioral activation/inhibition (Cools et al., 2011). Dopamine is thought to behave in complex ways pre- and post-synaptically to effect changes in synaptic function through two main groups of receptors, categorized as D1-like (D1 and D5) and D2-like (D2, D3, and D4) receptor families (De Mei et al., 2009). Serotonin's function may seem labyrinthine in comparison because it employs at least 14 different receptor subtypes (Hoyer et al., 2002).

Finally, recent research suggests that GABAergic neurons play an important role in reward processing as well, and, as with other neurotransmitters, this role is mediated through its interactions with dopaminergic neurons (Parker et al., 2011). Recently, GABAergic neurons have been shown to encode expected reward, such that they remain persistently active between the presentation of the cue and the reward (Cohen et al., 2012). Taken together, it seems apparent that a better understanding of neurotransmitter interactions within the reward circuit is needed in the field.

OUTSIDE THE BASAL GANGLIA

A drive-by observer of reward-related research may be forgiven for mistaking the basal ganglia for being the beginning and end of reward processing since a vast majority of research has focused on this body, especially in terms of dopaminergic function. Even so, there is currently no unified theory for basal ganglia function, and the story only grows murkier as the series of parallel circuits that form corticobasal ganglia-thalamocortical loops are taken into account (Alexander et al., 1986). As research has ventured beyond the basal ganglia, new and unexpected players have emerged, and given their prominent roles in non-reward-related functions, it has been suggested that reward be understood within a larger framework of animal behavior (Hikosaka et al., 2008). Because a detailed understanding of the basal ganglia has thus far not significantly improved understanding of drug addiction to the extent one might have predicted, it seems particularly pertinent to extend the roles of other subcortical and cortical nodes within the reward circuit.

AMYGDALA AND REWARD PROCESSING

By the middle of the twentieth century, it was evident that the amygdala plays a central role in emotional processing, but ensuing research resulted in some confusion as important differences in the distinct subareas of the amygdala had not yet been fully appreciated (LeDoux, 2007). Currently, there is much debate on whether the amygdala is really a single structural or functional unit, but studies on Kluver-Bucy syndrome and fear conditioning have suggested a general role for emotional processing, with an emphasis on fear. The lateral nucleus, in particular, has long been emphasized in fear learning, but, along with the basal and central amygdala, is now also considered important for reward learning and motivation more generally (LeDoux, 2007).

Within the context of this review, it is important to note that the amygdala seems to represent reward- and punishment-related predictions (Roesch et al., 2010), and is likely involved in associative learning in general (Murray, 2007). Whereas dopaminergic activity in the VTA closely resembles a neural prediction error (Schultz et al., 1997), amygdalar neurons behave as though they signal a different entity—associability, or the amount of attention devoted to cues (Li et al., 2011). Per the Pearce-Hall model of associative learning, the associability of a cue is determined by the positive or negative surprise accompanying previous presentations of that cue (Pearce and Hall, 1980), and likely modulates the rate at which learning from prediction errors takes place. Electrophysiological studies in animals (Roesch et al., 2010) and an fMRI study in humans (Li et al., 2011) have revealed similar computations taking place within the amygdala. Although much work is required to elucidate the precise role of the amygdala in reward learning and how it is made possible, it is evident that these learning-related computations have important implications for reward processing “upstream” in the prefrontal cortex (Hampton et al., 2007).

THE CONTRIBUTIONS OF THE LATERAL HABENULA TO REWARD PROCESSING

Although there is strong evidence for dopamine's role in positive surprise, there is much less support for its role in disappointment, which can be considered another important brain signal for reward-related processing. Thus, midbrain dopaminergic neurons code for positive prediction errors, but show relatively weak response to negative prediction errors (Schultz et al., 1997), suggesting that the latter is maintained elsewhere. From primate studies, we now know that habenular neurons show a transient dip in firing rate in response to cues predictive of rewards (Matsumoto and Hikosaka, 2007). Further, the lateral habenula has been shown to drive dopaminergic activity in the midbrain (Ji and Shepard, 2007) via GABAergic neurons in the rostromedial mesopontine tegmental nucleus (Jhou et al., 2009). Critically, the lateral habenula responds to the absence of a reward (Matsumoto and Hikosaka, 2007), or the presence of a punishment (Matsumoto and Hikosaka, 2007), suggesting an opponent role for the habenula vis-à-vis midbrain dopaminergic function.

THE ROLE OF THE MEDIAL PREFRONTAL CORTEX—EXPECTATION AND VIOLATION OF EXPECTATIONS

The medial prefrontal cortex (mPFC) frequently plays a prominent role in models for various cognitive processes, and reward learning models are no exception. The anterior cingulate cortex (ACC) in particular appears to encode anticipated, experienced, and fictive reward conditions (Hayden et al., 2009; Matsumoto et al., 2003), much like the dopaminergic neurons that project to it (Williams and Goldman-Rakic, 1993). However, although dopaminergic signaling follows a narrow dynamic range—positive prediction errors are represented as increases in firing rate, but negative prediction errors are encoded as a slight decrease in firing (Schultz et al., 1997)—the ACC may employ distinct neuronal populations for encoding positive and negative prediction errors whereby each type of prediction error is encoded as an increase in firing rate (Matsumoto et al., 2007). The ACC has also been suggested to set the learning rate in reinforcement learning-type models by mediating the degree to which stimulus-response outcomes will influence future behavior (Rushworth and Behrens, 2008). Human fMRI data suggest that the ACC may be involved in determining when to predict outcome based on experience over an extended history, and when to make predictions from recent events (i.e., the ACC assesses volatility in the environment) (Behrens et al., 2007). The ACC has also enjoyed prominence for its putative role in error detection and conflict monitoring (Kerns et al., 2004), both of which would influence reward learning in a broader fashion.

In general, the mPFC has proven difficult to deconstruct because it appears to participate in different roles depending on experimental context and methodology, but one attempt at presenting a unifying model for the mPFC's function posits that the mPFC is essentially an action-outcome predictor

(Alexander and Brown, 2011). Neurons here signal predictions for the outcome of an action, and its expected timing, through its firing rate, which is then inhibited by the outcome itself. The strongest signal here is thus observed when the expected outcome does not take place at the expected time; in other words, the ACC might be signaling negative surprise (Alexander and Brown, 2011). This model succeeds at reconciling several seemingly conflicting pieces of data on the mPFC, and places certain aspects of reward learning within the larger context of surprise and predictability.

THE ORBITOFRONTAL CORTEX AND VALUE ESTIMATION

There is near-consensus that the orbitofrontal cortex (OFC) is involved in the representation of decision-value. Data in support of such a role for the OFC in decision-making comes from rat, monkey, and human studies, all of which indicate OFC activation that correlates with behavioral measures of goal values (Wallis, 2007). One school of thought holds that the OFC explicitly signals goal-value (Montague and Berns, 2002), which it computes through its interconnections with the basolateral amygdala and the striatum (Rushworth et al., 2007).

To further appreciate the role of the OFC in reward processing, we need first differentiate between two types of decision-making systems—the rigid model-free system that maintains cached values representing a summary of its decision-value, and the flexible model-based system that computes these decision-values as and when needed from a model of the environment built from experience (Daw et al., 2005). Although dopaminergic activity together with dorsal striatal dopaminergic projections are thought to facilitate model-free learning (Daw et al., 2005), some evidence indicates that the OFC is critical for model-based representation (Schoenbaum et al., 2011). In this view, the OFC is not signaling value per se, but states relevant to reward that may be used to derive value (Schoenbaum et al., 2011). Reminiscent of the previous section on the ACC, the OFC in this framework is involved in processing not just reward, but all events that pertain to the reward, and it does so in a predictive manner (Schoenbaum et al., 2011).

Based on the preceding discussion, the reward system can be seen as a complex piece of computational machinery, with several vulnerable regions wherein the system could become dysregulated. Drug addiction is one such example of how disruptions in reward mechanisms can lead to disastrous consequences.

ADDICTION AND THE REWARD SYSTEM

One reason the mesolimbic dopamine system has attracted so much attention in addiction research is that all drugs of abuse—psychostimulants, opiates, alcohol, nicotine, and cannabinoids—appear to act on this system (Pierce and Kumaresan, 2006). For example, several commonly used drugs of abuse have been shown to enhance synaptic strength at excitatory synapses on midbrain dopaminergic neurons

(Saal et al., 2003). Behavioral investigations in animal models following pharmacological manipulations have revealed that the reinforcing effects of drugs of abuse are mediated at least in part by increased dopamine transmission in the nucleus accumbens (Pierce and Kumaresan, 2006). Although it remains to be determined whether these effects are sufficient to cause drug addiction, altered dopaminergic function may be critical at certain stages of the addiction process.

THE INITIATION . . .

Just as with natural rewards, acute administration of drugs of abuse have been shown to activate critical neural elements of the reward circuit (Breiter et al., 1997), and produce subjective feelings of pleasure and well-being. Novelty-seeking, a trait that is one of the best available predictors of drug use, has been shown to be inversely associated with D2-like receptor availability in the midbrain (Zald et al., 2008). Also, PET Imaging studies have revealed a link between D2-like receptor availability and the intensity of the subjective high from and the “liking” (Volkow et al., 2002) of methylphenidate administration. Specifically, lower D2 receptor levels lead to higher drug liking scores, and thus likely facilitate repeated use of the drug.

. . . AND TRANSITION TO COMPULSIVE USE

Along with the putative link between dopamine function and reward liking, there is evidence to suggest a role for extracellular dopamine levels following drug administration and drug wanting (Berridge, 2007). One model of addiction suggests that drug-induced increase in dopamine transmission results in a prediction error signal that cannot be compensated, which in turn leads to an ever-increasing value estimate for the drug with repeated drug administration (Redish, 2004). Everitt and Robbins have suggested that the transition from voluntary drug use to compulsive use is mediated by a shift in control from the prefrontal cortex to the striatum over drug-seeking behavior, with concomitant shifts from ventral to more dorsal striatal control circuits (Everitt and Robbins, 2005).

Concurrent with neural changes in the basal ganglia, impaired prefrontal function may underlie the transition to compulsive drug use. For example, the impaired response inhibition and salience attribution model posits that addiction is a syndrome characterized by attributing increased salience to drugs and drug-related cues, at the expense of other reinforcers, and decreased impulse control (Goldstein and Volkow, 2011). In this model, impaired prefrontal cortex functioning plays a crucial role in some of the cognitive and emotional deficits observed in the disease. Some researchers have focused on the OFC in particular, emphasizing drug (cocaine specifically) induced changes here that result in increased non-flexible or “model-free” drug-seeking behaviors (Lucantonio et al., 2012).

INDIVIDUAL DIFFERENCES IN THE REWARD SYSTEM AND THE RISK FOR ADDICTION

While all drugs of abuse influence the mesolimbic dopaminergic system, and have reinforcing effects, only about 20%

of individuals who experiment with drugs go on to become addicted to them (Odgers et al., 2008). In recent years, addiction models have evolved to accommodate individual differences in susceptibility to drug addiction. For animal models, this has translated into a shift from focusing on passive drug effects, or simply the willingness to self-administer drugs, to satisfying “addiction-life criteria” (Deroche-Gamonet et al., 2004). Through such modified paradigms, it is now appreciated that increased vulnerability to drug addiction may arise, for example, from decreased D2-like receptor function in the striatum (Dalley et al., 2007) or midbrain (Buckholtz et al., 2010) dopaminergic neurons resulting in deficits in impulse control. Relatedly, increased risk for drug addiction could arise from individual differences in the attribution of incentive salience to drug-related cues (Flagel et al., 2010). A recent study suggests that impaired glutamate receptor-mediated plasticity in the prefrontal cortex may also confer risk to future drug addiction (Kasanez et al., 2012). As mentioned previously, there are differences in the sensitivity to the reinforcing effects of drugs of abuse (Volkow et al., 2002). Because these studies were performed on non-dependent individuals, it is possible that genetically determined receptor levels predispose some individuals to be more sensitive to initial acute drug effects, supporting a gene x environment risk for addiction. These neural differences could play into susceptibility at the initiation phase of drug addiction, but not necessarily toward the transition to compulsive use.

NEGATIVE REINFORCEMENT AND DRUG ADDICTION

In addition to the neural mechanisms underlying positive reinforcement and how they might relate to drug addiction, drug-seeking behavior is also a function of negative reinforcement (Wise, 1988) as best conceptualized by anti-reward system mechanisms (Koob and Le Moal, 2008). Taking an aspirin for headaches or leaving home early for work to avoid traffic are daily examples of negative reinforcement. Negative reinforcement is at work when an individual is in or anticipates a negatively valued state and acts to terminate this state. The degree to which negative reinforcement controls behavior is determined by the change of frequency of different types of behavior as a function of the negative state. Reinforcers act via brain-related processes in several different ways: (1) activating neural substrates of approach or escape responses, (2) producing rewarding or aversive internal states, and (3) modulating information that has been stored in memory. As reviewed by Baker and colleagues (Baker et al., 2004), addicted individuals are thought to take drugs to escape or avoid aversive states such as withdrawal or stress. Baker has argued that the addicted individual learns to detect the interoceptive cues of the negative feelings that occur whenever drug levels begin to fall in the body, and acts to avoid the negative affect caused by these falling levels. Both interruptions of drug use or the presence of stressors generate a strong negative affective state, which enters consciousness and fosters renewed drug use. Therefore, negative affect is proposed to have the greatest motivational

impact on drug use among addicted users, is closely linked to withdrawal symptoms, and fosters learning by means of negative reinforcement. Baker further argues that signs of incipient withdrawal-induced negative affect are detected interoceptively, which subsequently serve as discriminative stimuli for instrumental behaviors. In addition, external stimuli that become associated with such discriminative interoceptive stimuli may function as conditioned stimuli. Therefore, both aversive internal states and conditioned (external) stimuli are important antecedents to non-adaptive behaviors (e.g. compulsive drug use).

EXAMPLES OF NEGATIVE REINFORCEMENT IN DRUG ADDICTION

Several studies provide compelling behavioral evidence for negative reinforcement mechanisms in addictive disorders, for example, in methamphetamine use (Simons et al., 2008) and alcohol consumption (Johnson et al., 2008). Direct evidence for different susceptibility to negative reinforcement has been mixed. Some have reported that increased anxiety sensitivity, a measure of the increased anticipation of aversive events, is a significant predictor of substance abuse (Wagner, 2001). There have been some experimental attempts to examine the effect of drug use on reinforcement and learning behavior. For example, chronic smokers made choices on a learning task that were not guided by error signals derived from counterfactuals (i.e., possible but not actual outcomes) despite ongoing and robust neural activation to these fictive errors (Chiu et al., 2008). Others have found that negative affect in smokers increases selective attention to drug cues and urge to smoke (Bradley et al., 2007). Finally, individuals with ventromedial frontal damage show selectively disrupted ability to learn from negative feedback (Wheeler and Fellows, 2008). However, much needs to be done to specifically link negative reinforcement processes to specific brain regions in drug-addicted individuals.

MODELS OF NEGATIVE REINFORCEMENT AND ADDICTION

Several negative reinforcement models have been proposed for drug addiction. As reviewed by Eissenberg (2004), withdrawal-based negative reinforcement models emphasize that avoidance or suppression of drug withdrawal by drug self-administration increases the likelihood of future drug self-administration. In comparison, classical conditioning models propose that stimuli that predict drug administration are important for the regulation of the internal milieu. Therefore, negative reinforcement may be particularly important for the avoidance of potential withdrawal rather than escape from existing withdrawal. One may even go as far as stating that the degree of drug dependence is related to the strength of the conditioned response (i.e., a stronger conditioned response is evidence for a greater dependence). Similar to Baker (Baker et al., 2004), Eissenberg emphasizes that in addition to exteroceptive cues, interoceptive stimuli (e.g., drug onset cues) may be particularly important in dependence development because these interoceptive cues predict the drug effect

perhaps more reliably than any external drug-associated cues. Self-medication models of drug dependence highlight the role that a drug of abuse might play in helping the user to escape or avoid emotional distress or negative affect that predates the initial drug use episode (Eissenberg, 2004). Importantly, negative affect is thought to not be a consequence of repeated drug use but instead is hypothesized to predate the initial drug use episode. Finally, opponent-process models of drug dependence propose that internal reward processes are set awry by drug use and that drug-induced increases in reward threshold yield compulsive drug self-administration (Solomon, 1980). These models have in common that a proposed interoceptive state is driven out of balance (or stability) and leads to non-adaptive restorative behaviors that are driven by the intent to reduce a negatively valenced state.

DRUG ADDICTION—A DYNAMIC ILLNESS

A central characteristic of addictive behaviors is their chronically relapsing nature (Miller, 1996). Relapse is a complex process and includes multiple dimensions such as the process prior to reuse of the drug, the event of using the drug, the level to which the use returns, and the consequences associated with use. Several models that stress cognitive behavioral, person-situation interactional, cognitive appraisal, and outcome expectation factors have been put forth to explain the process of relapse (Connors et al., 1996). These models differ in the extent to which the focus is on the person (decreased self-efficacy), the situation (exposure to high-risk environments), and/or their interaction (insufficient mobilization of coping skills) (Connors et al., 1996). On the other hand, psychobiological models of relapse have been based on opponent process and acquired motivation theories, craving or loss of control, urges or craving, withdrawal, and kindling processes (Reske and Paulus, 2008). These models focus on the fact that brain reward systems become sensitized to drugs and drug-associated stimuli (Robinson and Berridge, 2000) resulting in increased drug-wanting, which increase the susceptibility to relapse. Some investigators have suggested that relapse is best understood as having multiple and interactive determinants that vary in their temporal proximity from and their relative influence on relapse. Therefore, an adequate assessment and prediction model must be sufficiently comprehensive to include theoretically relevant variables from each of the multiple domains and different levels of potential predictors (Connors et al., 1996). Others have pointed out that relapse is not a binary but a continuous outcome across multiple dimensions (Miller, 1996), which include the threshold, duration, prior sobriety level, number of substances involved, and consequences. Moreover, relapse encompasses a multidimensional response pattern with (1) the occurrence of negative life events; (2) cognitive appraisal variables including self-efficacy, expectancies, and motivation for change; (3) subject coping resources; (4) craving (Bechara and Van der Linden, 2005) experiences; and (5) affective/mood status (Miller, 1996).

Some investigators have suggested that aberrant learning processes within subcortical circuitry underlie aspects of

observations that: (1) drug-seeking behavior becomes compulsive and habitual and (2) propensity for relapse to drug-seeking can be manifest even after long periods of sobriety (Everitt et al., 2001). Others have suggested that substance use disorders are consequences of imbalances between overactive “impulsive” amygdala systems, which signal pain or pleasure of immediate prospect, and weakened “reflective” prefrontal cortex system for signaling pain or pleasure of future prospect (Bechara, 2005). In particular, drugs and/or conditioned stimuli associated with the availability of drugs are thought to overwhelm the goal-driven cognitive resources important for exercising the willpower to resist drugs. Finally, some have argued that substance dependence is characterized by an overvaluing of drug reinforcers associated with an undervaluing of alternative reinforcers in combination with deficits in inhibitory control (Goldstein and Volkow, 2011). Based on animal experiments, Koob and LeMoal have conceptualized substance dependence or addiction as a cycle of increasing dysregulation of brain reward systems, which leads to compulsive drug use and a loss of control over drug taking. Both, sensitization and counter-adaptation processes contribute to this hedonic homeostatic dysregulation. The neurobiological mechanisms involved include the mesolimbic dopamine system, opioid peptidergic systems, and brain and hormonal stress systems (Koob and Le Moal, 2008). Based on these views, it is clear that brain processes that are candidates for monitoring clinical states involve learning, drug and conditioned cue-related processing, homeostatic regulation, inhibition, and decision making.

NEGATIVE REINFORCEMENT AND THE DYNAMIC STATE OF ADDICTION

Koob and colleagues (for a recent review, see Koob and Le Moal, 2008) have pointed out that negative reinforcement may be one of the key processes that leads to the transition from impulsive to compulsive drug use, which results in an addiction cycle that is comprised of three stages: (1) preoccupation and anticipation (of drug taking), (2) binge and/or intoxication (of the drug), and (3) withdrawal or negative affect (as a consequence of lack of drug). They propose a cycle of increasing dysregulation of brain reward/anti-reward mechanisms and suggest that whereas the positive reinforcement system is driven mainly by dopaminergic mechanisms, negative reinforcement systems may rely on the stress response, which is closely linked to the cortisol and corticotropin releasing hormone system. Finally, an allostatic state (i.e., an unstable set point) emerges because of the loss of function in the reward systems and recruitment of the brain stress or anti-reward systems. The opponent process model and its adaptation to drug addiction is not unlike the proposal by Baker and colleagues (Baker et al., 2004) of two types of urge networks: a positive-affect network, which is activated associatively and nonassociatively by appetitive stimuli; and a negative-affect network, which is activated associatively and nonassociatively by non-appetitive stimuli or consequences (e.g., punishment, signals of punishment, frustrating lack of reward), and by withdrawal and signals of withdrawal. Sinha and colleagues have reported that stress is closely linked to craving, drug-taking behavior, and relapse

(Sinha et al., 2011). These authors have conceptualized stress as internal and external events or stimuli that exert demands or load on the organism and demand mounting of adaptive resources in response to stressors. Brain regions such as the amygdala, hippocampus, insula, and orbitofrontal, medial prefrontal, and cingulate cortices are involved in the perception and appraisal of emotional and stressful stimuli (Sinha et al., 2011). The interplay among reward and anti-reward, appetitive, and aversive systems, with many of the characteristics of the interoceptive system, supports the idea that drug addiction is a dynamically dysregulated homeostatic disease.

WHAT CAN NEUROIMAGING TELL US ABOUT RISK, PREVENTION, AND TREATMENT OF ADDICTION?

In the following we describe some recent and ongoing efforts to apply what we have learned about addiction to improving treatment outcome and in preventing future substance dependence in current users.

A NEURAL MEASURE OF ADDICTION SEVERITY

Not all addicts are created equal; overall about 40–60% of addicted individuals undergoing treatment relapse within a year following discharge from treatment (McLellan, 2002); in the case of nicotine addiction, the recidivism rate can reach 95% (Cigarette smoking among adults—United States, 2000). One of the best predictors of response to treatment for cigarette smokers is the Fagerström Test for Nicotine Dependence (FTND). Functional magnetic resonance imaging is well-positioned to provide a neural predictor of treatment outcome because it provides a quick, non-invasive measure of anatomical integrity and neural function at a system level in humans. For example, functional connectivity strength (as measured through temporal correlations in the blood oxygen level-dependent (BOLD) fMRI signal between brain regions in the absence of task performance) of a dorsal ACC-ventral striatum circuit correlates with FTND scores in smokers and is not modified in the presence of a nicotine patch, used routinely (but generally unsuccessfully) in smoking cessation programs (Fig. 55.2A; Hong et al., 2009). Critically, this feature is related to a single nucleotide polymorphism in the cholinergic gene encoding the $\alpha 5$ subunit—CHRNA5 (Hong et al., 2010), and underscores the need to better understand the role of regions that express $\alpha 5$ -rich nicotinic receptors (e.g., the habenula) in nicotine addiction (De Biasi and Dani, 2011). In general, the identification of such neural correlates of severity of addiction may allow investigation of the neurobiological changes that are required for recovery from addiction, and to tailor treatment interventions accordingly.

TREATMENT-CENTERED APPROACHES

Recovery from addiction is typically assessed through duration of complete abstinence from drug use (e.g. clean urine tests), and many forms of addiction-treatment are labeled

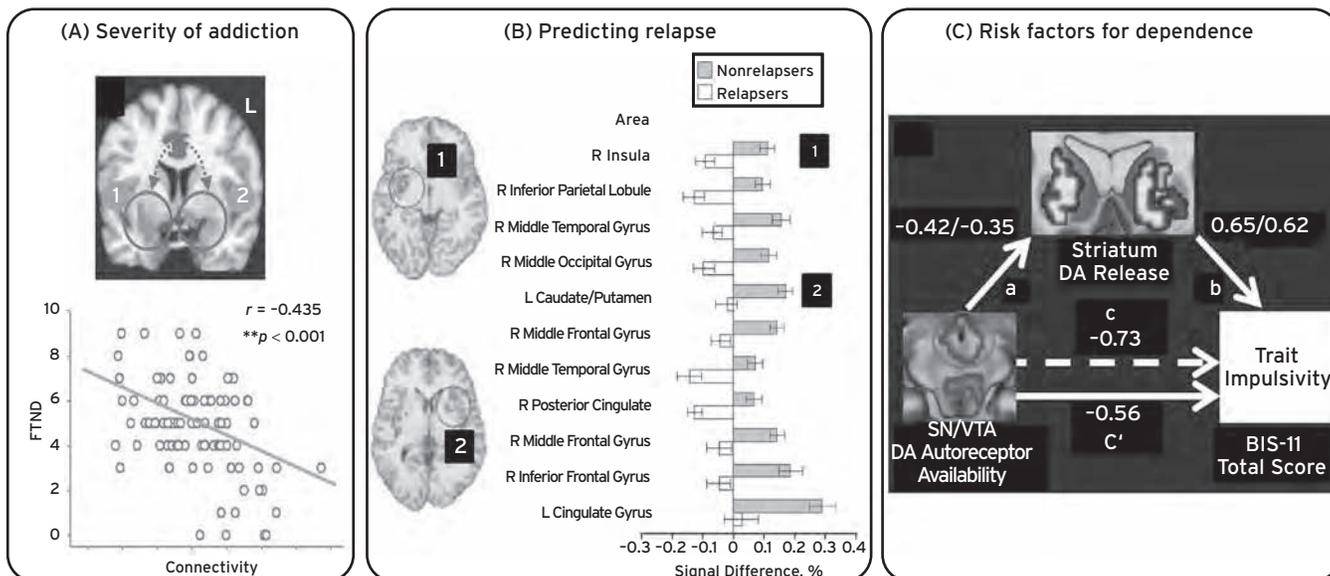

Figure 55.2 Examples of how neuroimaging may aid addiction research. (A) Uncovering the neural mechanisms determining the severity of addiction—resting state functional connectivity in dorsal ACC-striatal circuits (upper panel) is inversely correlated with severity of nicotine addiction as assayed through the Fagerstrom Test for Nicotine Dependence or FTND. (B) Identifying neural biomarkers for predicting relapse in substance-dependent individuals—fMRI activation patterns in regions including the insula (1) and striatum (2) during a binary forced choice task predicts relapse in methamphetamine-dependent individuals. (C) Identifying neural risk factors for future substance dependence—midbrain D2 receptor availability, measured through PET, is linked to trait impulsivity, likely via increased stimulated dopamine release in the striatum. (A from Hong et al., 2010. B from Paulus et al., 2005. C from Buckholtz et al., 2010.)

as unsuccessful based on relapse rates within 6–12 months following discharge (McLellan, 2002). But some have questioned this approach and suggested moving toward a model similar to other chronic diseases, such as diabetes, that report similar relapse rates following treatment cessation. In this framework, the success of an intervention would rest on the frequency and severity of addiction-related symptoms and the patient’s ability to resume a functional life under an extended treatment plan and not complete abstinence (McLellan, 2002). To extend the chronic disease analogy, recovery from addiction might then better be assayed through intermittent or continuous monitoring of biomarkers—by measuring the addiction equivalent of blood sugar levels. Currently, no reliable neural markers of recovery from addiction exist, but non-invasive neuroimaging methods and behavioral tests could be designed to serve this purpose. As a step in this direction, fMRI activation in the insula, posterior cingulate, and temporal cortex during a simple two-choice prediction task has been shown to predict relapse in methamphetamine-dependent individuals (Fig. 55.2B; Paulus et al., 2005). More recently, an fMRI based cue-reactivity signal has been proposed as a potential signature of relapse vulnerability (Janes et al., 2010).

Similarly, some treatments for addiction might be deemed unsuccessful if only a subset of patients benefit from them; this outcome too needs further consideration, as multiple treatment approaches matched to individual endophenotypes (i.e., personalized medicine) may lead to overall better outcomes. If so, the need appears to be better assessment tools of individual differences that merit differential treatment intervention, and to carry out prescription accordingly. The FTND, for example, predicts which patients stand to benefit from faster delivery

nicotine replacement medications (Stapleton and Sutherland, 2011), and pretreatment rate of nicotine metabolism, as measured by a nicotine metabolite ratio, can predict the efficacy of nicotine replacement therapy (Lerman et al., 2006). Again, a more detailed understanding of the neural underpinnings to these pretreatment differences—through neuroimaging, genetics, and behavioral metrics—may allow for customized and possibly more efficacious treatment plans. For example, fMRI activation in the insula, posterior cingulate, and temporal cortex during a simple two-choice prediction task has been shown to predict relapse in methamphetamine-dependent individuals. For example, reaction time performance in a simple social stressor task can predict how nicotine or varenicline (Chantix) modulates amygdalar reactivity, and both brain and behavioral responses identify different subgroups of smokers and differentiate them from non-smokers (Sutherland et al., 2013). A similar approach might benefit our understanding of another promising addiction-treatment—the GABA receptor agonist, Baclofen (Franklin et al., 2009).

Aside from providing tools for monitoring efficacy of treatment, fMRI could potentially offer a line of treatment itself. Real-time fMRI, which involves providing patients with immediate feedback of their BOLD activity, has shown potential in the treatment of pain. This technique could potentially be harnessed for alleviating symptoms (e.g., craving), or to ameliorate addiction-related cognitive deficits (e.g., impulse control), and could be used in conjunction with behavioral therapy to enhance treatment efficacy. However the available data using real time feedback is still extremely preliminary. Nevertheless, efforts to apply real-time fMRI to treatment of addiction have commenced (Childress et al., 2010), and this technique remains a promising new tool in the field.

IDENTIFYING RISK FOR FUTURE SUBSTANCE DEPENDENCE

As alluded to previously, the risk for substance dependence is not equal in all individuals—about one in five individuals who experiment with drugs go on to become dependent (Odgers et al., 2008). Major inroads would be made to understand addiction through better understanding of the variability in the transition from drug use to dependence. For one, it may help in the development of individualized, customized treatment of addiction. Second, a better understanding of addiction vulnerability may assist in guiding early treatment interventions. Third, identifying individuals who are at increased risk for future substance abuse would be a first step towards improved preventative measures. Finally, how certain life experiences could serve as protective factors against future substance dependence in the face of increased susceptibility could be approached.

At present, the most promising avenue for research on vulnerability to addiction is trait impulsivity, which is generally considered a core component of substance use disorders. In rats, deficits in impulse control have been shown to predict the transition from repeated use to stimulant dependence (Belin et al., 2008). Human and animal studies have pointed to a link between impulse control and D2-like receptor function in the ventral striatum and midbrain (Belin et al., 2008; Buckholtz et al., 2010; Fig. 55.2C), and low D2/D3 receptor function may drive a predisposition to stimulant dependence (Belin et al., 2008). More recently, a study employed diffusion tensor imaging in siblings of substance-dependent individuals, who presumably carry some genetic risk for addiction, found differences in white matter tract integrity in frontal areas that correlated with behavioral impulsivity measures (Ersche et al., 2012). Genetic and neuroimaging approaches to understanding other addiction-related traits such as novelty seeking (Zald et al., 2008) are progressing, and suggest a promising new direction for addiction research.

RESHAPING ADDICTION RESEARCH

Much has been uncovered regarding the neural mechanisms underlying the learning and representation of reward in the brain, but the precise roles of various components of the reward circuit remain poorly understood. Addiction research, in particular, may benefit from shifting the spotlight from dopamine-centered processing to less traditional members of the circuitry underlying positive and negative reinforcement, such as the insula, habenula, and orbitofrontal cortex. Also, a more comprehensive understanding of the interactions between these nodes is needed, especially in the context of addiction. Neuroimaging offers a valuable tool in this regard by allowing functional connectivity between multiple regions simultaneously, even in the absence of cognitive tasks. This functionality may prove especially useful for uncovering the complex interactions between reward and anti-reward systems. Finally, a recurring recent theme in addiction research is the appreciation of individual differences, especially in terms of vulnerability to addiction, reactivity to acute drug administration, and response to treatments. A continued appreciation of these individual differences may go a long way toward achieving breakthroughs in the field.

DISCLOSURES

Drs. Stein and Pariyadath have no conflicts of interest to disclose. They are funded entirely by the NIDA-IRP.

Dr. Paulus has no conflicts of interest to disclose. Grant Support: This work was supported by grants from the Veterans Administration and the National Institute on Drug Abuse (R01-DA016663, P20-DA027834, R01-DA027797, and R01-DA018307 to Martin Paulus).

56 | MAGNETIC RESONANCE SPECTROSCOPY STUDIES IN SUBSTANCE ABUSERS

LINDA CHANG, CHRISTINE C. CLOAK, AND JOHN L. HOLT

Magnetic resonance spectroscopy (MRS) is a quantitative technique that has been used in chemistry laboratories to identify chemical structures since the 1950s. More recently, MRS has become a useful imaging modality that can be applied both *in vivo* noninvasively and *ex vivo* in tissue extracts. Therefore, MRS is particularly useful as a clinical translational tool for evaluations and longitudinal monitoring of brain abnormalities associated with various brain disorders, including addiction to drugs. When performed *in vivo*, MRS can be performed in a select voxel (or volume of interest), which is typically referred to as localized or single voxel MRS, or across a grid of voxels in a slice to form an image of the metabolite of interest as in MRS imaging (MRSI) (Fig. 56.1). More advanced techniques also allow multiple slices of metabolite maps to be obtained with MRSI, so that a larger portion of the brain can be assessed.

Although the overwhelming majority of MRS studies in brain disorders focus on the proton (^1H) resonances associated with various brain metabolites and chemicals, resonances from other atomic nuclei also can be measured with MRS. Molecules with other nuclei include many that are relevant to neurobiology and neuropharmacology (e.g., lithium [^7Li], carbon [^{13}C], fluorine [^{19}F], sodium [^{23}Na], and phosphorus [^{31}P]). Owing to the requirement of specialized MRS equipment (e.g., specific coils), costs, and limited expertise, however, only few studies have employed the other nuclei, specifically ^{31}P MRS or ^{13}C MRS, to study brain abnormalities associated with drug abuse. We will discuss these MRS studies and how they can provide additional insights into the neuropathophysiology associated with major categories of drugs abused. At the end of the chapter, we will also compare and contrast how the brain may be affected by these different types of drugs, and some technical issues to be considered in the use of MRS to assess brain changes and to monitor treatment effects.

BRAIN METABOLITES MEASURED WITH MAGNETIC RESONANCE SPECTROSCOPY

Proton MRS can measure several major brain metabolites (see Fig. 56.1). The concentrations of these metabolites represent neuronal or glial cellular density or health, and hence are useful for assessing possible brain alterations associated with drug exposure or abuse. The metabolites observable with MRS are different from those measured in most other neurochemical

assays. Specifically, ^1H -MRS detects proton resonances from metabolites that are found in large (millimolar) quantities, whereas most of the neurochemicals measured in basic science research laboratories are in much smaller quantities (e.g., less than micromolar concentrations). Typical brain metabolites observed include *N*-acetylaspartate (NAA) at 2.02 ppm, glutamate (Glu) at 2.1–2.5 ppm with overlapping resonances from glutamine (Gln) and gamma amino butyric acid (GABA), total creatine (tCR) at 3.03 and 3.94 ppm, choline-containing compounds (Cho) at 3.2 ppm, myoinositol (MI) at 3.56 ppm, and less often lactate (Lac) at 1.35 ppm.

NAA is a putative neuronal marker, because it is found primarily in mature neurons and is reduced in conditions of neuronal damage or loss (Birken and Oldendorf, 1989). NAA is localized primarily in the neuronal cytosol and is the second most abundant amino acid in the brain. Although NAA is not known to have specific neurophysiological properties, it serves as an acetyl donor, an initiator of protein synthesis or a carbon transfer source across the mitochondrial membrane (Tsai and Coyle, 1995). Therefore, lower NAA has been reported in brain disorders that are associated with neuronal injury or mitochondrial dysfunction. Lower than normal brain NAA levels were reported in hypoxia, cerebral infarction, head trauma, dementias, chronic HIV infection, neurodegenerative disorders, and some individuals with substance abuse (Schuff et al., 2006) as described in the following.

Glu is an amino acid involved in the tricarboxylic acid cycle and is the major excitatory neurotransmitter in the CNS. Since the majority of the neurons in the brain are glutamatergic, Glu levels typically correlate well with NAA levels on MRS. Excess amounts of Glu in the extracellular spaces have been associated with neurotoxicity and cell death (McDonald and Johnston, 1990; Plaitakis and Shashidharan, 2000). However, Glu levels measured on MRS typically represent the neuronal cytosolic Glu pool, which is much larger than the extracellular pool. The proton resonances from Glu overlaps with those of glutamine and GABA, forming an overlapping range of resonances often reported as Glx; therefore, specialized MRS techniques are often required to measure Glu. These techniques include two-dimensional MRS or echo time (TE)-averaged point resolved spectroscopy (PRESS). The proton resonances from Glu are readily observed with shorter echo times (<50 ms) on MRS, which is more easily performed with localized MRS, rather than MRSI.

GABA, which is derived from Glu, is the predominant inhibitory neurotransmitter in the CNS and is often altered

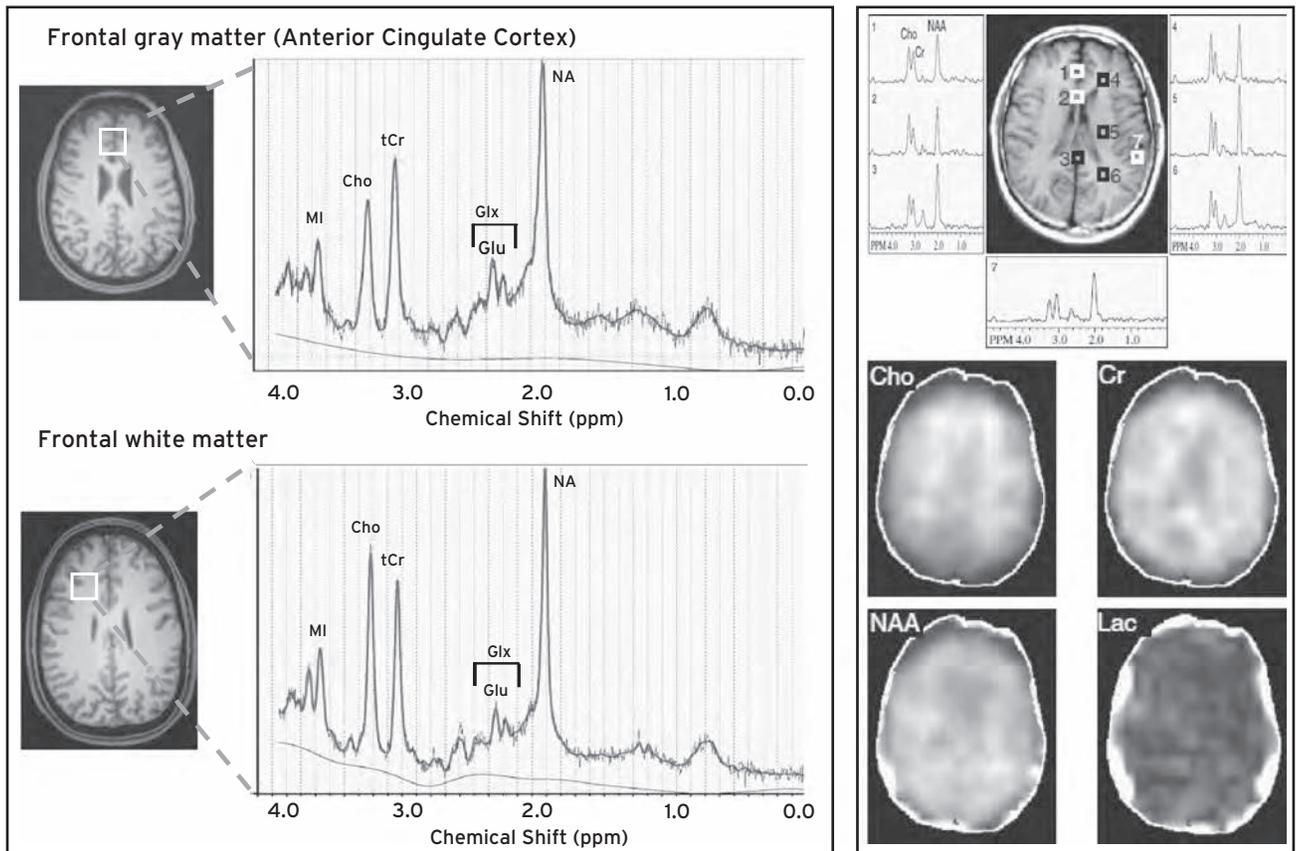

Figure 56.1 Left: Localized MR spectroscopy from a 40-year-old healthy man, showing voxel locations in the frontal gray matter (top) and frontal white matter (bottom) and the corresponding MR spectra with the major brain metabolite levels from these brain regions. Note higher N-acetyl compounds (NA) levels in the frontal gray matter, but higher choline (Cho) levels in the frontal white matter. Right: 2D MRSI data showing regional variability of metabolite concentrations in the different spectra (top) and spectroscopic images of choline-containing compounds (Cho); creatine (Cr); NA, which includes N-acetylaspartate (NAA); and lactate (Lac) across the brain slice (bottom). (Right panel is modified from Barker P.B., Lin D.D. (2006). *In vivo* proton MR spectroscopy of the human brain. *Prog Nucl Mag Res Sp* 49:99–128; permission to use obtained from Dr. Peter Barker and from Elsevier.)

in psychiatric or neurological disorders (Chang et al., 2003). Specialized editing techniques (e.g., J-resolved spectroscopy or MEGA-PRESS) are also needed to subtract out the much larger overlapping resonances from the total creatine resonances (at 3.0 ppm) or from Glx (~1.9 ppm) in order to detect the very small GABA resonances. Therefore, very few studies have been performed to evaluate GABA levels in substance-dependent individuals.

The Cho peak on MRS comprises the water-soluble choline-containing compounds, mainly free choline, phosphocholine, and glycerophosphocholine. These compounds are found in the pathways of synthesis and breakdown of choline-containing phospholipids; therefore, Cho is often increased in conditions associated with increased cell membrane turnover and breakdown, such as neoplasms, demyelinating conditions (e.g., multiple sclerosis), cerebral infarction, and even in neuroinflammatory or neuroinfectious conditions (e.g., infections with HIV or JCV). Cho is also found to be three times higher in glia than in neurons (Brand et al., 1993). Therefore, in conditions that glial activation are prominent, such as in psychostimulant users, Cho may be elevated as well.

MI is an organic osmolyte and a putative glial marker (Ross et al., 1992). *In vitro* studies showed that MI is present in high levels in glia, particularly astrocytes, but lower levels are

found in neuronal cells (Brand et al., 1993). Therefore, gliosis, with reactive glial proliferation including microglia, during brain degeneration or neuroinflammation, might lead to increased MI concentrations, often along with increased Cho and tCr. MI also is involved in plasma membrane metabolism and is enzymatically converted to inositol triphosphate (IP₃), an important intracellular second messenger (Worley et al., 1987). A defect or interference of this pathway also might result in a change in the MI concentration. Elevated MI levels have been noted in brain injury, infections, and degeneration (Mader et al., 2008). However, the proton resonances from MI are not visible on MRS studies performed with long echo-times (>100 ms). Therefore, short-echo time MRS studies are preferable in most instances and are more easily performed with localized MRS than with MRSI.

The proton resonance for tCR (at 3.0 ppm) includes free creatine and phosphocreatine, which likely reflects high-energy phosphate metabolism because phosphocreatine is involved in adenosine triphosphate (ATP) synthesis (Miller, 1991). tCR is often used as a reference metabolite in MRS studies because it was once thought to be relatively constant even in disease states; however, changes in tCR levels have been reported in multiple brain disorders as well as in substance abusers, as noted in the following.

Phosphocreatine (PCr) can also be measured with ³¹P MRS, which additionally can assess phosphomonoesters (PME), inorganic phosphate, phosphodiester (PDE), and three resonances associated with ATP (i.e., gamma-ATP, alpha-ATP, and beta-ATP). These phosphorous metabolites provide insights to the integrity of cellular energy stores, as well as cellular membrane composition and turnover. Several studies used ³¹P MRS to evaluate these energetic metabolites in individuals during methadone-maintenance (see discussion following). Last, ¹³C MRS can be used to study the metabolism of particular neurochemicals because the precursors of these chemicals can be enriched with ¹³C, and the levels of the metabolic products can be measured. One example is ¹³C-glutamate, which has been used to assess the neuronal health in individuals dependent on stimulants.

MAGNETIC RESONANCE SPECTROSCOPY STUDIES IN PSYCHOSTIMULANT ABUSE

Psychostimulants typically refer to several drugs that are commonly abused; these include but are not limited to cocaine, amphetamines (i.e., amphetamine, methamphetamine, and MDMA), and methylphenidate. MRS studies of stimulant users demonstrated abnormalities in brain metabolites associated with neurons, glia, and cellular metabolism. Findings often vary by the amount used, time since last use, and age of exposure to the stimulant drug.

MRS STUDIES IN COCAINE USERS

Several MRS studies of adult cocaine users have reported cerebral metabolite alterations (Table 56.1). Specifically, lower levels of the neuronal marker NAA were found in the anterior cingulate cortex (ACC) (Chang et al., 1999b) and thalamus (Li et al., 1999). Because the majority of neurons are glutamatergic, it is not surprising that Glu/tCR was also lower in the ACC of cocaine users, especially in those with a longer duration of cocaine use (Yang et al., 2009). In the same frontal region (ACC), cocaine users showed higher glial response with elevated MI, which also correlated with the duration of cocaine use (Chang et al., 1997). However, elevated tCR levels were found in both parietal (Chang et al., 1997; O'Neill et al., 2001b) and frontal white matter (Chang et al., 1997), as well as the ACC of cocaine users, especially in men (Chang et al., 1999b). The etiology of the elevated tCR is unclear, but similarly elevated tCR was also observed in children with prenatal cocaine exposure (Smith et al., 2001a). Although glial cells contain higher levels of tCR than neurons, the elevated tCR did not always coincide with the same brain regions that showed higher glial marker MI. Elevated tCR in the frontal lobe has been correlated with the frequency of cocaine use (Chang et al., 1997). In children with prenatal cocaine exposure, the higher frontal white matter tCR suggest aberrant cellular metabolism; however, these children had normal NAA, which indicated normal neuronal function and density (Smith et al., 2001a).

Although metabolites measured with MRS typically reflect cellular changes, one study found that acute cocaine

administration induced increases in basal ganglia Cho and NAA, showing a transient effect at lower doses, but greater and more sustained increases in these metabolites at higher doses (Christensen et al., 2000). The investigators of this study posited that cocaine might have induced osmotic stress, which led to increased intracellular water and hence increased transverse relaxation times (T2*) of the Cho and NAA, via cocaine's action as an indirect dopamine D1 receptor agonist. However, since cocaine causes vasoconstriction, probably via its effects on the dopamine receptors on the blood vessels, the tissue concentrations of these metabolites may be increased within the voxel accordingly.

Studies that evaluated individuals who abused both cocaine and alcohol found even greater neurotoxic effects than those who abused cocaine only. For instance, prefrontal cortex GABA concentrations were lower than normal in cocaine users, and were even lower in those who also used alcohol (Ke et al., 2004). Another study found that cocaine using alcoholics had higher frontal white matter choline, indicative of cellular damage or turnover, but non-alcoholic cocaine users showed normal Cho levels. Furthermore, lower NAA in the dorsolateral prefrontal cortex of cocaine users partially normalized with abstinence from alcohol (Meyerhoff et al., 1999), again suggesting that some of the metabolite abnormalities may reflect transient neuronal dysfunction rather than neuronal loss. Because alcohol abuse is very common among cocaine-dependent subjects, and cocaine is not known to be neurotoxic from preclinical studies, findings from these studies suggest that the metabolite abnormalities observed in prior MRS studies may primarily be caused by alcohol abuse or the synergistic effects of alcohol and cocaine (e.g., the neurotoxic effects of cocaethylene).

Few MRS studies evaluated the effects of pharmacological treatment for cocaine dependence. One small study found that the GABA levels in the prefrontal cortex of cocaine users increased after pramipexole treatment, but the GABA levels were not related to treatment success (Streeter et al., 2005). A preliminary study also found that cocaine users showed normalized glutamate levels after *N*-acetylcysteine treatment (Schmaal et al., 2012).

MRS STUDIES IN METHAMPHETAMINE-DEPENDENT INDIVIDUALS

MRS studies of methamphetamine (METH) users (Table 56.2) consistently reported metabolite alterations that suggest neuronal or cell membrane injury, but the findings vary depending on the age of the subjects, amount METH used, and duration of abstinence. Abstinent METH-dependent individuals showed lower NAA in the basal ganglia regions (Chang et al., 2005; Ernst et al., 2000), and those with the greatest cumulative METH usage had the lowest NAA in their frontal white matter (Ernst et al., 2000; Sung et al., 2007). Glial activation with elevated MI was also found in the frontal lobe regions (Chang et al., 2005; Ernst et al., 2000; Sung et al., 2007). Some of these metabolite alterations might normalize with longer duration of abstinence, since subjects with longer duration of abstinence had higher NAA (Sung et al., 2007). The one small

TABLE 56.1. MRS studies in cocaine users

REFERENCE	SUBJECTS (DURATION ABSTINENCE)	METHODS	BRAIN REGIONS	FINDINGS
Chang et al., <i>Biol. Psychiatry</i> 1997	26 cocaine (0–2 years) 26 controls	1.5 T STEAM concentrations and ratios	ACC, frontal WM	Cocaine users had higher frontal WM tCR and MI. tCR correlated positively with frequency of use; MI correlated positively with duration of use.
Chang et al., <i>Am. J. Psychiatry</i> 1999	64 cocaine (>5 months) 58 controls	1.5 T PRESS concentrations and ratios	ACC, frontal WM	Cocaine users had lower NAA and MI in the ACC, as well as higher frontal WM MI. In the frontal WM of cocaine users, only males showed elevated tCR, whereas females showed elevated MI.
Li et al., <i>Biol. Psychiatry</i> 1999	21 cocaine (active users) 13 control	1.5 T PRESS concentrations and ratios	BG, thalamus	Cocaine users had lower NAA, NAA/tCR, and Cho/tCR in thalamus.
Meyerhoff et al., <i>Addict. Biol.</i> 1999	7 cocaine (16 weeks) 15 cocaine + alcohol users 11 controls	1.5 T 2 slice MRSI integrals and ratios	29 spectra (subcortical and periventricular)	Both cocaine user groups showed lower NAA and NAA/tCR in DLPFC, and lower NAA/tCR and NAA/Cho in central WM. WM Cho/tCR was associated with longer duration of cocaine + alcohol use. Partial NAA recovery with abstinence from alcohol.
Christensen et al., <i>Biol. Psychiatry</i> 2000	30 recreational cocaine users given acute cocaine dose	1.5 T PRESS peak area	Basal ganglia	Both 0.2 and 0.4 mg/kg cocaine did not alter tCR or water peak areas. 0.2 mg/kg cocaine induced small, reversible increases in Cho and NAA. 0.4 mg/kg cocaine induced larger, sustained increases in Cho and NAA. No changes following placebo.
O'Neill et al., <i>Addict Biol.</i> 2001	8 cocaine 12 alcohol 17 cocaine + alcohol (5–39 weeks) 13 controls	1.5 T 2 slice MRSI concentrations	11 cortical regions of interest	Alcohol groups had lower gray-matter NAA than non-alcohol groups throughout the brain. Cocaine users had higher posterior parietal WM tCR than non-cocaine users.
Smith et al., <i>Pediatrics</i> 2001	14 prenatal cocaine 12 unexposed (3–16 years old)	1.5 T PRESS concentrations	Frontal WM, BG	Cocaine exposed children had higher FWM tCR and normal NAA.
Ke et al., <i>Psychiatry Res.</i> 2004	12 cocaine 23 cocaine + alcohol users (active users) 20 controls	1.5T 2D J-resolved normalized to est. tCR	Prefrontal cortex	Cocaine users had lower than normal GABA concentrations. Cocaine alcohol users had even lower GABA levels.
Streeter et al., <i>Psychopharmacology</i> 2005	28 cocaine [9 pramipexole 9 venlafaxine 10 placebo]	1.5T 2D J-resolved normalized to est. tCR	Prefrontal cortex	Compared to placebo treatment, pramipexole treated subjects showed increased GABA levels, and venlafaxine subjects showed only a trend for increased GABA levels. GABA levels were not related to treatment success (+/–urine).
Yang et al., <i>Psychiatry Res.</i> 2009	14 cocaine (active users) 14 controls	3 T TE-averaged PRESS ratios	ACC	Cocaine users showed lower than normal Glu/tCR that correlated with years of cocaine use. In both groups, Glu/tCR also correlated with NAA/tCR, which decreased with age.
Schmaal et al., <i>Neuropsychopharmacology</i> 2012	8 cocaine (<6 months; in treatment) 14 controls	3 T PRESS concentrations	Left dorsal ACC	Baseline, cocaine users had higher Glu than controls. After 1 dose (2400 mg) NAC, Glu reduced in the cocaine group but unchanged in controls. Higher baseline Glu was associated with higher Barratt Impulsiveness Scale scores; both were predictive of greater NAC-induced Glu reduction.

Notes: ACC, anterior cingulate cortex; BG, basal ganglia; GM, gray matter; NAC, N-acetylcysteine; WM, white matter

TABLE 56.2. MRS studies in methamphetamine users

REFERENCE	SUBJECTS (AVERAGE DURATION ABSTINENCE)	MRS METHODS	BRAIN REGIONS STUDIED	FINDINGS
Ernst et al., <i>Neurology</i> 2000	26 METH (>2 weeks) 24 controls	1.5 T PRESS concentrations and ratios	ACC, frontal WM, BG	METH users had lower BG and FWM NAA than controls. Frontal WM NAA correlated inversely with lifetime METH used. METH users also had lower BG tCR, and higher ACC Cho and MI.
Smith et al., <i>Neurology</i> 2001	12 prenatal METH 14 controls (3–16 years old)	1.5 T PRESS concentrations and ratios	Frontal WM, BG	METH-exposed had higher tCR than unexposed children in striatum but normal NAA and behavior.
Sekine et al., <i>Neuropsychopharmacology</i> 2002	13 METH (1.5 year) 11 controls	1.5 T PRESS ratios	Left and right BG	METH users had lower tCR/Cho than controls in both BG. tCR/Cho correlated with the duration of METH use and with positive BPRS symptoms.
Chang et al., <i>Am. J. Psychiatry</i> 2005	24 METH+HIV 44 HIV 36 METH (>1 week) 39 controls	1.5 T PRESS concentrations	ACC, frontal WM, BG	METH users had lower FWM and BG NAA, but higher ACC choline and MI. HIV(+) subjects had lower ACC NAA and tCR but higher FWM MI than HIV(-) subjects. HIV+METH showed additive deleterious effects on NAA in all three regions, on tCR in the BG, and on MI in the FWM.
Nordahl et al., <i>Arch. Gen. Psychiatry</i> 2005	8 METH (>1 year) 16 METH (<6 month) 13 controls	1.5 T PRESS ratios	ACC, PVC	METH users had low ACC NAA/tCR. ACC Cho/NAA values were high in the METH users with <6 months abstinence but not in those with >1 year abstinence. tCR did not differ between groups.
Salo et al., <i>Biol. Psychiatry</i> 2007	36 METH (>3 weeks) 16 controls	1.5 T PRESS ratios	ACC, PVC	METH users performed worse on the Stroop Interference task. ACC NAA/tCR was lower and Cho/NAA was higher in the METH users than controls. ACC NAA/tCR correlated with Stroop performance in the METH group only.
Sung et al., <i>Drug Alcohol Depend</i> 2007	9 METH (<6 months) 21 METH (>6 months) 20 controls	3 T PRESS concentrations	ACC, frontal WM	METH users had higher FWM MI than controls, and those with >100 gram lifetime dose had lower FWM NAA than those who used less. FWM NAA correlated inversely with the cumulative METH dose. ACC NAA in METH users correlated negatively with the cumulative METH dose and positively with the duration of abstinence.
Taylor et al., <i>J. Neurovirol</i> 2007	40 METH+HIV 66 HIV 48 METH 51 controls	1.5 T PRESS concentrations	ACC frontal WM, BG	HIV subjects had lower ACC and FWM NAA, and those with lower CD4 counts and higher plasma HIV viral loads had lower ACC and BG NAA. Plasma viral load correlated with FWM NAA and ACC and FWM MI in HIV+METH. Duration of METH use was associated with higher ACC Cho and higher BG MI.
Ernst and Chang, <i>J. Neuroimm. Pharmacol.</i> 2008	25 METH (<1 month) 12 METH (after 5 months) 28 controls	1.5 T PRESS concentrations and ratios	ACC, frontal WM, BG	METH users <1 month of abstinence had lower ACC Glx. Abstinence duration positively correlated with ACC and FWM Glx. After five months, changes in ACC Glx tended to increase with longer duration of abstinence. Subjects with craving symptoms had lower ACC Glx than those without craving.
Chang et al., <i>NeuroImage</i> 2009	49 Prenatal METH 49 controls (3–4 years old)	3 T PRESS concentrations	ACC, frontal WM, BG, thalamus	METH-exposed children had higher FWM tCR, NAA, and GLX, but lower thalamic MI, than unexposed. METH girls but not boys had higher FWM NA. METH children had poorer VMI scores, which correlated with thalamic MI.

(continued)

TABLE 56.2. (Continued)

REFERENCE	SUBJECTS (AVERAGE DURATION ABSTINENCE)	MRS METHODS	BRAIN REGIONS STUDIED	FINDINGS
Yoon et al., <i>Neuropsychopharmacology</i> 2010	16 METH treated with CDP-choline 15 METH with placebo	3 T PRESS concentrations	ACC	Over four-weeks of CDP-choline treatment for METH dependence, the rate of change in ACC NAA and Cho levels was greater with CDP-choline treatment than with placebo. Changes in ACC NAA but not Cho levels were positively associated with the number of negative urine results in CDP-choline-treated patients.
Sailasuta et al., <i>J. Cereb. Blood Flow Metab.</i> 2010	5 METH (>7 days) 5 controls	1.5 T ¹³ C MRS ratios	ACC	Steady-state bicarbonate concentrations showed no group difference. Glial ¹³ C-bicarbonate production rate (~glial TCA cycle) was reduced to 36% of normal in METH users.
Salo et al., <i>Drug Alcohol Depend</i> 2011	30 METH (<6 months) 17 (1–5 years) 24 controls	1.5 T PRESS ratios	ACC, PVC	Short-term abstinent METH users had higher ACC-Cho/NAA than controls, and lower ACC-NAA/tCR than both controls and long-term abstinent METH users. No differences between controls and the long-term abstinent group
Salo et al. <i>Neuropsychologia</i> 2011	51 METH (25 months) 22 controls	1.5 T PRESS ratios	ACC, PVC	Meth subjects had lower ACC NAA/tCR, inverse correlations between PVC and ACC NAA/tCR and spatial interference on the Spatial Stroop Attention task.
Cloak et al., <i>Drug Alcohol Depend</i> 2011	54 adolescent METH (days to years) 53 controls	3 T PRESS concentrations	ACC, frontal WM, BG, thalamus	METH males and female controls showed age-dependent increases in FWM tCR. Only male controls showed age-dependent increase in ACC choline, which was associated with faster performance on the Stroop Interference task. Male METH users had slowest performance on the Stroop Interference task and did not show age-appropriate levels of ACC choline.

Notes: ACC, anterior cingulate cortex; BG, basal ganglia; GM, gray matter; PVC, primary visual cortex; WM, white matter

study that used ¹³C MRS to evaluate the incorporation of ¹³C in the tricarboxylic acid cycle found lower glial ¹³C-bicarbonate production in METH users, but the sample size is too small to yield conclusive interpretations (Sailasuta et al., 2010).

Methamphetamine use is prevalent among HIV-infected individuals. MRS studies that evaluated the combined effects of METH and HIV consistently found additive effects of lower NAA levels in the frontal white matter (WM) and basal ganglia, as well as elevated myoinositol (Chang et al., 2005; Taylor et al., 2007). These findings demonstrate that METH use may exacerbate the neurotoxic effects of HIV, especially in the striatum.

A few studies evaluated METH subjects longitudinally to assess for possible treatment effects on brain metabolite abnormalities. Cell membrane turnover with elevated Cho/NAA in recently abstinent METH subjects may normalize with longer duration of abstinence (>one year) (Nordahl et al., 2005). In addition, Glx, which is the sum of Glu, Gln, and GABA, was lower in those during early abstinence but may normalize or become elevated with more than five months of abstinence (Ernst and Chang, 2008). In addition, METH users treated with cytidine-5'-diphosphate choline, but not those given

placebo, for one month showed increased NAA and choline levels, and greater increased NAA levels were associated with more negative urine results (Yoon et al., 2010). These findings suggest that alteration in the neuronal marker NAA may be reversible and that MRS may be useful for monitoring treatment effects.

These metabolite alterations might be related to behavioral consequences in METH users. For example, low basal ganglia tCR/Cho levels were associated with more psychiatric symptoms, even in abstinent METH users (Sekine et al., 2002). Lower ratios of NAA/tCR in the ACC also correlated with poorer executive function (Salo et al., 2007). In addition, abstinent METH subjects with the lowest ACC Glx had the greatest craving symptoms (Ernst and Chang, 2008). Because craving is an important symptom for relapse, Glx levels may be a useful marker for predicting relapse.

Unlike the consistent findings of possible neurotoxicity of chronic long-term METH abuse, acute dextroamphetamine administration to humans showed no metabolite changes in the ACC (McGrath et al., 2008), but increased glial metabolite ratio MI/tCR and PME/bATP in the temporal lobe (Silverstone

et al., 2002). These changes may reflect a glial response to the drug, which may be transient or reversible.

Although many chronic METH users first used METH during their teenage years, only one MRS study evaluated brain metabolite levels in adolescent METH users. In contrast to the lower NAA found in the adults, these younger subjects showed normal NAA levels, which may be because of their lower cumulative lifetime doses. However, these young METH users showed less steep age-dependent increases in their frontal lobe metabolites (frontal white matter tCR in the females and ACC choline in the males), and the young male METH users also showed poorer executive function (Cloak et al., 2011). In contrast, children with prenatal METH exposure showed elevated tCR in the basal ganglia (Smith et al., 2001b) and the frontal white matter (Chang et al., 2009), which is similar to children with prenatal cocaine exposure (Smith et al., 2001a). The girls with prenatal METH exposure additionally showed elevated frontal white matter NAA. These children also showed lower glial metabolite MI in the thalamus that correlated with poorer visual motor integration performance (Chang et al., 2009). Taken together, the neurotoxic effects of METH on the developing brain varied based on age of exposure and sex.

ECSTASY (3,4-METHYLENEDIOXY-N-METHYLAMPHETAMINE)

Findings from MRS studies of ecstasy users are somewhat conflicting (Table 56.3). Early MRS studies reported higher glial marker MI in the parietal white matter of ecstasy users that correlated with estimated lifetime usage of the drug (Chang et al., 1999a), as well as lower frontal gray matter NAA/tCR and NAA/Cho, both also correlated negatively with the estimated lifetime use (Reneman et al., 2002). Because lower ratios of NAA/tCR and NAA/Cho may reflect normal NAA and higher tCR and Cho, these findings may suggest glial activation or response in the brains of ecstasy users. Such glial response may or may not represent toxic effects to the neurons. However, another study found that lower NAA/tCR was associated with impaired memory in ecstasy users (Reneman et al., 2001), which suggested that the drug might have “neurotoxic” effects with cognitive consequences. However, more recent prospective studies, with larger sample size and similar comparison subjects who used multiple substances but not ecstasy, failed to find metabolite abnormalities on MRS in those who used ecstasy, despite alterations in other imaging measures (de Win et al., 2007, 2008a, 2008b). Even small studies that focused on metabolite levels in the hippocampus found little (Daumann et al., 2004) or no (Obergrösser et al., 2001) differences between the ecstasy users and comparison subjects. Two studies of polydrug users who used ecstasy also found no differences between the ecstasy users and comparison subjects (Cowan et al., 2007), but noted an association between lower frontal cortex NAA/tCR and more lifetime marijuana use in this population (Cowan et al., 2009). Taken together, the brain metabolite levels are relatively normal in ecstasy users, except for possible increased glial metabolites in some individuals. Given the extremely common co-abuse of other

psychostimulants and marijuana in ecstasy users, these glial responses also might have resulted from other drugs abused. Because preclinical studies of MDMA showed that the drug primarily affects the serotonergic nerve terminals, MRS does not appear to be the most sensitive imaging method for detecting the neurotoxic effects of ecstasy.

MRS STUDIES OF INHALANT (TOLUENE, ORGANIC SOLVENTS) ABUSE OR EXPOSURE

Few studies have addressed the neurotoxic effects of inhalant or solvent abuse using MRS. This is partly due to the transient usage pattern of inhalants or solvents by youths. Toluene and organic solvents are readily accessible to adolescents because they are common ingredients in household cleaning solutions, paint thinner, or glue. These inhalant or solvent abusers tend to progress to abusing other illicit drugs as adults. A few MRS studies evaluated individuals who abused inhalants, while others assessed individuals who had environmental (i.e., work place) exposure to chemicals that have abuse potential. Similar to other drugs of abuse, MRS studies showed metabolite abnormalities in inhalant users that reflect both neuronal and glial abnormalities. In addition, oxygen deprivation during the inhalation process also may exacerbate the neurotoxicity. A study of workers exposed to organic solvents on a daily basis found higher Cho/tCR in the parietal white matter, thalamus, and basal ganglia, and their duration of exposure correlated with metabolite abnormalities in the basal ganglia (Alkan et al., 2004). A case study of a woman who had abused toluene showed lower NAA/tCR in the centrum semiovale (Noda et al., 1996). This finding was validated in a larger study of individuals who abused toluene (paint-thinner), and showed lower NAA/tCR in the parietal and cerebellar white matter, as well as higher than normal MI/tCR in the same brain regions, especially in those with longer duration of abuse (Aydin et al., 2003). A similar study of toluene abusers found elevated Cho/tCR and Cho/NAA in the basal ganglia, and those with higher Cho/tCR ratios in the left basal ganglia had more psychiatric symptoms (Takebayashi et al., 2004). Therefore, findings from these few MRS studies clearly demonstrated the neurotoxic effects of toluene abuse, with evidence for glial activation and possible neuronal injury in the white matter and the striatum.

MRS STUDIES OF OPIATE USERS

Multiple MR studies of opiate-dependent individuals found brain abnormalities, including altered brain activation, structural neuroimaging abnormalities, and neuropsychological deficits. In particular, these brain abnormalities were typically found in the prefrontal brain regions of opiate-dependent individuals (Licata and Renshaw, 2010). However, only a few MRS studies evaluated opiate-dependent subjects (Table 56.4).

TABLE 56.3. MRS studies in ecstasy (MDMA) users

REFERENCE	SUBJECTS (DURATION ABSTINENCE)	MRS METHODS	BRAIN REGIONS STUDIED	FINDINGS
Chang et al., <i>J. Magn. Reson Imaging</i> 1999	22 MDMA (>2 weeks) 37 controls	1.5 T PRESS concentrations and ratios	Occipital GM, parietal WM ACC	MDMA users had higher than normal MI in parietal WM, which correlated with cumulative lifetime dose.
Reneman et al., <i>Biol. Psychiatry</i> 2001	8 MDMA (>1 week) 7 controls	1.5 T PRESS ratios	Prefrontal cortex, occipital GM, parietal WM	MDMA users had poorer word recall than controls and their prefrontal NAA/tCr correlated with delayed recall (on RAVLT).
Obergriesser et al., <i>Eur. Arch. Psychiatry Clin. Neurosci.</i> 2001	5 MDMA (variable) 5 controls	1.5 T MRSI PRESS concentrations and ratios	Slice centered around hippocampus	No group differences.
Reneman et al., <i>AJNR Am. J. Neuroradiol.</i> 2002	15 MDMA (>1 week) 12 controls	1.5 T PRESS ratios	ACC, occipital GM, parietal WM	MDMA users had lower NAA/tCr and NAA/Cho in ACC, which negatively correlated with lifetime use.
Daumann et al., <i>Neurosci. Lett.</i> 2004	13 MDMA (>1 week) 13 controls	1.5 T PRESS ratios	ACC, occipital GM, hippocampus	MDMA users showed only a trend for lower NAA/tCr in left hippocampus.
Cowan et al., <i>Psychiatry Res.</i> 2007	9 MDMA + polydrug (>3 weeks) 7 polydrug	4 T PRESS ratios	occipital GM	No group differences. MDMA user group used more other drugs.
de Win et al., <i>Neuropsychopharmacology</i> 2007	28 MDMA (before and after 8 weeks)	1.5 T PRESS concentrations and ratios	Frontal GM, occipital GM, frontoparietal WM	No group differences in brain metabolites, but lower regional blood volume in dorsolateral frontal cortex of MDMA subjects.
de Win et al., <i>Brain</i> 2008	59 novel MDMA users (19 weeks) 56 controls	1.5 T PRESS concentrations and ratios	Frontal GM, occipital GM, frontoparietal WM	No group differences in brain metabolites; lower rCBF in striatum and lower FA in several brain regions of MDMA users.
de Win et al., <i>Br. J. Psychiatry</i> 2008	33 MDMA + polydrug (8 weeks) 38 polydrug	1.5 T PRESS, ratios	Frontal GM, occipital GM, frontoparietal WM	No group difference in MRS metabolites or ADC. Ecstasy users showed abnormalities in thalamus on other studies (lower [123I]b-CIT binding, lower fractional anisotropy, and higher cerebral blood volume).

Notes: ACC: anterior cingulate cortex, GM: gray matter, WM: white matter

Patients enrolled in opioid maintenance therapy (OMT) with either methadone or buprenorphine have been studied with both ¹³P MRS and ¹H MRS. ¹³P MRS studies showed that methadone maintenance patients had elevated percentage of phosphomonoester in the white matter after seven days of treatment (Christensen et al., 1996; Kaufman et al., 1999), peaking between 15 and 28 days on treatment (Silveri et al., 2004), and normalized compared with controls following an average of 137 weeks of treatment (Kaufman et al., 1999). Reduced percentage of phosphocreatine was observed after seven days on treatment (Kaufman et al., 1999; Silveri et al., 2004), with continued decreases as a function of treatment duration up to 28 days (Silveri et al., 2004), and remained lower than controls after 137 weeks of treatment (Kaufman et al., 1999). Additionally, percentage of nucleotide triphosphates (β-NTP) and percentage of total nucleotide phosphates were lower than normal in the brains of cocaine and heroin-dependent

individuals (Christensen et al., 1996). These findings indicated that cerebral energy metabolism is significantly altered during opiate withdrawal and methadone maintenance.

Studies using ¹H MRS further showed evidence of neuronal injury, with lower frontal gray matter (GM) NAA (Haselhorst et al., 2002) and lower dorsal ACC NAA and Glx (Yucel et al., 2007). Possible cell membrane turnover was also implicated with higher Cho in frontal WM of OMT subjects (Hermann et al., 2012a). Such cell membrane turnover may result from neurotransmitter release or adaptation associated with neuroplasticity. ACC Glu concentration also correlated with the number of previous withdrawals, whereas Glx decreased with age in controls but increased with age in opiate-dependent subjects (Hermann et al., 2012a). Investigators from this study suggested that these findings may be related to a hyperglutamatergic state associated with more frequent withdrawals, which might result in kindling of withdrawal symptoms after repeated withdrawal episodes.

TABLE 56.4. Brain metabolite abnormalities associated with opiate use or dependence

REFERENCE	SUBJECTS (DURATION ABSTINENCE)	MRS METHODS	BRAIN REGIONS STUDIED	FINDINGS
Christensen et al., <i>Magn. Reson. Med.</i> 1996	9 polysubstance (2–7 days) 11 controls	1.5 T ³¹ P MRS-ISIS % metabolite	Frontooccipital GM slice, frontal WM slice	Polysubstance abusers. showed higher %PME, but lower %β-NTP and %NP in GM.
Kaufman et al., <i>Psychiatr. Res. Neuroimag.</i> 1999	15 MMT (7 at 39 weeks; 8 at 137 weeks) 16 controls	1.5 T ³¹ P MRS-ISIS % metabolite	Frontooccipital GM slice	MMT subjects showed higher %PME and %PDE, but lower %PCr. Short-term MMT had higher %PME and %PDE, but lower %PCr. Long-term MMT had lower %PCr despite continued drug use.
Haselhorst et al., <i>Neurology</i> 2002	12 opiate-dependent (10 IV methadone 2 heroin) 12 controls	1.5 T ¹ H MRS PRESS concentration	Frontal GM, frontal WM	Opiate-dependent subjects had lower NAA in GM but not in WM.
Silveri et al., <i>Psychiatr. Res. Neuroimag.</i> 2004	43 MMT (0–7, 8–14, or 15–28 days) 15 controls	1.5 T ³¹ P MRS-ISIS % metabolite	Axial slice (including frontal-occipital and BG)	MMT subjects had lower %PCr and higher %PDE. %PCr decreased and %PME increased with treatment duration.
Yucel et al. <i>Mol. Psychiatr.</i> 2007	24 opiate-dependent (24 hours) 24 controls	3 T ¹ H MRS-PRESS concentration	Dorsal ACC	Opiate-dependent patients (10 on methadone, 14 on buprenorphine) had lower Glx and NAA in dorsal ACC.
Hermann et al., <i>Addict. Biol.</i> 2012	17 opiate-dependent 20 controls	3 T PRESS concentration	ACC, frontal WM	OD patients (11 on methadone, 6 on buprenorphine) had ACC Glu concentration that correlated with number of previous withdrawals. Glx decreased with age in controls, but increased with age in OD subject.
METABOLITE ABNORMALITIES IN BRAIN REGIONS WITH OPIOID-INDUCED LEUKOENCEPHALOPATHY				
Kriegstein et al., <i>Neurology</i> 1999	3 heroin inhalation 1 control	1.5 T PRESS ratios	Cortical and cerebellar	Low NAA/tCR and Cho/tCR in GM in abnormal WM of 2 of 3 subjects. High cerebellar Lac/tCR in 1 patient
Vella et al., <i>Neuropediatrics</i> 2003	1 heroin-inhalation once only (8 days and 6 months) 5 controls	1.5 T PRESS concentration	Centrum semiovale supraventricular WM, occipital GM	Day 8: Lower than normal NAA, Cho, Glu, and higher Lac in centrum semiovale and supraventricular WM, and tCR, MI in SV WM. At 6 months: Lower NAA and higher Gln in centrum semiovale.
Bartlett et al., <i>Brit. J. Radiol.</i> 2005	2 heroin-inhalation 1 cocaine-inhalation	1.5 T not specified ratios	Occipital WM	Abnormal WM in heroin users showed higher Lac/tCR, MI/tCR, and lower NAA/tCR. The cocaine patient had higher Lac/tCR, Cho/ Cr and lipids.
Offiah & Hall, <i>Clin. Radiol.</i> 2008	5 of 6 heroin-inhalation No control	1.5 T PRESS visual reading	In abnormal WM	All 5 patients showed relative reduced NAA, Cho, and presence of Lactate doublet (TE 144 ms) in abnormal WM.
Salgado et al., <i>Am. J. Neuroradiol.</i> 2010	1 methadone overdose (27 days)	1.5 T ratios	Frontal WM	Markedly lower relative level of NAA, elevated relative level of Cho, and presence of lactic acid in abnormal WM.

Notes: ACC: anterior cingulate cortex, GM: gray matter, WM: white matter

In addition to the MRS studies in opiate-dependent individuals without gross structural brain abnormalities, several case reports or small series have used MRS to evaluate heroin-induced spongiform leukoencephalopathy, which is a rare condition resulting from inhalation of heroin vapors (aka “chasing the dragon”). These patients typically showed lactate and lower brain metabolite in the abnormal white

matter regions. Specifically, lower levels of NAA (Kriegstein et al., 1999; Offiah and Hall, 2008; Vella et al., 2003), NAA/tCR (Bartlett and Mikulis, 2005); tCR (Vella et al., 2003); Cho, Glu, and MI (Vella et al., 2003); as well as higher Lac (Offiah and Hall, 2008; Kriegstein et al., 1999; Vella et al., 2003), or Lac/tCR (Bartlett and Mikulis, 2005) were found in brain regions showing leukoencephalopathy. A longitudinal case study of a

16-year-old boy who inhaled heroin only once showed bilateral leukoencephalopathy with reduced levels of brain metabolites and presence of lactate eight days later, and the reduced NAA and elevated Gln persisted at six months (Vella et al., 2003). Similarly, methadone-induced leukoencephalopathy showed relatively lower NAA, elevated Cho and presence of Lac (Salgado et al., 2010), whereas a case of cocaine-induced leukoencephalopathy showed only elevated Lac/tCR, Cho/tCR and lipids (Bartlett and Mikulis, 2005).

Taken together, findings from these ^{13}P MRS and ^1H MRS studies suggest opiate abuse may lead to increased cell membrane turnover (elevated percentage of PDE and percentage of PME, and Cho), possibly related to neuronal damage (lower NAA) and alterations in cerebral metabolism (lower percentage of PCr and presence of lactate). However, interpretations of these findings are confounded by several factors. First, with the exception of patients with drug-induced leukoencephalopathy, most patients were enrolled in OMT. Variability in scan days from dosing of methadone may affect cerebral metabolism and/or phospholipids, especially in early treatment prior to methadone tolerance. Additionally, many subjects had active polydrug abuse or dependence (cocaine, amphetamine, barbiturates, alcohol, etc.), which may additionally alter MRS detectable metabolites. Finally, the lifestyles of these patients may make accurate histories difficult to obtain (Yucel et al., 2007). More studies are needed to determine whether MRS may be useful for monitoring the efficacy of treatments in these individuals.

BRAIN METABOLITES ABNORMALITIES IN ALCOHOL USE DISORDERS

The neuropathological consequences of alcohol use disorders (AUD) include neuronal loss in the dorsolateral frontal cortex, cerebellum, and hypothalamus (Harding et al., 1997; Korbo, 1999; Kril and Halliday, 1999), glial abnormalities in the hippocampi, and dorsolateral prefrontal cortex, (Harper, 2009; Miguel-Hidalgo et al., 2002), as well as reductions in density of both neuronal and glial cells in the orbitofrontal cortex (Miguel-Hidalgo et al., 2006) (Table 56.5). Based on these neuropathological findings, most ^1H MRS studies were evaluated for neuronal loss (NAA), cellular (Cho), glial (MI), and metabolic (tCR) alterations in the frontal lobes, cerebellum, and subcortical regions. Almost all ^1H MRS studies of recently detoxified alcohol-dependent (RDA) individuals within two weeks of detoxification found consistent evidence of neuronal loss or injury, with lower NAA levels, lower NAA/tCR or NAA/Cho in the frontal lobe GM (Fein et al., 1994; O'Neill et al., 2001a), frontal WM (Bartsch et al., 2007; Durazzo et al., 2004; Durazzo et al., 2008; Ende et al., 2005; Gazdzinski et al., 2008a; Jagannathan et al., 1996; Schweinsburg et al., 2001), cerebellum (Bendszus et al., 2001; Jagannathan et al., 1996; Parks et al., 2002; Seitz et al., 1999), anterior cingulate cortex (Mon et al., 2012), parietal lobe (O'Neill et al., 2001a), and thalamus (Jagannathan et al., 1996). Only one study of individuals during early (three to five days) abstinence reported normal levels of frontal WM NAA (Parks et al., 2002). Another major metabolite abnormality in RDA subjects is lower Cho levels and lower Cho/Cr or Cho/NAA, which were found in the cerebellum (Bartsch et al., 2007; Ende

et al., 2005; Seitz et al., 1999), frontal WM (Ende et al., 2005), anterior cingulate cortex (Lee et al., 2007; Mon et al., 2012), and the occipital region (Modi et al., 2011). The lower Cho or Cho/tCR ratios suggest alterations in myelin or cell membrane, or decreased cellular synthesis. Additionally, elevated MI concentrations, suggestive of glial activation, have been reported in the thalamus and ACC (Schweinsburg et al., 2000), as well as in the frontal and parietal WM (Schweinsburg et al., 2001).

MRS also may be useful for predicting relapse because the odds of relapse to alcohol use within 6–12 months were greater in those with lower NAA in the temporal GM and frontal WM and lower Cho in the frontal GM (Durazzo et al., 2008). A more recent study further confirmed that relapsers had significantly lower NAA than non-relapsers in many brain regions, including the dorsolateral prefrontal cortex (DLPFC), ACC, insula, cerebellar vermis, and the corona radiata; therefore, the authors speculated that connectivity of components of the rewards system may be impaired in those at risk for relapse (Durazzo et al., 2010). A small study that evaluated patients with bipolar disorder with and without alcoholism found only higher Glx levels in the DLPFC in the bipolar subjects, whereas those with alcoholism actually had normal brain metabolites despite their worse outcome and treatment refractoriness for their bipolar symptoms (Nery et al., 2010).

Recent studies have investigated the role of Glu and its metabolite Gln in AUD. Glu has been implicated in both AUD neuropathology and in the development of alcohol dependence. Young (<40 years old) RDA subjects abstinent for two weeks, without gross brain atrophy on MRI (GM, WM, and CSF volumes), showed significantly lower than normal ACC tCR, Cho, and Glu/tCR (Lee et al., 2007). Some of these metabolite abnormalities might be transient because older subjects (>40 years) with longer histories of AUD showed lower than normal NAA, Glu, and tCR in the ACC at baseline, mild elevation of Glu during early abstinence, and normalization of these metabolite abnormalities four weeks later (Mon et al., 2012). Furthermore, despite lower than normal Glu and Gln in RDA subjects, those who had been abstinent for at least one year also showed normal brain metabolite levels. Finally, in a placebo-controlled study of acamprosate, decreased Glu/tCR ratios were found only in the RDA subjects who were on acamprosate after four weeks, but not in the placebo treated RDA subjects. Because acamprosate is a medication approved for the treatment of alcohol dependence that reduces craving and relapse, the decreased Glu/tCR ratio after treatment may be a potential surrogate marker for future studies. Unfortunately, craving and relapse measures were not evaluated in relation to the changes in Glu/tCR in the subjects studied, and no correlations with CSF glutamate or other clinical measures were performed. Nevertheless, the various studies that evaluated brain GLX or glutamate demonstrated that MRS may be useful to evaluate the altered brain glutamatergic system in alcoholics, which may represent the effects of alcohol consumption or a predisposing susceptibility to AUD.

Several studies suggested that much of the neuropathological damage associated with AUD is reversible. With sustained abstinence, recovery has been observed in WM volume (Monnig et al., 2012), GM volume (Sullivan and Pfefferbaum,

TABLE 56.5. Brain changes associated with AUD: selected MRS studies

REFERENCE	SUBJECTS (DURATION ABSTINENCE)	MRS METHODS	BRAIN REGIONS STUDIED	FINDINGS
Seitz et al., <i>Alcohol Clin. Exp. Res.</i> 1999	11 RDA (3–6 days) 10 controls	1.5 T STEAM ratios	Cerebellar vermis	Compared with controls subjects, RDA subjects had lower NAA/tCR at TE = 135 msec and lower Cho/tCR at TE = 5 msec.
Behar et al., <i>Am. J. Psychiatry</i> 1999	5 RDA (34 days) 5 hepatic encephalopathy 10 controls	2.1 T homonuclear editing short-TE	Occipital GM	GABA is lower in RDA and HE subjects than in controls.
Schweinsberg et al., <i>Alcohol Clin. Exp. Res.</i> 2001	37 RDA (average 28 days) 15 controls	1.5 T PRESS concentration	Frontal WM Parietal WM	RDA subjects have lower FWM NAA and higher MI in FWM and PWM.
Bendszus et al., <i>Am. J. Neuroradiol.</i> 2001	17 RDA (1–3 days and 36–39 days) 12 controls	1.5 T PRESS ratios	Midline frontal lobe Cerebellum	Low NAA/tCR in frontal lobes and cerebellum at day 1–3, but significant increases after 1 month.
O'Neill et al., <i>Alcohol Clin. Exp. Res.</i> 2001	12 recovering alcoholics (128 weeks) 8 active heavy drinkers	1.5 T MRSI concentration	Frontal, Parietal, Remainder	Recovering alcoholics had fewer WM lesions and more GM volumes, but no difference in brain metabolites, compared with heavy drinkers.
Parks et al., <i>Alcohol Clin. Exp. Res.</i> 2002	31 RDA (3–5 days, 3 weeks and 3 months) 12 controls	1.5 T PROBE-P concentration	Vermis Frontal WM	No group differences in WM at 3–5 days, but RDA had lower NAA and Cho in cerebellum. 11 RDA subjects who remained abstinent at 3 months had increases in cerebellar NAA.
Ende et al., <i>Biol. Psychiatry</i> 2005	33 RDA (3 weeks, 3 months, 6 months) 30 controls	1.5 T spin echo multislice	DLPFC GM, WM, Vermis	RDA had lower Cho in frontal lobe and cerebellum, and low NAA in frontal WM. Cho increased at 3 months; no differences between 3 months and 6 months.
Ende et al., <i>NeuroImage</i> 2006	24 very light use 18 moderate use	1.5 T PRESS	Frontal WM, ACC, Cerebellum	Frontal WM and ACC Cho correlate with alcohol consumption.
Bartsch et al., <i>Brain</i> 2007	15 RDA (5 days and 6 weeks) 10 controls	1.5 T PRESS concentration	Frontomesial, Cerebellum	RDA had low frontal NAA and low cerebellar Cho. Increases in both at 6 weeks.
Durazzo et al., <i>Alcohol Alcoholism</i> 2008	26 RDA abstainers (1 month) 44 RDA resusers	1.5 T MRSI concentration	Frontal WM, BG, Cerebellar vermis	Lower NAA in temporal GM and frontal WM and lower Cho in frontal GM predicted relapse within 6–12 months.
Gazdzinski et al., <i>Alcohol</i> 2008a	35 RDA (1 week) 32 HD 38 controls	1.5 T MRSI concentration	Major lobes, Subcortical nuclei, Midbrain, Vermis	RDA had lower NAA, Cho, and MI than non-treated heavy drinkers.
Durazzo et al., <i>J. Stud. Alcohol Drugs</i> 2010	51 RDA (1 week) 33 resusers 26 controls	1.5 T MRSI concentration	DLPFC, Insula, ACC, Vermis, Superior corona radiata	RDA with lower NAA and tCR were more prone to relapse within 6–12 months.
Nery et al., <i>J. Psychiatr. Res.</i> 2010	22 ALC with BD 26 BD 54 controls	1.5 T PRESS concentration	DLPFC	ALC subjects with BD had normal Glu levels, whereas non-ALC BD subjects had higher Glx levels than other groups.
Umhau et al., <i>Arch. Gen. Psychiatry</i> 2010	33 RDA (4 days and 25 days after treatment) 15 RAD+Acamprosate 18 RDA on placebo	3 T TE-Avg PRESS ratios	ACC	RDA treated with acamprosate showed decreased Glu/tCR in the ACC but not RDA treated with placebo.
Yeo, et al. <i>Biol. Psychiatry</i> 2011	146 RDA (≤21 days)	1.5 T PRESS concentration	ACC	Number and length of copy number variation deletions correlated with lower ACC NAA, tCR, MI, and Glx.

(continued)

TABLE 56.5. (Continued)

REFERENCE	SUBJECTS (DURATION ABSTINENCE)	MRS METHODS	BRAIN REGIONS STUDIED	FINDINGS
Hermann et al., <i>Biol. Psychiatry</i> 2011	47 RDA (1 and 14 days) 57 controls	3T PRESS concentration	ACC	Both RDA and animals had higher Glu and Glu/Gln during acute withdrawal in prefrontal GM. Elevated Glu and Glu/Gln normalized after a few weeks.
Modi et al., <i>Eur. J. Radiol.</i> 2011	9 RDA (1 week) 13 controls	1.5 T PRESS ratios	Occipital lobe	RDA had higher Cho/tCR in occipital lobe.
Thoma et al., <i>Neuropsychopharmacology</i> 2011	6 RDA (1 year) 7 current AUD 17 controls	3T PRESS concentration	ACC	Lower Glu and higher Gln were found in both RDA and current AUD subjects than in controls. However, the two AUD groups did not differ on any of the brain metabolites.
Mon et al., <i>Drug Alcohol Depend</i> 2012	20 RDA (9 days) 36 RDA (34 days) 16 light drinkers	4T STEAM and MEGA PRESS concentration	ACC, POC, and DLPFC cortices	At baseline, compared with LD subjects, RDA subjects had lower tCR, Cho, and NAA in the ACC, but normal Glu and MI. After 5 weeks of abstinence no differences were noted between RDA and LD subjects. 11 RDA scanned at both time points had increased ratios of Glu, NAA, and Cho to water in the ACC, and of Glu to water in the POC.

Notes: ACC, anterior cingulate cortex; BG, basal ganglia; DLPFC, dorsolateral prefrontal cortex; GM, gray matter; POC, Parietooccipital cortex; WM, white matter; RDA, recently detoxified alcoholic

2005) and cognitive function (see following). When compared with control subjects after 35 to 39 days (Bendszus et al., 2001; Mon et al., 2012), or three months of abstinence (Ende et al., 2005), RDA subjects showed relatively normal levels of frontal (ACC) NAA, Glu, and Cho (Mon et al., 2012), NAA/tCR (Bendszus et al., 2001), frontal GM and WM Cho (Ende et al., 2005), cerebellar Cho/NAA (Martin et al., 1995), NAA/tCR and Cho/tCR (Bendszus et al., 2001), and Cho levels (Ende et al., 2005). In longitudinal follow-up studies of RDA subjects who were scanned after three days, three weeks, and three months of abstinence, frontal WM metabolites were normal at three days, whereas the cerebellar NAA and volume were lower at baseline but continued to increase toward normalization at three months, suggesting that the cerebellum is particularly sensitive, and may recover slower from the alcohol induced brain injury (Parks et al., 2002).

BRAIN METABOLITE ABNORMALITIES IN AUD ARE RELATED TO COGNITIVE PERFORMANCE

Alcohol may induce cognitive impairments, particularly in the learning and memory domains, which may be associated with alterations in brain metabolites measured with ¹H MRS. For example, deficits in delayed recall on the Hopkins Verbal Learning Test were negatively correlated with occipital GABA plus homocarnosine in RDAs (Behar et al., 1999), and improvements in verbal learning assessed on day 2 and day 38 of abstinence were correlated with increases in frontal NAA/tCR (Bendszus et al., 2001). Furthermore, levels of

the glial marker MI in either the ACC or the parietal cortex of RDA subjects negatively correlated with verbal learning, delayed visual memory, visuomotor scanning speed, and visuospatial memory, after 2 days of abstinence, and with auditory-verbal learning after 35 days of abstinence (Mon et al., 2012). Additionally, poorer short-term memory function was associated with lower Glu/tCR in the ACC of young RDA who had no evidence of GM or WM atrophy (Lee et al., 2007). Furthermore, poorer visuospatial learning was associated with higher DLPFC Glx after 2 days of abstinence, but with higher Cho on day 35 of abstinence, whereas poorer working memory was associated with higher glial marker MI also on day 35 (Mon et al., 2012). However, the degree of improvement on these cognitive measures from day 2 to day 35 did not correlate with changes in metabolite concentrations (Mon et al., 2012). Moreover, the neuronal marker NAA also may predict cognitive performance. In one study, cerebellar NAA/tCR in RDA subjects correlated with their performance on the Concentration Load test both after 2 days and after 38 days of abstinence (Bendszus et al., 2001). In heavy drinkers, the lower than normal frontal WM NAA also correlated with poorer executive and working memory functioning (Meyerhoff et al., 2004).

BRAIN METABOLITE ABNORMALITIES IN TREATMENT-NAIVE AUD

Most studies were performed on RDA subjects, who may not be representative of the majority (85%) of people with AUD who do not seek treatment (Gazdzinski et al., 2008a). RDA

subjects typically have more severe medical and psychiatric comorbidities (Meyerhoff et al., 2013), and may have up to 50% greater lifetime alcohol consumption (Fein and Landman, 2005). Lifetime consumption of alcohol is an important consideration, because even light to moderate drinkers without AUD showed reductions in frontal Cho levels that correlated with alcohol consumption within 90 days of their MRS (Ende et al., 2006). The few studies that compared current heavy drinkers (HD) to RDA and healthy controls reported conflicting results. Surprisingly, RDA participants typically showed lower brain metabolite levels than HD subjects. For example, although NAA, Cho, tCR, or MI were typically lower in HD subjects than in controls (Gazdzinski et al., 2008a), including HD subjects with a negative family history of AUD, the brain metabolite abnormalities in these HD subjects were less severe than those observed in RDA individuals (Meyerhoff et al., 2004). In contrast, although both current drinkers and AUD subjects who had been abstinent for one year showed lower brain Glu and higher Gln than controls, both AUD subject groups showed no differences in NAA, tCR, Cho, MI, Gln, or Glx in their ACC (Thoma et al., 2011). Similarly, despite group differences in regional brain volumes and the amount of white matter lesions, recovering alcoholics (median abstinence 128 weeks) and active heavy drinkers showed no differences in their brain metabolites in any brain regions studied (O'Neill et al., 2001a). Therefore, MRS may not be sensitive for differentiating the brain health of HD and RDAs. However, the lack of differences between RDA, HD, and control subjects in these two studies might have resulted from normalization of the brain metabolites in the RDAs following abstinence.

ALCOHOL USE WITH TOBACCO SMOKING

Cigarette smoking is the most common comorbidity among drug users, including those with AUD. Up to 80% of alcohol-dependent individuals regularly smoke (Romberger and Grant, 2004) and 50–90% are dependent on nicotine (Daepfen et al., 2000). Only a few MRS studies specifically evaluated brain metabolite abnormalities in tobacco smokers. One study of current tobacco smokers showed lower hippocampal NAA, and their ACC Cho correlated with lifetime nicotine exposure (Gallinat et al., 2007). Another study of tobacco smokers who “slipped” or relapsed from smoking cessation (with nicotine replacement therapy) showed lower baseline Glu/tCR, GABA/tCR, and Cho/tCR than those who were able to remain abstinent from the treatment (Mashhoon et al., 2011). Therefore, these metabolite ratios may be useful for predicting treatment outcomes (Table 56.6).

Smoking appeared to have additive effects with alcohol use in that RDA subjects who smoked had the lowest metabolite concentrations. RDA subjects with greater alcohol consumption also smoked more and had worse neuropsychological performance (Durazzo et al., 2004). Furthermore, after one month of abstinence, compared with RDA subjects who smoked (sRDA), non-smoking RDA (nsRDA) subjects showed greater increases (normalization) in medial temporal lobe Cho and NAA (Gazdzinski et al., 2008b), frontal WM NAA and Cho, and thalamic Cho (Durazzo et al., 2006).

Additionally, diffusion tensor imaging indicated lower than normal fractional anisotropy in brain regions of RDA subjects who showed lower NAA concentrations (Durazzo et al., 2006), as well as in the frontal WM, superior corona radiata, and adjacent WM in sRDA, but not nsRDA subjects (Wang et al., 2009). Therefore, comorbid tobacco smoking with alcohol use may lead to greater brain metabolite abnormalities, which may be related to the direct neurotoxic effects from these comorbid conditions, or indirect effects from hypoxia associated with smoking. Prior studies of individuals with AUD often did not account for concurrent tobacco smoking. Because NAA and Cho may normalize in alcohol users who became abstinent, but not in AUD with concurrent tobacco smoking, some of the metabolite abnormalities found in subjects with AUD may be caused by comorbid tobacco smoking.

MRS STUDIES IN MARIJUANA SMOKERS

Marijuana or cannabis smoking is also very common among drug users and is often used for medicinal purposes. Medicinal marijuana use is now legal in more than half of the United States. Few studies have used MRS to measure brain metabolites in chronic marijuana users (see Table 56.6). Because marijuana use is common among HIV-infected individuals, one study evaluated the independent and combined effects of chronic marijuana use in subjects with or without HIV-infection. Regardless of HIV-infection status, abstinent marijuana users showed lower levels of basal ganglia NAA, Cho, and glutamate, but elevated thalamic tCR (Chang et al., 2006). Similarly, young men who smoked marijuana daily showed mild memory and attention impairments and lower levels of NAA/tCR in the dorsolateral prefrontal cortex, and the NAA/tCR levels in their lentiform nuclei positively correlated with hair cannabidiol levels (indicative of amount of marijuana smoked recently) (Hermann et al., 2007). A small 2D MRS study of marijuana-dependent young men reported lower than normal global MI/tCR levels (from one large voxel that included basal ganglia, thalamus, hippocampus, and surrounding regions) (Silveri et al., 2011). Furthermore, young regular marijuana users showed lower levels of glutamate, NAA, tCR, and MI in the ACC; however, some of these marijuana users were also heavy alcohol users and/or were medicated for depression (Prescot et al., 2011). Last, a study of polydrug users who used ecstasy and marijuana found only an association between lower frontal cortex NAA/tCR and more lifetime marijuana use but not with other drug use (Cowan et al., 2009). Taken together, the few studies that evaluated brain metabolite changes in chronic marijuana users found decreased neuronal and/or glial metabolites in the basal ganglia and in the frontal lobe. Longitudinal studies are needed to evaluate the relationship between marijuana use and brain metabolite abnormalities, and whether these alterations are reversible or may normalize with longer duration of abstinence. Because marijuana is often used by adolescents, when their brains are still undergoing development, future evaluations should assess the

TABLE 56.6. MRS studies in tobacco (TOB) or marijuana (MJ) smokers or exposure

REFERENCE	SUBJECTS (DURATION ABSTINENCE)	METHODS	BRAIN REGIONS	FINDINGS
Epperson et al., <i>Biol. Psychiatry</i> 2005	16 TOB (48 hours) 20 controls	2.1 T J-edit GABA concentration est. from tCR	Occipital GM	Short-term TOB abstinence did not affect GABA. Female TOB had reduced GABA during the follicular phase but no cyclicity in GABA levels across the menstrual cycle. Male TOB users had normal GABA levels.
Gallinat et al., <i>J. Clin. Psycho-pharmacol.</i> 2007	13 TOB (current) 13 controls	3 T PRESS concentration	ACC, HIPC	TOB smokers had lower NAA in the hippocampus, whereas their ACC Cho correlated positively with pack years smoked.
Durazzo et al., <i>Alcohol Clin. Exp. Res.</i> 2004	14 TOB+alcohol (1 wk) 7 TOB10 alcohol (1 wk) 19 controls	1.5 T MRSI 3 slices concentration	3 cortical, 4 WM, 5 other regions	Alcohol effect: lower frontal NAA and lower frontal, parietal, and thalamic Cho. TOB+alcohol had lower FWM and midbrain Cho than alcohol. TOB effect: lower midbrain NAA and choline and CBV. Correlations with cognitive measures varied by group.
Durazzo et al., <i>Alcohol Clin. Exp. Res.</i> 2006	14 TOB+alcohol (1 month) 9 TOB11 alcohol (1 month) 20 controls	1.5 T 3 slice (subcortical and cortical) MRSI concentration	3 cortical, 4 WM, 5 other regions	After 1 month of abstinence from alcohol, PWM Cho increased in the alcohol group and PWM NAA decreased in the TOB+alcohol group. Metabolite/cognition correlations varied between alcohol and TOB+alcohol.
Mason et al., <i>Biol. Psychiatry</i> 2006	7 TOB+alcohol (1–13 days) 5 TOB5 alcohol (2–7 days) 3 controls	2.1 T J-edit GABA concentration est. from tCR	Occipital GM	At 1-week sobriety, GABA was higher in alcohol users relative to others but normalized after 1 month. Glx was higher in smokers.
Gazdzinski et al., <i>Psychiatry Res.</i> 2008	13 TOB+alcohol 11 alcohol (both at 6 and 32 days) 14 controls	1.5 T 1 slice MRSI concentration	Slice centered around HIPC	Hippocampal NAA Cho and MI increased to near normal levels after 1-month alcohol abstinence for alcohol group but not TOB+alcohol group. Cho changes positively correlated with memory changes.
Wang et al., <i>NMR Biomed.</i> 2009	26 TOB+alcohol (1 month) 22 alcohol (1 month) 26 controls (light drinkers)	1.5 T MRSI–3 slices concentration	7 WM regions	TOB+alcohol had lower NAA in frontal WM with abnormal fractional anisotropy (FA) on DTI. Alcohol users had normal NAA. No NAA group differences were detected in FWM with normal FA on DTI.
Mashhoon et al., <i>Prog. Neuropsychopharmacol. Biol. Psychiatry</i> 2011	9 TOB on NRT (5 relapse, 4 6-wks abstinent)	4 T 2D_J PRESS Ratios	Dorsal ACC, occipital GM	Subjects who relapsed had lower baseline dACC Glu/tCR, GABA/tCR, and Cho/tCR compared with abstinent subjects.
Chang et al., <i>J. Neuroimm. Pharmacol.</i> 2012	26 prenatal TOB24 controls age 3–4 years	3 T PRESS concentration	ACC, Frontal WM, BG, thalamus	Prenatal TOB exposed children had higher ACC Glx. Those with highest Glx had poorest vocabulary and visual motor integration.
MRS IN MARIJUANA SMOKERS				
Chang et al., <i>J. Neuroimm. Pharmacol.</i> 2006	24 MJ (0–2 yrs) 21 HIV21 HIV+MJ (0–2 years) 30 controls	4 T PRESS concentration	ACC, Frontal WM, BG thalamus	MJ users had lower NAA, Cho, and Glu in BG but elevated tCR in thalamus. MJ users, but not HIV+MJ, also had lower Glu in FWM.
Hermann et al., <i>Biol. Psychiatry</i> 2007	12 active MJ users 10 controls	1.5 T MRSI 3 slices ratio	HIPC, frontal WM, BG, thalamus, DLPFC, ACC	MJ users had lower NAA/tCR in DLPFC; NAA/tCR in BG correlated with hair cannabidiol. MJ users had poor cognitive performance.
Cowan et al., <i>Pharmacol. Biochem, Behav.</i> 2009	17 polydrug (>4 days)	3 T PRESS ratio	Occipital GM, temporal WM, LFC	NAA/tCR in LFC correlated inversely with lifetime marijuana use only, but not with other drugs used (MDMA, alcohol, or cocaine).

impact of marijuana usage on brain metabolites or cognitive changes during brain development.

SUMMARY MRS FINDINGS IN VARIOUS DRUGS OF ABUSE AND DRUG DEPENDENCE

MRS can detect neurochemical alterations that reflect neuronal loss, dysfunction, or glial activation associated with various drugs of abuse. Specifically, neuronal markers such as NAA and Glu or Glx are shown to be lower than normal in many brain regions of the drug users discussed in the preceding, except for those who used ecstasy. Decreased NAA often correlated with the cumulative exposure of the drug, cognitive performance, severity of psychiatric symptoms, and may even predict the likelihood of relapse (e.g., in alcoholics). However, NAA levels also may normalize with longer duration of abstinence from alcohol or methamphetamine use, which indicates that some of the neuronal injury may be reversible. The magnitude of the lower NAA levels are typically in the range of 5–7%, which are less than those found in neurodegenerative disorders, such as frontotemporal dementia (>25%) and Alzheimer’s disease (>10%), or in neuroinflammatory conditions such as multiple sclerosis (up to >30%, especially in secondary progressive disease) and chronic HIV infection (5–20%). However, such decreased NAA may differ across brain regions and may vary greatly depending on the stage of the disease (Table 56.7).

Similarly, the glial marker MI is often elevated in the white matter of drug users which may reflect glial activation or neuroinflammation associated with drug abuse. Specifically, elevated MI has been reported in the white matter of psychostimulant (cocaine, methamphetamine, and ecstasy) users, inhalant users, opiate-dependent individuals, and alcoholics. The magnitude of the elevated MI in drug users (10–15%) are only slightly less than those observed in neuroinflammatory responses associated with other chronic brain disorders. For example, MI is often elevated in patients with chronic HIV infection (up by 10–20%) or neurodegenerative disorders such as Alzheimer’s disease (also 10–20%, depending on the brain region), but may be higher in those with more acute neuroinflammation such as progressive multiple sclerosis (10–35%). Limited data on cocaine or marijuana users reported lower MI in the ACC, but these subjects might have had other confounding variables (e.g., depression).

Because tCR and choline compounds are in both neurons and glia, their levels are more variable depending on the brain regions assessed, usage patterns, or duration of abstinence. tCR was consistently found to be elevated in the white matter of adult cocaine users and in children with prenatal exposure to either cocaine or methamphetamine, although most of these individuals also had tobacco exposure. In contrast, adult methamphetamine users showed lower tCR levels in both the basal ganglia and white matter, and alcoholics also showed lower tCR in the DLPFC and WM, especially during early abstinence and in those who relapsed. Since tCR reflects energetic metabolites, its level may reflect the energy states of the brains of drug users during various states of recovery.

Glutamate or Glx levels, which reflect primarily Glu, tended to be lower during early abstinence (e.g., in methamphetamine users and RDA), but may normalize with longer duration of abstinence, with pharmacotherapy (e.g., RDA treated with acamprosate), and may also correlate with number of withdrawals (e.g., in opiate users). Glx is also elevated in the frontal lobes of tobacco smokers, individuals with AUD, and in those with prenatal stimulant exposure. However, quantitative measurements of Glx and Glu are often less reliable than other metabolites, and are not possible with studies performed using longer echo times. Therefore, better techniques are needed for future analyses (see the following). The few studies that evaluated GABA also found reduced levels in cocaine and alcohol dependent individuals, and the lower levels may predict relapse (e.g., tobacco smoking). This plethora of studies demonstrate that MRS provides valuable *in vivo* neuropathological assessment of the brains of drug addicted individuals, which may be useful both for initial assessments but may also be used as a surrogate marker to predict treatment outcome or relapse to drug use.

TECHNICAL CONSIDERATIONS AND FUTURE DIRECTIONS

MRS complements other neuroimaging techniques well because it can often be acquired with structural imaging, which is required for voxel placements for MRS studies. This approach was used in a study of alcohol users (Wang et al., 2009); the investigators used diffusion tensor imaging to assess axonal integrity, which demonstrated abnormal fractional anisotropy,

TABLE 56.7. Brain metabolite abnormalities (in selected brain regions) associated with drugs of abuse or exposure

BRAIN METABOLITES	COCAINE	AMPHETAMINE/ METHAMPHETAMINE	ECSTASY (MDMA)	INHALANTS/ SOLVENTS	OPIATES	MARIJUANA	ALCOHOL	TOBACCO
NAA or NAA/tCR	↓ (ACC, thalamus, DLPFC, WM) ↑ (BG—acute)	↓ (BG, FWM, ACC) correlated with usage or behavior ↑ prenatal exp (FWM)	Normal	↓ (PWM, cerebellum)	↓ (GM, dorsal ACC); ↓↓ in leukoencephalopathy	↓ (DLPFC, ACC, BG)	↓ (most brain regions), in relapsers; may normalize with abstinence	↓ (hippocampi, midbrain)
tCR or %PCr	↑ (FWM) in both adults and prenatal exposed; sex-differences ↑ (PWM)	↓ (BG, FWM) ↑ prenatal exposure (BG, FWM)			↓ (GM) decreased with MMT	↓ (ACC) ↑ (THL)	↓ (DLPFC, WM, Vermis) in relapsers; may normalize with abstinence	
Choline or Cho/tCR Cho/NAA	↓ (TH) ↑ (BG-acute)	↓ (ACC, BG) ↑ (ACC)		↓ (thalamus, BG, PWM); correlated with psychiatric symptoms	↓ in leukoencephalopathy	↓ (BG)	↓ (FGM, ACC, cerebellum); normalized with abstinence ↑ (OGM)	↓ ACC in relapsers ↑ (FWM, vermis, midbrain); correlated with pack years
Myoinositol or MI/tCR	↑ (FWM) correlated with duration; sex-differences ↓ (ACC)	↑ (ACC, FWM) ↑ after dextro-amphetamine ↓ prenatal (thalamus)	↑ (PWM) correlation with lifetime dose	↑ (PWM, cerebellum)	↑ (OWM)	↓ (ACC)	↑ (thalamus, ACC, FWM, PWM)	
Glx or Glx/tCR		↓ or ↑ (ACC and FWM) vary with duration of abstinence ↑ prenatal exp (FWM)			↓ (dorsal ACC)		↑ (DLPFC)	↑ ACC (prenatal) ↑ (OGM)
Glutamate (Glu) or Glu/tCR	↓ or ↑ (ACC) ↓ correlated with duration				Correlated with times withdrawal	↓ (ACC, BG)	↑ or ↓ (ACC) ↓ (ACC) after acamprosate	↓ ACC in those who relapse
GABA or GABA/tCR	↓ (PFC)						↓ (Occipital)	↓ ACC in relapsers
Lac or Lac/tCR					Only in leukoencephalopathy			
%PDE or %PME					↑ (GM) with MMT			
%B-NTP or %NP					↓ (GM) with MMT			

Notes: ACC, anterior cingulate cortex; BG, basal ganglia; CBV, cerebellar vermis; DLPFC, dorsolateral prefrontal cortex; GM, gray matter; POC, Parieto-occipital cortex; RDA, recently detoxified alcoholic; WM, white matter

and selected brain regions for MRS evaluation from previously collected MRSI. Therefore, MRSI has the advantage that once the data are collected, selected brain regions can be queried retrospectively. However, because of the magnetic field inhomogeneity from different tissues across the brain, localized MRS often allows better assessments of brain metabolite concentrations in selected brain regions, especially at short-echo time acquisitions (<100 ms). This is important because some of the metabolite resonances are visible only at shorter echo time MRS (e.g., myoinositol, glutamate, lactate, lipids).

Aside from technical issues related to the MRS acquisition, many clinical variables may influence the metabolite measurements. For example, the duration of abstinence from the drug use, the cumulative amount of drug exposure, age of the drug exposure, and comorbid drug use (e.g., tobacco or marijuana smoking) all may affect the brain metabolite levels. Therefore, study designs and interpretations of the metabolite levels from MRS need to include these variables. Furthermore, normal variations in brain metabolites can be caused by sex differences (e.g., men have higher choline than women in the frontal WM) and age-dependent changes (e.g., tCR increase and Glu decrease with age), which need to be controlled when evaluating brain metabolite abnormalities in drug users.

Future studies with advanced MRS techniques may further assess other neurochemicals that may be affected with drug dependence. For example, glutathione levels can be measured to assess the oxidative capacity of brain tissue using MEGA-PRESS or 2-D MRS techniques. Similarly, glutamate levels are difficult to delineate and may be better assessed using these same techniques. Given the abundance of glutamatergic neurons and the important role of glutamate in addiction, more MRS studies to evaluate this neurochemical are needed. More studies are also needed to determine whether MRS may be a useful surrogate marker for predicting treatment outcomes. MRS may be used along with other neuroimaging techniques as endophenotypes to evaluate genetic variations or deletions on how the brain may be impacted by drugs of abuse (e.g., rare copy number deletions in AUD [Yeo et al., 2011]) and to predict the likelihood of relapse, which may guide treatment approaches. Because MRS can be performed noninvasively in both humans and in animals, it can be a powerful research tool for clinical-translational studies, especially those that require longitudinal assessments (e.g., MRS were performed in both humans and rodents during alcohol withdrawal and abstinence [Hermann et al., 2012b]).

DISCLOSURES

Dr. Chang has no conflicts of interest to disclose. Dr. Chang is funded by the National Institutes of Health (K24-DA016170, R24-DA027318, R01-DA035659, U54-NS056883).

Dr. Cloak has no conflicts of interest to disclose. Dr. Cloak is funded by the National Institutes of Health (K01-DA021203), and the Hawaii Community Foundation (Geist Foundation: 12ADVC-51341).

Dr. Holt has no conflicts of interest to disclose.

57 | PHARMACOTHERAPY OF SUBSTANCE USE DISORDERS

JANE B. ACRI AND PHIL SKOLNICK

OVERVIEW

There has been a dramatic retreat from research and development of medications to treat psychiatric disorders over the past four to five years (Brady and Insel, 2012; Jarvis, 2012; Paul et al., 2010). Moreover, the development of pharmacotherapies to treat substance use disorders (SUDs) has traditionally lagged well behind efforts to develop novel medicines to treat other psychiatric disorders, including schizophrenia, depression, and anxiety. Thus, despite remarkable progress in our understanding of the neurobiological bases of drug abuse (Koob and Volkow, 2010), there are no approved pharmacotherapies to treat either stimulant (e.g., cocaine, methamphetamine) or cannabis abuse. Moreover, approved pharmacotherapies to treat other SUDs (e.g., opiates, tobacco) are far from ideal. For example, no more than 20% of smokers are able to sustain long term (12 month) abstinence, despite the availability of multiple options to treat tobacco dependence (nicotine replacement therapies, bupropion, and varenicline). Although heroin abuse remains a significant public health issue, abuse of prescription opioids is far more pervasive, with approximately 2% of the US population (age 12 and older) reporting nonmedical use of prescription opiates during the past month (2010 National Survey On Drug Use and Health; <http://oas.samhsa.gov/nsduhLatest.htm>). Here too, progress in developing medications to treat opiate addiction has been incremental, with reformulations of long approved medications (e.g., depot naltrexone, and implantable buprenorphine) aimed at enhancing adherence the most significant therapeutic advances in this area. This lack of progress is attributable, in large part, to a lack of interest (and investment) by the pharmaceutical industry. There are multiple factors that contribute to this indifference, ranging from a perceived small market size (translating to a lack of return on investment) to the perception of a high regulatory bar for approval, as detailed in the following.

ECONOMIC CONSIDERATIONS

The development of a new chemical entity, from the laboratory through FDA approval, generally requires more than 15 years and a capital outlay estimated between \$1 and 2 billion (Paul et al., 2010). More recently, it has been argued that these values grossly underestimate the true costs of bringing a drug to market, which may range from \$4 to 11 billion (<http://www.forbes.com/sites/matthewherper/2012/02/10/the-truly-staggering-cost-of-inventing-new-drugs/>). Given the cost and risks associated with drug development, a perceived small market size

is one of the reasons most often given for the limited interest in developing medications to treat SUDs. However, with several available treatment options including methadone, Subutex®, and Vivitrol®, annual sales well in excess of \$1 billion for Suboxone® (a combination of sublingual naloxone and buprenorphine that discourages abuse) belie the notion that the treatment of SUDs is not an attractive market. Perhaps even more compelling is an estimate of the market size for a first in class medication to treat cocaine use disorders. Based on a 2009 survey by SAMSHA, 1.6 million Americans used cocaine in the past month. If this population, rather than the much larger (>5 million) cohort who reported using cocaine in the past year is considered as the target treatment group, and 20% of this cohort seek treatment, the potential market is 320,000 patients. Assuming treatment duration of six months to achieve abstinence at a cost of \$700/month, annual sales for this medication would be in excess of \$1.2 billion. Although both the cost and duration of treatment are clearly assumptions, the current cost of Vivitrol® (approximately \$1,200/month) can be viewed as a valid comparator. Thus, many third-party payors will reimburse because of the favorable health and economic outcomes compared with other types of maintenance therapy (Baser et al., 2011).

Most drug candidates for the treatment of SUDs are repurposed compounds that have either been approved, are currently in development, or have failed in another indication. Because of the contraction of research and development in psychiatry, there may be a bumper crop of “parked” molecules available with the potential to treat SUDs on the near-term horizon. These compounds were in various stages of development that were either halted for strategic reasons, and cannot be out-licensed or otherwise monetized. Although repurposing is clearly a less costly strategy than a *de novo* development campaign, approval would nonetheless require multiple, double-blind, placebo-controlled efficacy trials. Although off label prescribing of drugs is an option, FDA approval (amounting to a change in current labeling) is important both for reimbursement by third payors and establishing treatment guidelines. In the absence of patent protection, the effectiveness of a repurposing strategy is questionable, absent some form of *de jure* economic incentives such as a period of market exclusivity.

DIFFICULTIES IN EXECUTING A CLINICAL CAMPAIGN

Pharmacotherapy trials in SUDs pose unique challenges that can dampen sponsor enthusiasm. Thus, treatment centers

specializing in SUDs are often either not equipped or trained to conduct a trial based on good clinical practice guidelines that are essential for FDA approval. Patients with SUDs, particularly intravenous drug users, often have comorbid conditions, including HIV and hepatitis C. If these individuals are enrolled in a trial, concomitant medications administered to these patients such as cocktails of antiretroviral therapies (Perelson et al., 1997) pose formidable drug interaction challenges. In addition, interpretation of negative data in SUD trials may be confounded by low rates of medication adherence. When monitored by measurement of drug levels in urine, the compliance rate has been reported at less than 40% in a trial examining the effects of vigabatrin in cocaine use disorder (<http://ir.catalystpharma.com> press release 9.30.2009). In contrast, compliance assessed by self-report/pill count was ~85%. This trial failed to replicate an earlier study (Brodie et al., 2009) demonstrating that vigabatrin produced a significant increase (28% vs. 7.5% in placebo) in the percentage of abstinent individuals at end of study. However, the Brodie et al. (2009) study required three weekly in-clinic doses of vigabatrin, whereas the study with a negative outcome was an outpatient trial. In a study assessing the efficacy of modafinil in treating methamphetamine use disorder, Anderson et al. (2012) recently reported very low agreement (intraclass correlation coefficient, 0.21) between compliance assessed by pill count/self-report (93% rate of compliance) and weekly measurement of modafinil in urine. Approximately 10% of the subjects never had detectable levels of modafinil in urine during the entire 12 week trial. Thus, it is perhaps not surprising there were no significant differences between the modafinil and placebo groups on either primary or secondary outcomes. Noncompliance is an important and often overlooked issue in

both the conduct of clinical trials (Czobor and Skolnick, 2011) and real world practice (Cutler and Everett, 2010), but may be viewed as particularly cogent in the absence of approved medications to treat cocaine, methamphetamine and cannabis use disorders.

REGULATORY HURDLES

In contrast to other psychiatric disorders, medication trials in SUDs can assess efficacy with a biomarker measuring the abused substance in a biological matrix such as urine. A clean (drug-free) urine (generally sampled two–three times/week during an in clinic visit) is generally taken as prima facie evidence that a medication is effective in reducing or eliminating drug use. Many contemporary medications trials look at group means (i.e., the percentage of patients with drug free urine) over the course of a study (Heinzerling et al., 2010; Jayaram-Lindstrom et al., 2008; Shearer et al., 2009).

Although positive signals have been reported from this type of analysis (e.g., naltrexone reducing the percentage of patients with cocaine-positive urines during the course of a 12-week trial; see Fig. 57.1), the FDA currently views an analysis based on success/failure, rather than reduction in group means, as an acceptable outcome measure (Winchell et al., 2012). The success must be clinically meaningful, preferably defined by a period of abstinence that lasts through the end of treatment (reviewed in Donovan et al., 2012; McCann and Li, 2011). Blunting of subjective ratings related drug effects such as liking and wanting as well as reductions in craving scale scores (e.g., Jayaram-Lindstrom et al., 2008) would not likely be viewed as a primary outcome measure unless associated with a salutary outcome for the patient (Donovan et al., 2012).

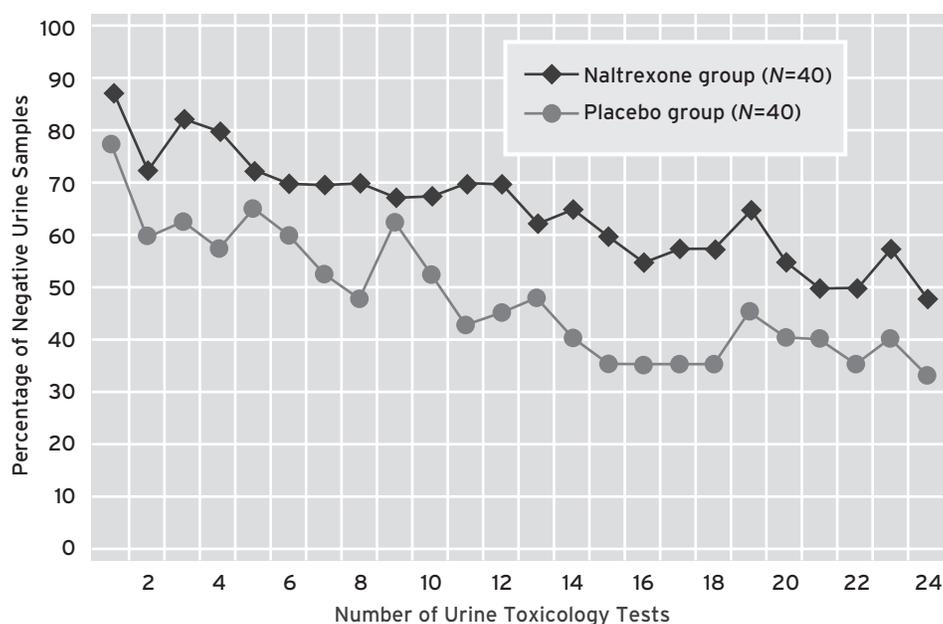

Figure 57.1 Percentage of negative urine samples in the naltrexone (N =40) and placebo (N =40) groups during a 12-week trial for the treatment of amphetamine dependence (Intent to treat analysis). The FDA does not accept analyses based on reduction in group means but currently views an analysis based on success/failure, defined as a period of abstinence at the end of the trial as a clinically meaningful endpoint (Winchell et al., 2012). (Data and Image from Jayaram-Lindstrom N, Hammarberg A, Beck O, and Franck J. 2008 with permission from the American Psychiatric Association.)

Abstinence may be viewed as analogous to remission in other psychiatric disorders. When viewed in this context, abstinence may be considered a very high, perhaps unattainable or unrealistic endpoint for a medication, even if combined with psychotherapy (Donovan et al., 2012). Certainly, drugs have been approved for the treatment of other psychiatric disorders (e.g., schizophrenia) if there is a statistically significant improvement in a subset of symptoms (e.g., positive symptoms) absent complete remission. However, a compelling counterargument can be made that this analogy is flawed, because no amount of an illegal substance can be linked to a beneficial health outcome. Indeed, for this reason, sustained abstinence is the primary outcome measure in contemporary smoking cessation trials (Hatsukami et al., 2011). Although many experts have proposed reduced use as an acceptable outcome in clinical trials (Donovan et al., 2012), reduced use per se (e.g., a 50% reduction in the frequency or amount of cocaine used) may not provide clear expectations for the prescriber or patient. Further, it may not be realistic to expect reimbursement by third party payors for a medication that results in reduced use, absent evidence that reduced use will produce a tangible, measurable benefit for the patient (and thereby reduce health costs for the insurer). Certainly, drugs such as varenicline that have been approved for smoking cessation produce a significantly higher rate of long-term abstinence compared with placebo (Fagerstrom et al., 2012). There are also notable examples of producing short-term abstinence to cocaine (vigabatrin; Brodie et al., 2009) and methamphetamine (bupropion; McCann and Li, 2011) compared with placebo in double-blind, placebo-controlled trials, but these studies require replication.

OTHER ISSUES

There are other issues that have prevented the pharmaceutical industry from viewing SUDs (other than smoking cessation medications) as an attractive market. Often mentioned are the negative aspects of linking a company's name and reputation with the use of illegal substances. A fragmented advocacy, sending mixed, and often contradictory and polarizing messages ("... why substitute one addiction for another") about treatment of SUDs also can intimidate potential investors. Nonetheless, the commercial success of a medication like Suboxone®, which entered an arguably crowded space (including methadone, buprenorphine, and naloxone), may serve as an impetus for investment, especially in SUDs for which there are no approved medications.

ANIMAL MODELS

There is no single animal model that can either adequately capture all aspects and stages of SUDs (e.g., reward, conditioning, craving, acquisition, maintenance, withdrawal) or that is necessarily predictive of clinical efficacy. Thus, targets and compounds are viewed as high value if they are active in several models, and when studies in genetically engineered animals (e.g., when the gene encoding the target is silenced) are

consistent with results from these models. Several commonly used animal models are briefly discussed in the following text. There are variations of each procedure, and there is an ongoing debate regarding the aspects of drug abuse that each model captures, as well as their appropriateness and predictive validity to evaluate potential medications (Koob et al., 2004). Treatments for SUDs are only considered effective if they alter drug-taking behavior in humans, rather than addressing the theoretical constructs of addiction, compulsion, or dependence. Therefore, compounds that selectively alter the behavior of drug taking in animals might be effective in altering drug taking in humans, whether or not the model has captured all aspects of addiction.

The etiology of human drug abuse cannot be adequately modeled in animals beyond one significant and overriding factor, exposure to the drug of abuse. When animals are exposed to a drug of abuse, they undergo behavioral changes that are consistent with those that occur in humans: drug seeking and drug taking. In self-administration models, animals exposed to drugs of abuse will develop consistent patterns of behavior that result in self-administration depending on the drug, dose, duration of action, route of administration, operant training schedule, length of the session, and a number of additional environmental factors (see Mello and Negus, 1996 for review) (Fig. 57.2). It is the intrinsic reinforcing effects of the drug that maintain self-administration behavior, based on the observations that animals do not self-administer psychoactive drugs not producing pleasurable effects in humans (e.g., haloperidol, imipramine, or topiramate) (Balster, 1991; Brady et al., 1984; Griffiths and Balster, 1979). The self-administration model has been used to demonstrate the efficacy of FDA-approved medications for smoking (Le Foll et al., 2011; Levin et al., 2012; O'Connor et al., 2010), alcohol (Jimenez-Gomez et al., 2011), and opioids (Harrigan and Downs, 1981; Negus, 2006; Winger et al., 1992), but must be used with appropriate controls for non-specific effects. The examples of effective medications that reduce self-administration in animals suggest that use of the method has predictive validity, but the literature is rife with studies that either did not incorporate appropriate controls for sedating or other non-specific effects; or that did not address the dose of drug being self-administered in the test.

The conditioned place preference model utilizes Pavlovian conditioning processes in which environmental stimuli are coupled to administration of a drug of abuse resulting in a "preference" for the specific environment in which the drug was experienced. In this procedure, animals are placed in one distinctive chamber following an injection of drug, and in another distinctive chamber following administration of saline. After several pairings of drug and saline with their respective chambers, animals given free choice to roam between the two chambers will spend proportionally more time in the drug-paired chamber. This is generally interpreted as indicative of the intrinsic rewarding effect of the drug of abuse in which the chamber itself becomes a conditioned stimulus and a conditioned reward (see Schechter and Calcagnetti, 1998; Tzschentke, 2007, for reviews).

Animal models of relapse have been developed in part because cocaine use has been described as a chronic, relapsing

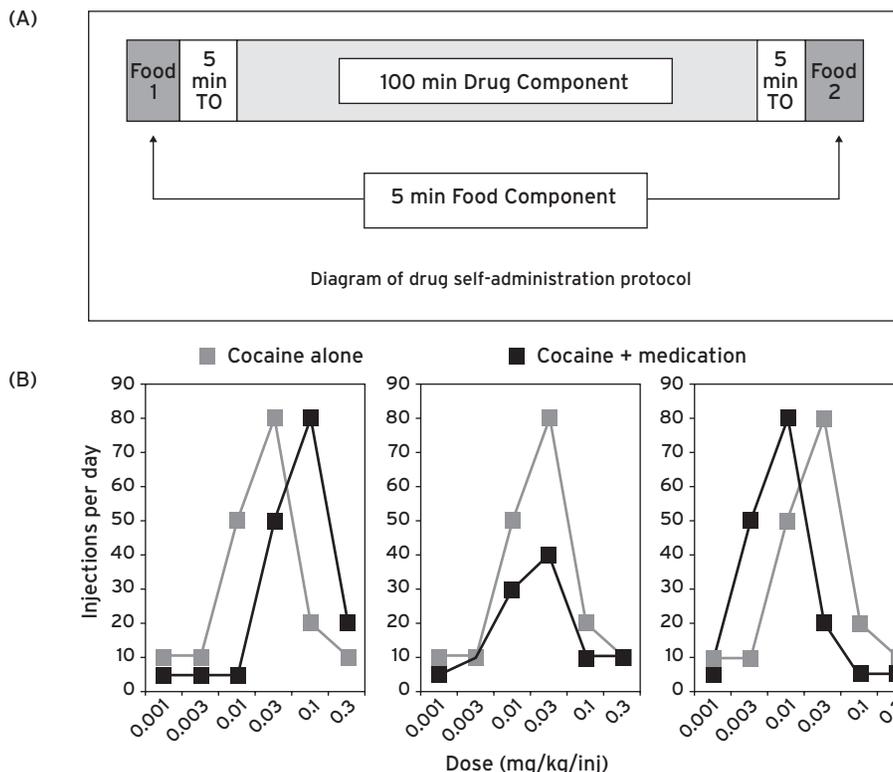

Figure 57.2 (A) A self-administration protocol in which animals that are trained to self-administer cocaine also have the opportunity to lever press for food pellets after test medication administration but before exposure to cocaine (Food 1), and then again after exposure to cocaine (Food 2). This paradigm allows comparisons between changes in rates of lever pressing for food and cocaine in response to the same dose of test drug and in the same session. This is an important control for compounds that might reduce lever pressing for cocaine because of generalized CNS depression or motor impairment. (B) Illustration of the importance of assessing a test compound against the entire inverted-U shaped dose–effect curve of cocaine, in order to understand the nature of decreases in responding for the “peak” dose of cocaine, which can occur as a result of rightward, downward, or leftward shifts in the cocaine dose–effect curve. An assessment of a test compound against one dose of cocaine may yield misleading results. (Adapted from Mello N.K., and Negus S.S., 1996. Preclinical evaluation of pharmacotherapies for treatment of cocaine and opioid abuse using drug self-administration procedures. *Neuropsychopharmacology* 14 (6): 375–424.)

disorder based on epidemiological and experimental evidence that users can maintain abstinence for short periods of time, but typically report a resumption of use despite good intentions to remain abstinent. In clinical studies, the “triggers” for relapse have been described by self-report, and increasingly, by imaging studies aimed at addressing craving in humans. Although the contingencies involved in animal reinstatement studies and human relapse are not parallel, it is compelling that the same types of stimuli produce reinstatement in animals and reports of craving in humans. These so-called triggers consist of a priming effect of the drug (Gawin and Kleber, 1986, O’Brien et al., 1998), exposure to psychological stress (Fox et al., 2011; Sinha, 2001), and environmental stimuli or cues (Childress et al., 1993).

Relapse models (see Fig. 57.3) use variations of several behavioral paradigms. Most commonly, operant self-administration techniques are used, although there is an increasing use of the conditioned place preference paradigm for this purpose (Itzhak and Martin, 2002; Mueller and Stewart, 2000; Mueller et al., 2002). Most of the operant models involve training animals to self-administer a drug of abuse, followed by extinction or forced abstinence and subsequent reinstatement testing. That is, after a period of training in which responding reaches stable levels, animals undergo a period of either forced abstinence

where there is no opportunity to self-administer, or extinction, during which time lever pressing is not followed by drug availability, until responding reaches very low levels. Finally, animals are tested following exposure to one of the relapse triggers, and responding is said to be reinstated if lever-pressing ensues (see Bossert et al., 2005 and Epstein et al., 2006 for reviews).

A model called the “incubation of craving” examines the number of lever presses following different periods of forced abstinence, and has produced responses that increase over time in response to cues, but not to drug primes (Lu et al., 2004). This model can also be used to examine effects of compounds for possible clinical utility in blocking resumption of drug taking after a period of drug unavailability.

TARGETS FOR SUBSTANCE USE DISORDERS

Based on preclinical studies in established animal models of self-administration (Mello and Negus, 1996) and relapse (Epstein et al., 2006), multiple targets for intervention have been identified (Koob et al., 2009; Vocci et al., 2005). These targets range from “classical” biogenic amine receptors (e.g., Bubar and Cunningham, 2008; Heidbreder and Newman, 2010) that

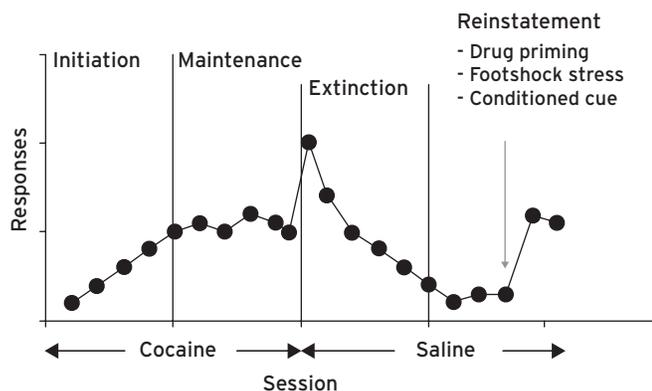

Figure 57.3 Schematic diagram of operant reinstatement model illustrating the phases of training and the point at which testing occurs. During the initiation phase, animals are trained to self-administer cocaine and then subsequently maintained at stable levels of responding for a specified period of time. Then cocaine is replaced by saline in the infusion pump and animals undergo experimental “extinction,” during which time the cocaine is absent and responding gradually falls to low level for a specified period of time. On the test day, animals are exposed to one of the three reinstatement triggers, which could be (1) a priming dose of cocaine, (2) an intermittent footshock stressor, or (3) a cue that was previously paired with cocaine infusions such as a light or tone. Any of these stimuli can reinstate responding at least to maintenance levels and usually higher. Doses of a test compound can be administered prior to the reinstatement trigger to determine if a compound can block reinstatement. Control studies of the effects of the test compound under extinction conditions for food responding are assessed in a different group of animals in order to control for non-specific effects on lever pressing behavior as a result of motor impairment or CNS depression.

have long been linked to other psychiatric disorders to DNA modification (epigenetic) strategies (Adachi and Monteggia, 2009; Renthal et al., 2009; Robison and Nestler, 2011) and biological approaches (Skolnick and Volkow, 2011) aimed at limiting the entrance of abused substance (e.g., nicotine, cocaine) into the central nervous system (Fahim, 2011; Shen and Kosten, 2011). Although converging lines of evidence indicate that many of these targets may be valid, a significant subset may not be “druggable.” From a drug development perspective, this means that it is not possible (within the known chemical space) to synthesize a compound with sufficient specificity, druglike (e.g., favorable solubility, absorption, metabolism, and distribution profile) and safety characteristics. From a biological perspective, a target may be so widely distributed and play such a fundamental role in cell homeostasis, that chronic target engagement (as would be required in toxicology and carcinogenicity studies) would result in unacceptable safety margins for an indication in SUDs.

Given the large number of potential targets and indications, molecules active in several models of SUDs (e.g., self-administration, cue- and prime-induced relapse) and against multiple substances of abuse (e.g., cocaine, nicotine) are of the highest potential value. There are several targets with molecules that fulfill these criteria, but among this subset, few have drug candidates that are sufficiently advanced (or approved) to enable a clinical test of the hypothesis. Several of the most promising targets that fulfill these criteria are described later.

TYPE 5 METABOTROPIC GLUTAMATE RECEPTORS

Type 5 metabotropic glutamate receptor antagonists and negative allosteric modulators (mGluR5) bind to a subclass of Group 1 metabotropic glutamate receptors and these compounds modulate glutamatergic neurotransmission in brain regions that converging lines of evidence have linked to CNS disorders (see Conn, 2003; Schoepp, 2001 for reviews). Over the past decade, accumulating evidence has begun to elucidate the role of glutamate, and specifically, mGluR5 receptors in SUDs (see Olive, 2009, that for review). Several compounds representative of this class that have been tested in animal models have produced effects suggestive of efficacy for SUDs.

Data implicating mGluR5 receptors in drug abuse-related behaviors date back to 2001, when it was first reported that mice lacking the mGluR5 receptor exhibited an impaired locomotor stimulant response to cocaine, and further, failed to acquire cocaine self-administration (Chiamulera et al., 2001). During the past decade, several compounds that have been widely used as research tools for this mechanism have been tested in animal models relevant to SUDs for alcohol, nicotine, cocaine, and methamphetamine.

MPEP (2-methyl-6-[phenylethynyl]-pyridine) and MTEP (3-[2-methyl-1,3-thiazol-4-yl]ethynyl-pyridine), two compounds originally developed by Merck, have been valuable as research tools because they are relatively selective for mGluR5. Both are negative allosteric modulators, but MTEP is more potent and selective than MPEP (Lea and Faden, 2006). These compounds have been used extensively to both characterize the function of the mGluR5 receptor, and study its role in models of drug abuse. A few examples are described next.

There are multiple studies using MPEP and MTEP in models of cocaine self-administration, reinstatement, and conditioned place preference. Tessari et al. (2004) and Kenny et al. (2003) have reported that MPEP reduces operant cocaine self-administration in rodents while having no effect on responding for food. Responding for food is generally used as a control for impairment in lever pressing produced by CNS depression. In relapse models in which animals no longer produce an operant response after extinction training, reinstatement by a cocaine priming injection can be reduced in monkeys (Lee et al., 2005; Platt et al., 2008) and reinstatement by a cocaine cue can be reduced in rats (Backstrom and Hyttia, 2006) by MPEP and MTEP. Finally, in models of cocaine-conditioned place preference in which animals seek an environment previously paired with cocaine, MPEP administered during conditioning dose dependently reduced the acquisition of the preference (McGeehan and Olive, 2003), as well as its reinstatement.

Schroeder et al. (2005) have shown that MPEP dose dependently reduced operant ethanol drinking in rats without affecting inactive lever presses. Similarly, Cowen et al. (2005) reported that MTEP reduced operant self-administration of ethanol by both Fawn-Hooded rats and an inbred strain of alcohol-preferring (iP) rats. In a model of relapse in rats, Backstrom et al. (2004) reported that MPEP dose-dependently reduced responding stimulated by cues previously associated alcohol and therefore reduced reinstatement of ethanol self-administration.

5HT2 RECEPTORS

The data using nicotine as the drug of abuse are similarly compelling. Paterson et al. (2003), Tessari et al. (2004), and Palmatier et al. (2008) have all reported that MPEP reduced nicotine self-administration in rats, and similarly, Tessari et al. (2004) and Bespalov et al. (2005) have reported that MPEP decreases responding for nicotine prime and nicotine cue in reinstatement models.

Taken together, these and other studies suggest that mGluR5 negative allosteric modulators should be evaluated in SUDs. There are several compounds of this class that have been advanced to clinical studies for various indications according to publicly available information including pharmaceutical research services (<http://www.Thomson-pharma.com>), pharmaceutical company websites, and <http://www.clinicaltrials.gov>. Fenobam is a compound developed in the 1970s that had been evaluated first as an anxiolytic, and more recently, as a treatment for Fragile X type mental retardation (Berry-Kravis et al., 2009), recently designated an orphan disease. Other compounds that have either reached Phase I or Phase II for Fragile X include Mavoglurant (Novartis), STX106 (Seaside Therapeutics), and RO-4917523 (Roche). Dipraglurant (Addex) has completed a Phase IIa safety and exploratory efficacy trial for levodopa-induced dyskinesia in Parkinson's disease, and RG07090 (Roche/Chugai Pharmaceuticals) may be in clinical trials for treatment-resistant depression. It is likely that one or more of these compounds will become available for proof-of-concept trials in substance abuse disorders.

Fenobam, for example, has been tested both in animal models of anxiety, and in small, Phase II trials for anxiety. In animal models, fenobam was shown to reverse stress-induced hypothermia at doses of 20 and 30 mg/kg in mice, and it was reported to have anxiolytic effects in the Vogel test at a dose of 30 mg/kg in rats (Porter et al., 2005). It also was shown to increase punished responding in the Geller-Seifter test with an MED of 10 mg/kg (Porter et al., 2005). In a human trial conducted at St. Mary's Hospital in Montreal, nine patients were randomized to fenobam, nine to diazepam, and eleven to placebo. The study lasted five weeks, during which time fenobam was compared to both placebo and diazepam. Over the five weeks of the study, fenobam and diazepam were not significantly different, and both were superior to placebo. Dosing of fenobam began at 100 mg, and subjects were individually titrated. Most adverse events occurred at doses of 200 and 300 mg/day of fenobam (Pecknold et al., 1982) but for the most part, fenobam was well-tolerated. Fenobam was additionally reported to be effective in patients with severe anxiety (Pecknold, 1980).

National Institute on Drug Abuse (NIDA) contract studies have suggested that fenobam sulfate blocks cocaine-priming induced reinstatement at a dose of 60 mg/kg, although the effect was not behaviorally selective. Other NIDA laboratories have shown the same dose reduces cocaine self-administration and cocaine seeking in response to cues in an incubation of craving model (Xi and Gardner, in preparation). These doses are somewhat higher than those that produced anxiolytic effects in animal studies (Porter et al., 2005), suggesting that doses in humans that resulted in anxiolysis may be slightly below an effective dose for substance use disorders.

Serotonergic neurotransmission is mediated through a family of receptors that include both G-protein coupled receptors and ligand-gated ion channels. Serotonin has been implicated in many CNS functions including mood, appetite, sleep, and cognition. Moreover, serotonin is an important modulator of dopaminergic function, with serotonergic projections to most of the major dopaminergic pathways including the nigrostriatal, mesolimbic, and mesocortical. Both 5HT2A and 5HT2C receptors modulate the release of dopamine via glutamatergic and GABAergic mechanisms that have not been fully elucidated (see Alex and Pehek, 2007, for review).

These receptors have also been implicated in modulating the behavioral effects of cocaine and nicotine (Grottick et al., 2001, Levin et al., 2011), and specifically, compounds that either stimulate 5HT2C receptors or block 5HT2A receptors have been shown to attenuate the effects of drugs of abuse in relevant animal models (see Bubar and Cunningham, 2008, for review).

Serotonin 2A and 2C receptors are widely expressed throughout the brain, and can be pre- or postsynaptic, although they appear to be largely postsynaptic. Both have distinct expression patterns on dopaminergic, glutamatergic, and GABAergic neurons, and appear to modulate the function of dopaminergic pathways originating in the VTA through multiple mechanisms (see Bubar and Cunningham, 2008, for review). Compounds acting at these receptors have also been shown to modulate psychostimulant-induced dopamine efflux and the resulting changes in behavior. Engagement of these receptors elicits opposite effects on cocaine-evoked dopamine release, with 5HT2A antagonists reducing, and 5HT2C antagonists enhancing release, respectively (Broderick et al., 2004; Deurwaerdere et al., 2004; Leggio et al., 2009). Such opposing actions have been demonstrated in behavioral studies using measures of cocaine-induced locomotor stimulation; drug discrimination, self-administration, and reinstatement (see Bubar and Cunningham, 2008, for review).

The research tools that have been most widely used to delineate the function of these receptors include M100907 (volinanserin) and ketanserin, 5HT2A antagonists, and WAY 163909 and Ro 60-0175, 5HT2C agonists. Volinanserin was in clinical development as an antipsychotic in the 1990s, and again more recently as a sleep aid. It has been used extensively by the research community as M100907.

Although Fletcher et al. (2002) originally reported that the selective 5HT2A antagonist M100907 did not decrease rates of responding for cocaine or nicotine in rats, a selective reduction of cocaine self-administration across the dose-effect curve of cocaine by M100907 has been observed in primates (unpublished NIDA contract studies). The non-selective 5HT2A antagonist, ketanserin, has been reported to decrease nicotine self-administration in rats (Levin et al., 2008). The effects of 5HT2A antagonists in reinstatement models have also been reported. Pockros et al. (2011) reported that microinfusion of M100907 into the ventromedial prefrontal cortex attenuated cocaine cue induced reinstatement, and Nic Dhonnchadha et al. (2009) reported reductions in cue induced reinstatement after systemic treatment with M100907. Fletcher et al. (2012)

recently reported that M100907 reduced both nicotine prime and cue induced reinstatement in rats. NIDA contract studies are also consistent with reported decreases in cue reinstatement, with no effect on cocaine primed reinstatement following treatment with M100907. Controls for impairment of lever pressing demonstrated that the blockade of cocaine cue reinstatement was not the result of motor impairment.

5HT2C receptor activation can recapitulate many of the behavioral effects of 5HT2A receptor blockade. The 5HT2C receptor agonist, WAY 163909, dose dependently reduced cocaine self-administration in rats, and also blocked cocaine cue-induced reinstatement at doses lower than those that suppress locomotor behavior, suggesting that these effects are not attributable to a generalized suppression of behavior (Cunningham et al., 2011). Another 5HT2C agonist, Ro60-0175, has been reported to reduce nicotine self-administration (Grottick et al., 2001) as well as both cue and primed-reinstatement in rats (Fletcher et al., 2012). It also reduced cocaine self-administration and prime-induced reinstatement in squirrel monkeys (Manvich et al., 2012). In NIDA contract studies, Ro60-0175 was shown to reduce cocaine-prime induced reinstatement, and lorcaserin, a selective 5HT2C agonist developed as a treatment for obesity (Hurren and Berlie, 2011) reduced both methamphetamine prime- and cue-reinstatement. Lorcaserin also has been reported to reduce nicotine self-administration in rats, after both acute and repeated administration, without altering responding for food (Levin et al., 2011). Similarly, Higgins et al. (2012) reported that lorcaserin decreased nicotine self-administration and reinstatement at similar doses to those that affected palatable food, a model related to the obesity indication.

Taken together, these findings indicate that 5HT2A antagonists and 5HT2C agonists may be useful for treating SUDs. Several of these compounds that have advanced to human studies, including 5HT2A antagonists volinanserin and eplivanserin for sleep disorders (Sanofi-Aventis), APD 125 for sleep disorders (Arena Pharmaceuticals), and pimavanserin for psychosis associated with Parkinson's disease (Acadia Pharmaceuticals). Two 5HT2C agonists that have advanced to humans, are vabicaserin for psychosis (Wyeth/Pfizer) and lorcaserin (Belviq), which was recently approved for the treatment of obesity (Arena Pharmaceuticals). Compounds either approved, or in late-phase clinical studies could potentially become available for testing in SUDs (e.g., lorcaserin, pimavanserin). The development of several of these compounds (e.g., vabicaserin, volinanserin) has been halted, making treatment of SUDs an attractive rescue indication, for a potential licensee, given the market size.

Volinanserin was originally developed as an antipsychotic, and was found to block amphetamine stimulated locomotor activity (commonly used as a screen for antipsychotic efficacy) at doses that did not effect locomotor activity alone (see Schmidt et al., 1995 for review). The proposed clinical dose for antipsychotic activity, based on 90% occupancy of 5HT2A receptors, was 20 mg daily, which resulted in plasma concentrations of 18 ng/ml (Talvik-Lotfi et al., 2000). Volinanserin was subsequently dropped from development after it failed to demonstrate an antipsychotic effect compared to haloperidol

(de Paulis 2001). Subsequently, it was developed a second time for sleep maintenance. No data are publically available regarding efficacy for this indication, but receptor occupancy studies suggest dosing was in the range of 20 mg (Grunder et al., 1997; Teegarden et al., 2008). Doses effective in animal studies of cocaine reinstatement were well below 0.1 mg/kg (Nic Dhonnchadha et al., 2009), suggesting that efficacy for substance use disorders may occur at doses lower than those that have been tested in the clinic.

Lorcaserin was effective in reducing weight at doses of 10–20 mgs daily, and was generally well-tolerated in two clinical trials (Hurren and Berlie, 2011). In the first trial, completers who achieved greater than 5% body weight reductions were taking daily doses of 10 (12.8%), 15 (19.5%), and 20 mg/day (31.2%) (Smith et al., 2009). In the second trial, which was larger and multisite, at the end of one year, 47.5% of patients in the lorcaserin group (20 mg/day) and 20.3% in the placebo group lost 5% or more of body weight (Smith et al., 2010). Effects in animal models of food intake and obesity were obtained at doses ranging from 9 to 36 mg/kg (Smith et al., 2008); whereas in animal models of SUDs it was effective at doses up to 1.0 mg/kg. These differences in potency may be the result of differences in route of administration (oral vs. subcutaneous dosing). Nonetheless, these data suggest that lorcaserin would be effective in SUDs at or below doses that were effective for weight loss.

BIOLOGICALS

Substance abuse disorder is the only area in psychiatry currently amenable to the use of biologicals as therapy. Because two proof of principle studies in humans (reviewed in Hatsukami et al., 2011; Shen and Kosten, 2011) have yielded promising results, these studies will be overviewed here. The principle underlying biological approaches to treat SUDs is pharmacokinetic: preventing or slowing the entry of abused substance into the central nervous system. There are three principal strategies for developing biologicals as pharmacotherapies: (1) vaccines that result in the production of antibodies directed toward a specific drug of abuse, (2) monoclonal antibodies directed toward a specific drug of abuse, and (3) genetically engineered enzymes that catalyze the degradation of a specific drug of abuse.

VACCINES

Vaccines directed against nicotine, cocaine, and heroin are in various stages of development (see reviews by Fahim et al., 2011; Koob et al., 2011; Shen and Kosten, 2011). Perhaps the major obstacle to developing vaccines directed against drugs of abuse is that these low molecular weight molecules are not inherently antigenic (i.e., they are not recognized by the immune system). In order to render a small molecule antigenic, the strategy most often employed is chemical modification of the abused substance so that it is capable of covalently bonding to a protein that is now recognized as “foreign” by the immune system. As exemplified by the nicotine vaccine NicVax®, the parent molecule is first chemically converted to 3'aminomethylnicotine,

and it is this molecule that covalently bonds (in the presence of succinaldehyde) to both the amino acid side chains and terminal amino groups of a recombinant protein (Exoprotein A) from *Pseudomonas aeruginosa* (Fahim et al., 2011). An amino acid deletion to this recombinant carrier protein renders it nontoxic, but highly antigenic (Fahim et al., 2011). One proof of concept study with this nicotine vaccine (NicVax®) yielded a positive efficacy signal in a subset of smokers with the highest levels of antinicotine antibodies (Hatsukami et al., 2011). In this cohort (subjects with the highest tertile of antibodies), a significantly higher level of sustained end of trial (eight weeks) abstinence was reported compared with placebo (24.6% vs. 12%, $p = 0.024$). However, this vaccine failed to achieve its primary endpoint in two Phase III trials (<http://www.nabi.com>). No additional details have been publicly disclosed by the sponsor. Other companies have engineered nicotine vaccines with the potential to yield higher antibody titers, and at least one of these is currently in clinical development (<http://www.selectabio.com>). There has been one reported clinical study examining the efficacy of a cocaine vaccine. This vaccine is a cocaine derivative that was linked to an inactivated form of cholera toxin B (Shen and Kosten, 2011). In a 24-week double-blind, placebo-controlled trial, Martell et al. (2009) reported significantly more cocaine-free urine samples during weeks 9–16 in methadone-maintained patients with the highest tertile of anticocaine antibody levels compared with either subjects with lower antibody levels or placebo (45% vs. 35%, respectively). A second efficacy trial with this vaccine is currently in progress. At least one alternative approach, coupling a cocaine analog to a disrupted adenovirus, has yielded very high antibody levels and anticocaine effects (blocking reinforcing and psychostimulant actions) in animals (Hicks et al., 2011; Koob et al., 2011; Skolnick and Volkow, 2011; Wee et al., 2012). This vaccine has the potential for translation to the clinic, whereas other vaccines (e.g., for heroin) are in preclinical development (Stowe et al., 2011).

Despite attempts to make highly antigenic and effective vaccines, based on the clinical data obtained to date, additional innovation is required. Thus, five injections were required for both the successful proof of concept study with NicVax (Hatsukami et al., 2011) as well as the Martell et al. (2009) study using a cocaine vaccine. Compared with other commercial vaccines, a product requiring five vaccinations administered over a period spanning several months is far from ideal. It has been noted (Shen and Kosten, 2011) that although the cocaine vaccine used in the Martell et al. (2009) study produced robust antibody responses to cholera toxin B in every patient, far lower levels of anticocaine antibodies were produced in a significant proportion of subjects. Clearly, strategies aimed at producing higher levels of drug-directed antibodies in response to a vaccine, including newer, more powerful adjuvating agents (both the Nabi and Celtic vaccines used an alum adjuvant), will be required to make a commercially viable product.

MONOCLONAL ANTIBODIES

Although the vaccines described here all require multiple immunizations to produce therapeutic levels of antibodies

(Hatsukami et al., 2011; Koob et al., 2011; Martell et al., 2009), this passive immunization strategy is effective upon administration. The most advanced monoclonal antibody is directed against methamphetamine (Owens et al., 2011), with first-in-human studies in progress. Perhaps the major drawback of passive immunization strategies is the need to readminister the monoclonal antibody because of a limited biological half-life. However, it is now feasible (<http://www.xencor.com>) to genetically engineer mABs with significantly longer biological half-lives, which could ultimately lower the treatment costs of this approach.

ENGINEERED ENZYMES

Cocaine is hydrolyzed in plasma by butyrylcholinesterase. Point mutation studies have demonstrated it is possible to increase the rate of catalysis in an engineered butyrylcholinesterase by more than 1,000-fold compared with the wild type enzyme. This enzyme is capable of reducing the pharmacological actions of cocaine in animals (e.g., administration blocks cocaine lethality as well as cocaine primed reinstatement of drug-seeking behavior) (Brimijoin, 2011; Gao et al., 2005 review). Teva Pharmaceutical is pursuing the development of an engineered esterase (presentation by Dr. M. Bassan at CPDD, June 2012). Like mABs, proteolysis of an engineered butyrylcholinesterase limits its biological half-life, requiring frequent (perhaps weekly or bimonthly) injections. However, gene transfer of an engineered butyrylcholinesterase using an adenoviral vector can produce high levels of this enzyme (that was sustained in rats for several months). This strategy was recently reported (Anker et al., 2012) to block reinstatement to cocaine for up to six months.

There are both advantages and disadvantages to treating SUDs using biological approaches. Among the most compelling reasons to develop these as therapeutics is the potential for a long-lived protective effect, requiring a patient to make one good decision to receive a biological therapy, compared with one (or multiple) daily decisions to remain compliant with traditional pharmacotherapies. The specificity of an effective biologic such a heroin vaccine could dramatically reduce its use, but would neither preclude a patient from receiving maintenance therapy nor prevent the abuse of a structurally unrelated opiate, such as oxycodone. The ability of a patient to circumvent a specific therapy by taking drugs other than the one targeted by the biologic (e.g., an effective cocaine vaccine would not preclude abuse of heroin) is a limitation of these biological approaches. However, this is also a limitation of current medications, exemplified by the use of cocaine while on methadone maintenance therapy (Martell et al., 2009).

Active immunization therapies currently in clinical trials can take weeks or months before antibody titers reach pharmacologically relevant levels (Hatsukami et al., 2011; Martell et al., 2009). This therapeutic lag, along with the requirement for multiple immunizations and high patient expectations of a cure, could negatively impact the commercial success of such a product. Nonetheless, biological approaches represent appealing alternatives that have the potential to change the practice of addiction medicine.

CONCLUSIONS

The contraction of research and development in psychiatry has produced a bumper crop of parked compounds that cannot be either out-licensed or otherwise monetized. This contraction, in combination with a new appreciation of the market potential in treating SUDs, may facilitate the repurposing of compounds developed for other indications. There may be unprecedented opportunities in both the short- and midterm horizons for translating some of the targets identified by preclinical research as promising for the treatment of SUDs. In addition, biological approaches are now viewed as a viable alternative to small molecules. In the case of vaccines, improvements in antibody specificity and titer through the use of more immunogenic recombinant proteins and better adjuvants will be required for commercially viable products. Similarly, genetically engineered monoclonal antibodies and catalytic enzymes with improved biological half-lives also have the potential to transform future addiction treatment and, based on development costs, may be more attractive than small molecules.

Clearly, the pharmaceutical and biotechnology sectors must be more engaged in order to address the need for SUD treatments. Both the funding and expertise required for drug development are simply beyond the scope of academia and the public sector. Despite progress in understanding the neurobiology and genetics of substance abuse, the investment required to bring a molecule to market remains feasible only for the private sector, barring a paradigm shift toward public-private partnerships, government-sponsored cooperative agreements, or other models in which the financial risks are shared or blunted.

DISCLOSURES

Dr. Acri and Dr. Skolnick have no conflicts of interest to disclose. The authors are full time employees of the National Institute on Drug Abuse, National Institutes of Health.

DENISE B. KANDEL, MEI-CHEN HU, AND PAMELA C. GRIESLER

The epidemiology of drug use in the general population includes two distinct streams of research. The more common stream measures consumption patterns by asking individuals whether they have ever used specific classes of drugs, and, if so, how frequently they have done so. The second stream, and one implemented more rarely, measures the extent of problematic drug use by asking individuals about behaviors and symptoms that meet criteria for a substance use disorder.

Currently, the most extensive data on substance use disorders in the US population are provided by four national surveys implemented since 2001. The ongoing National Survey on Drug Use and Health (NSDUH-Substance Abuse and Mental Health Services Administration [SAMHSA], 2011) surveys respondents 12 years of age and older annually. This survey also provides excellent data on patterns of use. The National Epidemiologic Survey on Alcohol and Related Conditions (NESARC) (Compton et al., 2005; Conway et al., 2006; Grant et al., 2004a, 2004b), carried out in 2001–2002, and the National Comorbidity Survey Replication (NCS-R) (Kessler et al., 2005a, 2005b), carried out in 2001–2003, surveyed adults 18 years and older. The National Comorbidity Survey for Adolescents (NCS-A) (Kessler et al., 2012a, 2012b), carried out in 2001–2004, surveyed youths 13–18 years old. These surveys have different strengths and weaknesses and generate somewhat different estimates of rates of substance use and substance use disorders and their comorbidity with other psychiatric disorders in the population.

In this chapter, we present data on the epidemiology and phenomenology of substance use disorders from comparative and developmental perspectives. We discuss six issues:

- The definition and measurement of substance use disorders and characteristics of existing epidemiological studies
- The prevalence of substance use and substance use disorders for legal drugs (cigarettes, alcohol), illegal drugs (marijuana, cocaine), and non-medical use of prescribed psychoactive drugs in different studies among adults and adolescents
- The prevalence of substance use disorders by age, gender, and race/ethnicity
- The comorbidity of substance use disorders with other psychiatric disorders
- Developmental stages of involvement in drugs
- Adolescence as a critical exposure period

The data presented in the chapter are based on publications from these studies and secondary analyses of the data sets that we implemented to illustrate points for which the documentation was not available in published reports.

DEFINITION AND MEASUREMENT OF SUBSTANCE USE DISORDERS

The currently available data on rates of disorders are based on the diagnostic criteria for substance use disorders specified by the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV and DSM-IV-TR; American Psychiatric Association, 1994, 2000). The DSM-IV covers two maladaptive patterns of substance use: abuse, and dependence (addiction); abuse is less severe than dependence and is diagnosed only if criteria for dependence are not met. The criteria for dependence have evolved over the past 30 years with a shift of emphasis from the necessary physiological criteria of tolerance and withdrawal to behavioral criteria for compulsive use. Tolerance and withdrawal form two of the seven potential criteria (Koob et al., 2008: p. 354). Three criteria need to be experienced within a 12-month period in order for the diagnosis of a substance dependence disorder to be made. The seven criteria are: (1) tolerance; (2) withdrawal; (3) impaired control, the substance taken in larger amounts or over a longer period than intended; (4) unsuccessful quit attempts; (5) time spent obtaining, using the substance, or recovering from its effects; (6) neglect of important social, occupational, or recreational activities; (7) continued use despite persistent or recurrent physical or psychological problems caused or exacerbated by the substance. These criteria closely resemble those outlined by the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10; World Health Organization, 1992). In both systems, the specific withdrawal symptoms vary across drugs (Koob et al., 2008: p. 354). Withdrawal from cannabis (marijuana) is not included as a criterion although a cannabis withdrawal “syndrome is now well established (Budney et al., 2003).” (Koob et al., 2008: p. 355) As noted by Hughes (2006), generic criteria are based in part on shared genotype across different drugs, common underlying neurobiological processes, as well as by common behavioral correlates, such as antisocial syndromes (Compton et al., 2005; Koob et al., 2008: p. 354; Nelson et al., 1999).

Abuse is a distinct diagnostic category that excludes individuals who meet criteria for dependence. Abuse requires recurrent substance use during a twelve-month period resulting

Notes: Secondary analysis of data sets.

^a Asked of those who ever consumed at least 12 drinks in a year.

^b Based on having ever smoked at least 100 cigarettes, or 50+ cigars, or 50+ times pipes, or used snuff or chewing tobacco 20+ times lifetime in NESARC. Last 12-month question asked of those who ever smoked tobacco daily for a two-month period in NCS-R and NCS-A.

in at least one of four harmful consequences: failure to fulfill major role obligations at work, school, or home; hazardous use, such as driving an automobile or operating a machine when impaired by substance use; legal problems, for example, arrests for substance-related disorderly conduct; and continued use despite social or interpersonal problems caused by the substance.

The criteria for tobacco (nicotine) dependence are the same as for alcohol and illicit drugs. Abuse does not apply to tobacco.

These definitions differ substantively from those in the fifth edition (DSM-5) of the American Psychiatric Association, which will become the standard as of 2013. In the DSM-5, the distinction between abuse and dependence will be eliminated and, for all substances including tobacco, the criteria for drug disorder will be 2 out of 11 criteria (Hasin, 2012a, 2012b; O'Brien, 2011; Schuckit, 2012). This decision was based on secondary analysis of several large-scale epidemiological data sets. Craving was considered, in addition to the seven traditional DSM-IV criteria. The methods used to determine the relationship between abuse and dependence included factor analysis to establish unidimensionality, item response theory to assess the relationship of abuse to dependence criteria, criterion/item characteristic curves to examine the severity and discrimination of each criterion relative to each other, and total information curves to allow comparisons of two or more sets of criteria (Hasin, 2012a; Hasin et al., 2012; Saha et al., 2012). The evidence suggested that abuse and dependence formed one disorder. Craving was added as a diagnostic criterion but legal difficulties was eliminated (O'Brien, 2011), leaving a total of 11 criteria. Based on analyses of existing data sets, this definition is expected to generate rates of substance use disorders similar to those derived from combining rates of DSM-IV dependence and abuse. However, the rates will in all likelihood be higher than the rates of DSM-IV dependence discussed in this chapter, which do not include abuse.

LIMITATIONS OF MEASUREMENT: DIFFERENCES ACROSS SURVEYS

There are important differences among the surveys regarding the measurement of drug use, drug abuse, and drug dependence. Methodological features affect comparability across studies, the rates they each report, and lead to substantial variations in prevalences.

Discrepancies in estimates of prevalence and the correlates of substance use and substance use disorders between the NSDUH and NESARC were discussed in detail by Grucza et al. (2007). A discussion of NSDUH methodology compared with other surveys is also provided by Hedden et al. (2012). Two limitations of the assessments regarding alcohol and illicit drugs implemented by the National Comorbidity Studies, both the replication among adults (NCS-R) and the adolescent survey (NCS-A), have also previously been highlighted (Cottler, 2007; Grant et al., 2007). In the NCS, abuse symptoms were used as a screen so that respondents were not asked the dependence questions unless they had endorsed at least one abuse symptom. Because in the DSM-IV abuse symptoms are not

required for the dependence diagnosis, this strategy results in an underestimate of dependence in the population. As illustrated by NESARC, a substantial number of individuals meet criteria for dependence although they are negative for abuse, 33.7% for those dependent on alcohol and 22.4% for those dependent on an illicit drug (Hasin and Grant, 2004; Hasin et al., 2005). The underestimate is especially pronounced among women and minorities. Second, in the NCS the assessment of abuse and dependence on marijuana and other illicit drugs was made for different illicit drugs as a group rather than for each drug separately, thereby creating a generic diagnosis of drug abuse or drug dependence, rather than one that was drug specific, as specified by the DSM-IV (Cottler, 2007). Asking about symptoms for drugs as a group may have led to underestimates of reports compared with asking about each drug separately. The principal investigators of the NCS-R and NCS-A studies acknowledged the validity of the first criticism but not the second (Kessler and Merikangas, 2007).

A third limitation of the NCS, not previously noted, pertains to the assessment of nicotine dependence. Among smokers, assessment was restricted to those who had smoked daily for a two-month period. This reduced the number of smokers eligible to report symptoms of dependence. Craving, a symptom that is not part of the DSM-IV definition, was included first in a list of eight criteria of nicotine dependence; tolerance and withdrawal were listed second and third. The logic and skip patterns of the interview schedule resulted in the inclusion of two different groups among those defined as nicotine dependent: (1) tobacco users who endorsed the first three criteria, but who were not asked the remaining five criteria, and (2) tobacco users who had endorsed up to two criteria among the first three and were asked all remaining five criteria. Finally, the definition of nicotine dependence applied to adolescents (NCS-A) did not apply the DSM-IV requirement that three symptoms be experienced within a 12-month time frame.

There are additional differences in the assessment of drug use and the eligibility of respondents for answering abuse and dependence questions across surveys. In NESARC, respondents were asked which illicit drugs they had used from a list of ten drug classes. Non-medical use of medically prescribed drugs was listed first; the last class included "any other medicines or drugs (not otherwise defined)." More detailed questions about drug-specific patterns of use were then asked for each drug reported to have been used. Symptoms of dependence were ascertained first without reference to any drugs. Respondents were then asked which "medicines or drugs did this happen with?" during the last 12 months, and before the last 12 months. The NSDUH asked only about symptoms experienced in the last 12 months but not lifetime. In NESARC, being a smoker was defined as having ever smoked at least 100 cigarettes. The nicotine dependence questions were ascertained in this restrictive group of smokers, whereas the NSDUH asked these questions of anyone who had ever smoked, even if only a puff. As noted earlier, in the NCS the last 12-month smoking and nicotine dependence questions were restricted to individuals who had smoked daily for at least two months. The alcohol abuse and dependence questions were restricted to those who had ever drunk 12 drinks in a year.

TABLE 58.2. Lifetime and last 12-month prevalence of substance abuse and dependence among persons aged 18 and older in NSDUH 2010 (N = 39,259), NESARC 2001–2002 (N = 43,093), and NCS-R (N = 5,692)

ⁱ DSM-IV in NCS-R and NESARC; last 30 days NDSS in NSDUH.

^j Based on having ever smoked at least 100 cigarettes, or 50+ cigars, or 50+ times pipes, or used snuff or chewing tobacco 20+ times lifetime in NESARC. Asked of those who ever smoked tobacco daily for a two-month period in NCS-R.

There are also differences in mode of survey administration that impact on the resulting rates of self-reported drug behavior. Of the surveys, NSDUH is the only anonymous one. In addition, the assessment of lifetime symptoms based on retrospective reports may lead to undercounts compared with repeated prospective assessments (Moffitt et al., 2010).

Thus, existing surveys have different strengths and weaknesses. NESARC has the most systematic assessment of substance use disorders and psychiatric disorders. The repeated annual NSDUH surveys provide the best data on patterns of use of legal and illegal drugs in the population. They also include detailed DSM-IV assessments of abuse and dependence on alcohol, specific illicit drugs, and the non-medical use of medically prescribed drugs for the last 12 months but not lifetime. Nicotine dependence is measured by the NDSS (Shiffman et al., 2004) rather than the DSM-IV. Anonymity in the NSDUH may have led to higher rates of self-reported drug use than in NESARC, whereas differences in instrumentation may have led to higher rates of last 12-month substance use disorder among the self-acknowledged drug users in NESARC than NSDUH. The NSDUH surveys respondents as of age 12, making possible comparisons between adolescents and adults. The nature of the NCS-R and NCS-A assessments greatly limit the quality of the data collected on substance use disorders, although they allow comparisons between adults and adolescents, because the same methodology (although flawed) was implemented in both surveys.

We implemented extensive secondary analyses of the four data sets in order to increase comparability across studies. For reasons of confidentiality, the public use NSDUH data included 84.5% of the original sample, so that in certain instances the figures in this chapter differ very slightly from published ones. To increase comparability of NCS with the other surveys, we reran NCS data on abuse excluding cases that met criteria for dependence. We also applied the DSM-IV requirement of experiencing three criteria within a 12-month period for nicotine dependence in NCS-A. We included nicotine dependence in summary measures of drug disorder for all the surveys. Finally, we excluded respondents 18 years old from the NCS-A sample to obtain a sample 13–17 years old and increase comparability with the sample of adolescents 12–17 years old in NSDUH.

Taking into account the issues discussed earlier, the data presented by any one study must be interpreted with caution. Comparisons across studies are subject to many limitations.

PREVALENCE OF SUBSTANCE USE AND DISORDERS

PREVALENCE OF SUBSTANCE USE AND DISORDERS AMONG ADULTS

The lifetime and last 12-month prevalence of use of specific substances in the NSDUH, NESARC, and NCS-R for persons aged 18 and over are presented in the first two panels of Table 58.1.

The rates of use for alcohol are very similar across the three studies, whereas those for tobacco and illicit drugs (as a group) are similar in the NSDUH and NCS-R, but much lower in NESARC (see Table 58.1, Panels 1 and 2). The discrepancy

for tobacco is explained by the fact that, in NESARC, smoking at least 100 cigarettes lifetime was required to be defined as a smoker. Yet, 36% of smokers in the NSDUH never smoked 100 cigarettes. When restricted to those who smoked at least 100 cigarettes, the rate in NSDUH is identical to NESARC. It is not clear why the overall rates of lifetime or last year illicit drug use in NESARC are half those of the other two surveys. Lack of anonymity may be one explanation. The discrepancies are especially large for cocaine, with 16.3% and 16.2% in NSDUH and NCS-R, respectively, reporting lifetime use compared with only 6.1% in NESARC (see Table 58.1, Panel 1) (see Grucza et al., 2007). Despite these differences in absolute rates across studies, the relative rankings for overall prevalence of use are the same. Alcohol is the substance that is used most widely, followed by tobacco and illicit drugs. Half the adults 18 and over in the United States have used an illicit drug, including non-medical use of a prescribed drug, representing 113 million individuals in 2010. Of these drugs, marijuana is the most prevalent, followed by cocaine; almost three times as many individuals have ever used marijuana as have used cocaine (Table 58.1, Panel 1). The higher rates in NSDUH and NCS-R than NESARC increase the base of individuals eligible for being asked the questions relevant to drug abuse and dependence and the absolute number identified as meeting criteria for abuse or dependence.

Lifetime and last 12-month rates of abuse or dependence in the total adult population, lifetime rates among lifetime users of each drug, last 12-month rates among last 12-month users, and last 12-month rates among lifetime abusers or dependents are presented in Table 58.2. None of the published reports from the studies include nicotine dependence in any substance use disorder. This is a serious omission inasmuch as tobacco is one of the two most addictive substances that are used, second to heroin. Table 58.2 presents rates of abuse and dependence separately for alcohol, illicit drugs as a group, nicotine, any substance use disorder as reported in the literature (Row 5), and rates including nicotine dependence that we calculated from secondary analysis of the public use data (Row 9). The conditional rates among users specify the risk of abusing or becoming dependent on a drug among those who consumed the drug in their lifetime or the last 12 months. The conditional rates of last 12-month abuse or dependence among those who met lifetime criteria index chronicity of abuse or dependence.

Except for illicit drug dependence, the rates of lifetime and last 12-month abuse and dependence for all drug classes in the total adult population and among last 12-month users were consistently the lowest in NCS-R (Table 58.2, Panels 1, 2 and 4).

In NESARC, close to 40% of the population 18 years old and over ever met criteria for a substance disorder (abuse and/or dependence), including nicotine dependence; 17.7% met criteria for nicotine dependence, 12.5% for alcohol dependence, 2.6% for illicit drug dependence (Table 58.2, Panel 1). The 12-month rates were 80% to 28% lower than lifetime rates. Slightly less than 20% of the population met criteria for a substance use disorder within the last year in NESARC, a rate very similar to the NSDUH (Table 58.2, Panel 2). The proportion meeting criteria for abuse or substance dependence on a given

drug among individuals who used the drug varied greatly across drug classes. Across all surveys, conditional upon lifetime use, nicotine emerged as the most addictive of the substances, with 37.8% of tobacco users in NESARC meeting criteria for lifetime dependence (Table 58.2, Panel 3). This compares with 28.2% among heroin users (Compton et al., 2005). Among last year users, however, heroin emerged as the most addictive substance in NSDUH, followed by tobacco, sedatives, cocaine, and analgesics. The ranking in NESARC, wherein heroin could not be ranked because of the small number of users, was tobacco, cocaine, and stimulants (data not presented). The conditional last 12-months rates among last 12-month users were the highest in NESARC for any substance use disorder with or without nicotine (Table 58.2, Panel 4), although there were differences among specific illicit substances. The rates were higher in NESARC than NSDUH for cocaine and stimulants, lower for analgesics and sedatives, and the same for alcohol, marijuana, inhalants, hallucinogens, and tranquilizers (data not presented). The proportion of individuals with an alcohol-related disorder among those who consumed alcohol in the last year was among the lowest of any of the substances. However, because so many individuals consume alcohol, this percentage translates into a large number of affected individuals. Detailed comparison across drug classes could not be made in the NCS-R.

Substance use disorders are chronic disorders. As illustrated by NESARC, close to half of those who met lifetime abuse or dependence criteria on any substance still experienced these symptoms within the last year (Table 58.2, Panel 5). These rates could not be calculated for NSDUH, which only measured last 12-months abuse and dependence. While rates of chronicity of dependence are consistently lower in NCS-R than NESARC, the patterns across drug classes are identical. Nicotine is by far the most chronic of the addictions, with 72.0% of tobacco users in NESARC meeting criteria for last 12-month dependence among those who ever met lifetime criteria. Chronicity is slightly higher for dependence on alcohol (30.5%) than illicit drugs (24.2%) (Table 58.2, Panel 5). Chronicity of dependence is also relatively high among those who consume prescribed drugs non-medically, especially analgesics (data not presented).

PREVALENCE OF SUBSTANCE USE AND DISORDERS AMONG ADOLESCENTS

The behavior of adults 18 years old and over could be compared with that of adolescents 12–17 years old in NSDUH and 13–17 years old in NCS-A. Except for inhalants, the prevalence of lifetime use of various substances is lower among adolescents than adults, with wide differences across substances (Table 58.1, Panels 3 and 4). Although the absolute rates differ between NCS-A and NSDUH, the patterns are strikingly similar in both surveys. As illustrated by NSDUH, the lifetime adolescent rates for alcohol and any tobacco use are about 40% and those for any illicit drug about 50% of those observed among adults, and only 10% for use of 100 cigarettes or more. There are great variations across specific illicit drugs in the ratio of adolescent to adult prevalence rates. Inhalants is the only drug class for which the rates are the same. With respect

to last 12-month use, the age patterns reverse for illicit drugs, where adolescents have higher rates than adults, 19.6% versus 15.0% in NSDUH and 16.2% versus 11.0% in NCS.

The overall rates of any substance use disorders among lifetime users are the same among adolescents and adults, although there are differences across substances. Lifetime dependence on illicit drugs among lifetime users is higher among adolescents, whereas tobacco dependence is lower than among adults (NCS, Tables 58.2 and 58.3, Panel 3). The last 12-month rates among 12-month users are consistently higher among adolescents than adults in both surveys, except for tobacco dependence in NSDUH (Tables 58.2 and 58.3, Panel 4). The differences are greater in NCS-A than NSDUH, where three times as many adolescents (31.0%) as adults (10.1%) meet criteria for any substance use disorder among those who used those drugs within the last 12 months (NCS, Tables 58.2 and 58.3, Panel 4). Persistence is also much higher among adolescents than adults (Tables 58.2 and 58.3, Panel 5), reflecting the fact that duration since onset of drug use is much shorter for adolescents than adults.

COMORBIDITY OF USE AND DISORDERS ACROSS SUBSTANCES

Consideration of each drug class by itself underestimates the extent of drug use in the population because many individuals use more than one class of drugs. Thus, in 2010, only 8.2% of the population aged 18 and over had not experimented with any substance; 44.2% had experimented with all three major classes: alcohol, tobacco, and illicit drugs (based on NSDUH 2010).

Similarly, substance use disorders on multiple drugs tend to cooccur. In NESARC, 40.3% of individuals 18 and over who met criteria for abuse or dependence on one drug class also met criteria for abuse or dependence for at least another drug; 11.7% met criteria for two other substances. The highest comorbidity was between dependence on an illicit drug and dependence on alcohol (70%) or nicotine (69%) (secondary analysis of NESARC). Yet, only a minority of addicted individuals have been treated for their addiction (Compton et al., 2007).

PREVALENCE OF SUBSTANCE USE AND DISORDERS BY AGE, GENDER, RACE/ETHNICITY

There are important differences in the prevalence of use and substance use disorders in different subgroups in the population, but the patterns are not necessarily consistent across surveys. Age differences were examined in all four surveys, but only in NSDUH and NESARC for gender and race/ethnicity.

AGE

Differences between adolescents and adults were discussed earlier. Adulthood itself can be differentiated into periods. Four age

TABLE 58.3. Lifetime and last 12-month prevalence of substance abuse and dependence among persons aged 12–17 in NSDUH 2010 (*N* = 18,614) and aged 13–17 in NCS-A (*N* = 9,525)

Notes: Based on secondary analysis of data sets.

^a Asked of those who ever consumed at least 12 drinks in a year in NCS-A.

^b DSM-IV in NCS-A; last 30 days NDSS in NSDUH.

^c Asked of those who ever smoked tobacco daily for a two-month period in NCS-A.

groups (ages 12/13–17 to ages 50+) could be differentiated in NSDUH and NCS and three age groups (ages 18–25 to 50+) in NESARC. Rates of last 12-month use by age in the population are presented in Figure 58.1A–C, and rates of last 12-month dependence among last 12-month users are presented in Figure 58.1D–F. Age-related trends are presented for tobacco users in NCS, and for all cigarette users in NSDUH as well as for those who smoked at least 100 cigarettes, the NESARC definition of being a smoker, to maximize comparability between the two surveys.

Age-related patterns are very similar across the surveys, although the absolute rates of use or dependence may differ. The prevalence of substance use varies greatly by age. With the exception of tobacco (cigarettes), age-related differences are stronger for use in the population than for dependence among those who used a particular substance.

Rates of use of all substances increase sharply throughout adolescence, and decline also sharply from ages 18–25 for illicit drugs (see Fig. 58.1A–C). Use of cigarettes declines more

slowly; the decline for those who smoked at least 100 cigarettes occurs at older ages. In NSDUH and NESARC, the prevalence of drinking alcohol remains at fairly stable levels from ages 18 to 49, when rates start to decline. In NCS-R, rates decline as of ages 26–34.

Among last 12-month users, age-related patterns for dependence differ from those for use itself (see Fig. 58.1D–F). For all cigarette users (NSDUH), conditional rates of nicotine dependence rise sharply from adolescence to the mid-thirties and then more slowly thereafter (see Fig. 58.1D). Rates of nicotine dependence (for those who smoked 100 cigarettes or more or used tobacco daily) change little with age in NSDUH and NCS but decline as of age 35–49 in NESARC (see Fig. 58.1D–F). The rates of alcohol dependence decline gradually as of ages 18–25, except for a sharp drop from ages 18–25 to 26–34 in NESARC. In the three surveys, the conditional rates of dependence on illicit drugs decline slowly over time as of age 18–25 (see Fig. 58.1D–F).

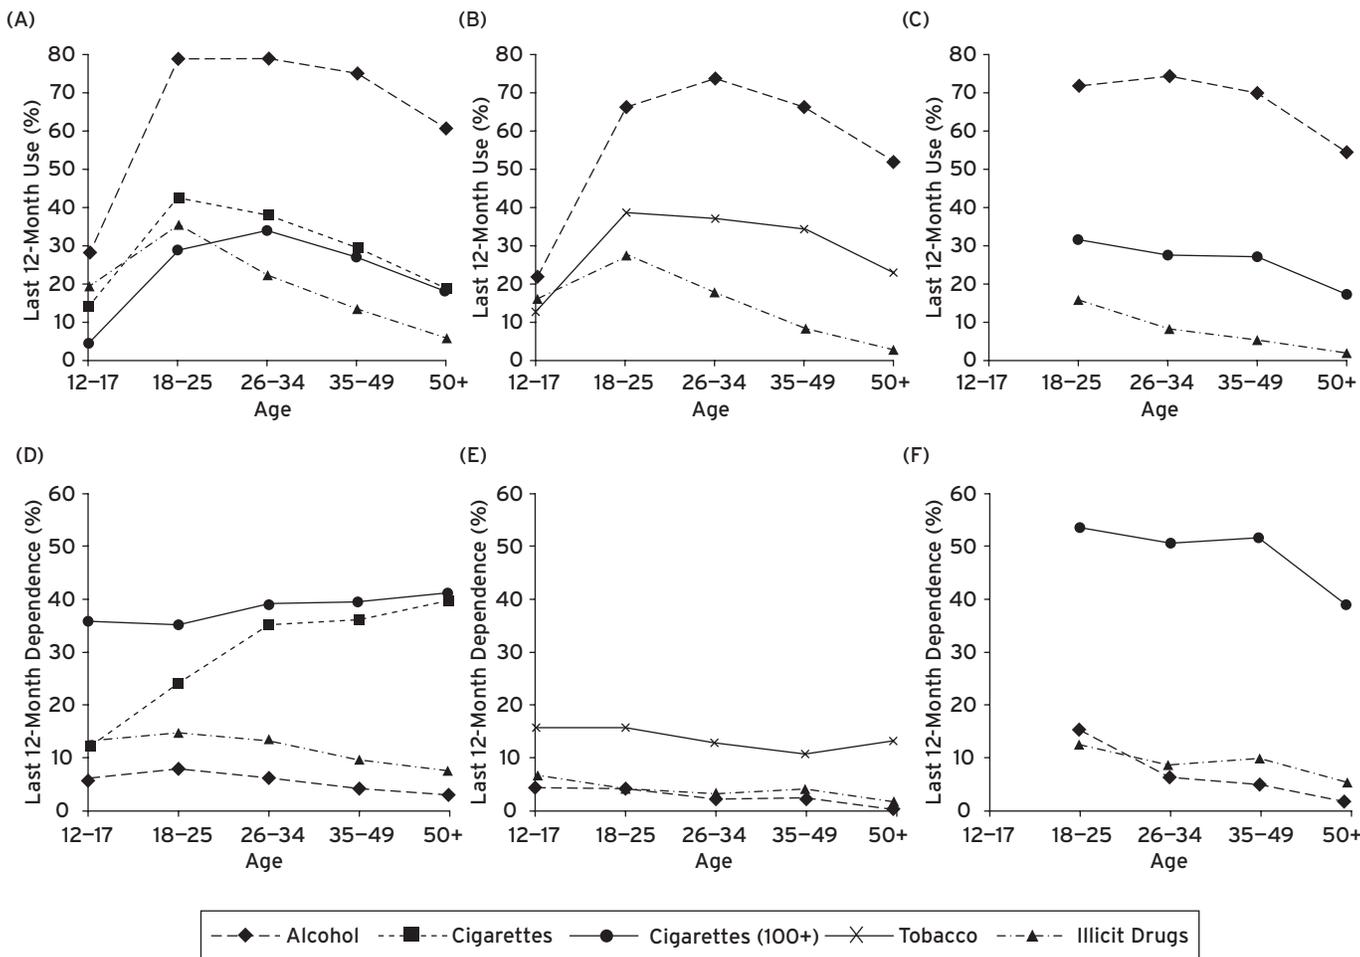

Figure 58.1 Prevalence of last 12-month use by age of alcohol and illicit drugs in (A) NSDUH, (B) NCS-R, NCS-A, (C) NESARC; of any cigarettes (NSDUH); of any cigarettes 100+ lifetime (NSDUH, NESARC); or of tobacco (NCS-R, NCS-A); and prevalence of last 12-month dependence by age among last 12-month users in (D) NSDUH, (E) NCS-R, NCS-A, (F) NESARC.

GENDER

Gender patterns for substance use and substance use disorders are similar in NSDUH and NESARC (Table 58.4). For all substances, including nonmedical use of psychotherapeutics, males have consistently higher rates of use than females, with the rates higher by 10–20% for alcohol, and 50–60% higher for tobacco and all illicit drugs combined. Gender differences are especially pronounced for marijuana and cocaine.

Among drug users, the rates of abuse and dependence on alcohol and illicit drugs are also consistently higher for males than females, except for nicotine, for which the rates of dependence are the same for males and females in NSDUH but significantly higher for females than males in NESARC (see Table 58.4). Combining all substances, the conditional rates of overall substance use disorders, including nicotine, are 39% higher in NSDUH and 28% higher in NESARC among males than females.

RACE/ETHNICITY

Racial/ethnic differences in patterns of substance use and disorders in the population are similar in NESARC and NSDUH

(Table 58.5). In both surveys, Asians have the lowest rates of use and disorder for every drug class, except for tobacco dependence and illicit drug abuse in NESARC. In NESARC, whites have the highest rates of any group for alcohol abuse and nicotine dependence; African-Americans and Hispanics have the highest rates of illicit drug dependence. In the NSDUH, ethnic patterns are less consistent. Whites have much higher rates of nicotine dependence among last 12-month smokers than any other racial/ethnic group. African-Americans tend to have higher rates of dependence on illicit drugs than any other group. The most striking differences are the higher rates of alcohol use and nicotine dependence among whites than any other group, and the higher rate of dependence on illicit drugs among African-Americans (see Table 58.5).

COMORBIDITY OF SUBSTANCE USE DISORDERS WITH PSYCHIATRIC DISORDERS

“There is extensive comorbidity between addiction and mental illness, as documented by NESARC. Among individuals

TABLE 58.4. Last 12-month prevalence of nonmedical substance use and last 12-month DSM-IV abuse and dependence among last 12-month users aged 18 and older by gender in NSDUH 2010 and NESARC 2001–2002

^a Based on having ever smoked at least 100 cigarettes, or 50+ cigars, or 50+ times pipes, or used snuff or chewing tobacco 20+ times lifetime in NESARC.
^b DSM-IV in NESARC; last 30 days NDSS in NSDUH.

with a diagnosis of abuse or dependence on illicit drugs, 40.9% met criteria for mood disorder, 29.9% for anxiety disorder (Conway et al., 2006), 18.3% for antisocial personality disorder, and 57.5% for any psychiatric disorder (unpublished analysis). The rates were at least 50% higher among those who met criteria specifically for illicit drug dependence (i.e., 61.7% for mood, 47.2% for anxiety, 32.9% for antisocial personality, and 78.2% for any psychiatric disorder) (Koob et al., 2008: p. 362) (Table 58.6). The rates among those dependent on alcohol or nicotine were similar and lower than those for the seven classes of illicit drugs that were considered. For alcohol dependence, the rates were 40.0% for mood, 32.3% for anxiety, 14.3% for antisocial personality, and 55.9% for any disorder. Comorbidity rates among those dependent on nicotine were similar to those dependent on alcohol, namely 36.6%, 30.8%, 11.2%, and 52.2%, respectively. The associations between psychiatric disorders and substance dependence are highly statistically significant for all substances and all classes of psychiatric disorders. The associations are somewhat higher with mood than anxiety disorders, and much higher—by a factor of two or three—with antisocial personality than mood or anxiety disorders” (Koob et al., 2008: p. 362) with odds ratios ranging from 15 to 23 for illicit drugs (Table 58.6). Among the mood disorders, mania has the highest association with dependence for every illicit drug, as does panic with agoraphobia among anxiety disorders (Conway et al., 2006, see Tables 4 and 5).

For all three broad classes of psychiatric disorders, the lower the overall prevalence of dependence on a specific substance in the population, the greater its comorbidity with psychiatric disorders (Compton et al., 2005; Conway et al., 2006).

“A particularly strong comorbidity, observed in clinical samples but not in the general population, because of the small numbers of affected individuals, is that of schizophrenia with smoking and nicotine dependence. Rates of smoking are three to four times higher among schizophrenics than in the general population and higher than among individuals diagnosed with other psychiatric disorders (Kumari and Postma, 2005; Volkow, 2009; Wing et al., 2012). Smoking may represent self-medication for the cognitive and negative symptoms prominent in schizophrenia, given the interaction of nicotine with dopaminergic and glutamatergic transmitter systems (de Leon and Diaz, 2005; Kumari and Postma, 2005).

As suggested by Compton et al. (2005), the strong association with antisocial personality disorder across various substances may reflect an underlying comorbidity factor rather than substance specific links. This has important implications regarding the potential commonality of selected mechanisms and genetic factors underlying substance use disorders and psychiatric disorders, especially antisocial personality disorder.” (Koob et al., 2008: p. 362)

To the extent that gender differences appear, comorbidity of psychiatric disorders with substance use disorders is consistently higher among females than males. Comorbidity is higher for any mood disorder with alcohol and nicotine dependence, and for antisocial personality with alcohol, nicotine,

and any illicit drug dependence (Compton et al., 2005; Grant et al., 2004a; Unpublished analysis of NESARC; data not presented). There are several gender differences in the association of specific anxiety and mood disorders with specific illicit drug disorders (see Conway et al., 2006). “Although rates of psychiatric disorders vary substantially across racial/ethnic groups, the association between alcohol dependence and illicit drug dependence with mood and anxiety disorders is similar among whites, African-Americans, Hispanics, and Asians (Smith et al., 2006).” (Koob et al., 2008: p. 362) Hispanics have the highest rate of mood disorder comorbid with nicotine dependence, while African-Americans have the lowest, and Asians the highest, rates of antisocial personality disorder comorbid with nicotine and illicit drug dependence (unpublished analysis of NESARC).

DEVELOPMENT OF PSYCHIATRIC COMORBIDITY WITH DRUG DEPENDENCE

“These cross-sectional associations do not inform on developmental processes underlying comorbidity, whether mental illness follows and causes drug dependence or whether drug dependence follows and causes mental illness. For some cases, mental illness and addiction may cooccur independently (Grant et al., 2004b); for others, there might be a sequential relationship. The direction of causality between psychiatric disorders and dependence is ambiguous because both pathways of influence have been documented. For instance, among adolescents and young adults, when drug use and psychiatric disorders have their onset, depression, social anxiety, and

disruptive disorders predict the onset of smoking and nicotine dependence (Breslau et al., 2004; Karp et al., 2006; Kessler, 2004), but prior smoking and nicotine dependence also predict depression, disruptive disorders, panic attacks and disorder, and agoraphobia (Boden et al., 2010; Breslau et al., 2004; Isensee et al., 2003; Klungsoyr et al., 2006).” (Koob et al., 2008: p. 362) Analysis that we conducted in a longitudinal sample of adolescent smokers (mean age 16.7) indicated that DSM-IV psychiatric disorders preceded and, for the most part, predicted the onset of nicotine dependence, while nicotine dependence rarely predicted psychiatric disorder (Griesler et al., 2008, 2011). Anxiety, mood, and disruptive disorders had their onset at least 2.5 years before nicotine dependence. Psychiatric disorders started, on average, between ages 10.6 and 11.7, tobacco use at age 13, the first symptom of nicotine dependence at age 14.3, and full nicotine dependence at age 14.7. Panic disorder, attention-deficit hyperactivity disorder, and oppositional defiant disorder predicted the onset of nicotine dependence; nicotine dependence predicted the onset of oppositional defiant disorder. Depression and nicotine dependence did not predict each other. In adults, psychiatric disorders predicted persistent course of alcohol, nicotine, and illicit drug dependence but substance use disorders did not predict persistence of mood or anxiety disorders (Hasin and Kilcoyne, 2012).

The mechanisms underlying the comorbidity between substance use disorders and psychiatric disorders are not properly understood. Both classes of disorder may be caused by shared genetic or environmental factors. “It is likely that different neurobiological factors are involved in comorbidity depending on its development. When mental illness is followed by dependence on some types of drugs, comorbidity might reflect self-medication. However, when drug dependence is followed

by mental illness, chronic drug exposure itself may lead to changes in the brain that would increase the risk for mental illness, particularly in persons with genetic vulnerability. For example, the high prevalence of smoking after individuals become depressed could reflect the antidepressant effects of nicotine and of monoamine oxidase A (MAOA) and B (MAOB) inhibition by cigarette smoking (Fowler et al., 2003).” (Koob et al., 2008: p. 362)

DEVELOPMENTAL STAGES OF INVOLVEMENT IN DRUGS

“Not only are there regular patterns of cooccurrence of use and dependence across drugs, but there are regular sequences of progression from the use of one drug class to another. The existence of a developmental sequence of involvement in drugs is one of the best replicated findings in the epidemiology of drug use (Kandel, 2002). In the United States and other Western societies, a regular sequence of progression has consistently been found. The use of cigarettes or alcohol precedes the use of marijuana and, in turn, the use of marijuana precedes the use of other illicit drugs (Fig. 58.2). Very few individuals among those who have tried cocaine have not previously used marijuana (2%), cigarettes (3.6%), or alcohol (2.2%) (based on NSDUH 2010). The majority (66.8%) of individuals have used alcohol or cigarettes prior to marijuana use or at the same age. Such behavioral regularities have given rise to the gateway hypothesis” (Koob et al., 2008: p. 360) to emphasize that certain drugs serve as gateways for the use of other substances. The drugs used earlier increase the risk of using other drugs. Even now, when rates of marijuana use among

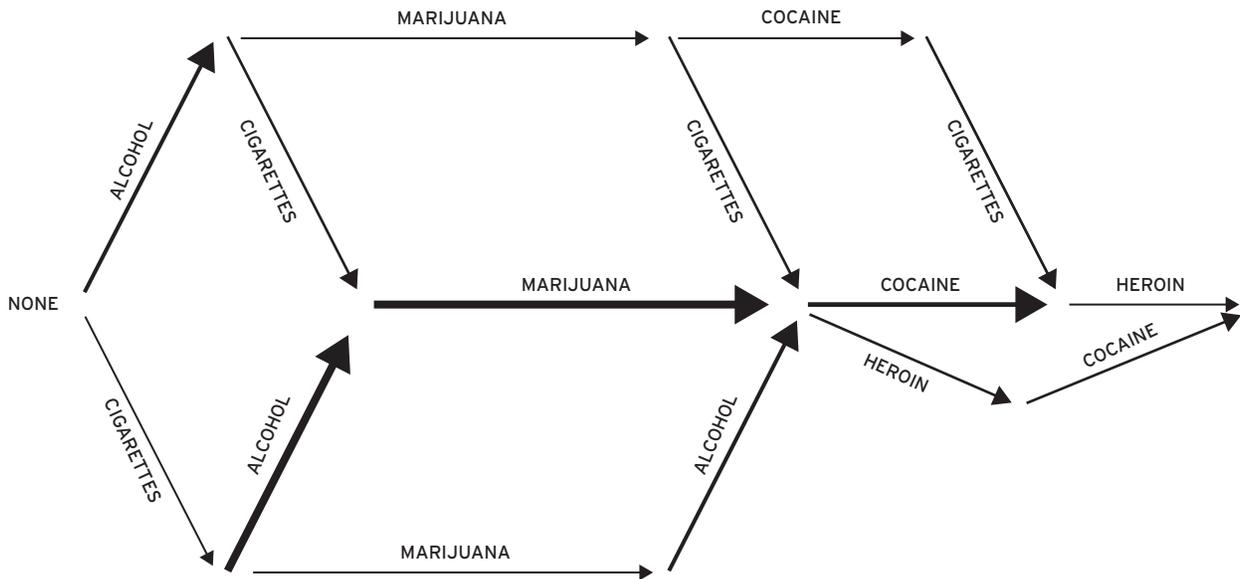

Figure 58.2 Pathways of drug involvement.

young people have greatly increased and even surpass slightly those of cigarette use, the majority of those who have experimented with marijuana or cocaine had first experimented with cigarettes or alcohol. Thus, among high school seniors in the 2010 *Monitoring the Future* (MTF) Survey, 42.2% ever smoked cigarettes, 71.0% ever drank alcohol, 43.8% ever used marijuana or hashish, and 5.5% ever used cocaine (Johnston et al., 2010). Yet, 54.8% had started smoking cigarettes or using alcohol prior to using marijuana and 33.7% had started using these drugs in the same grade; only 8.6% of marijuana users had started to use marijuana before smoking or drinking alcohol; 2.9% had only used marijuana. Parallel percentages for cocaine are 73.3% who smoked or drank alcohol prior to starting using cocaine; 19.9% started in the same grade, and 6.8% used cocaine prior to cigarettes or alcohol (unpublished analysis of MTF).

However, since publication of the original observation in 1975 (Kandel, 1975; Kandel and Faust, 1975), “surprisingly little progress has been made in addressing fundamental questions that derive from the finding that the use of one class of drug is followed by the use of another class. We still do not know (1) whether the use of a class of drugs used first, such as tobacco, is a cause of the use of the second class, such as cocaine, or whether the sequence is determined exclusively by availability of the drug or other social factors; and (2) what biological mechanisms underlie this progression in drug use. Although epidemiological studies have established the sequence between substances and specified their association, epidemiological studies cannot establish a causal progression nor can they identify the underlying cellular and molecular mechanisms that could contribute to the gateway sequence of drug use.” (Koob et al., 2008: p. 360)

To obtain biological insights into the transition from nicotine to cocaine in the development of drug abuse and address how gateway drugs exert their effects, Kandel and colleagues at Columbia University have bridged the epidemiology of drug

abuse and molecular biology by developing a mouse model of this epidemiological sequence so as to explore the behavioral, physiological, and molecular genetic mechanisms underlying the gateway sequence. Animal models can provide a rigorous test of drug use progression in which drug-taking behavior can be observed in relation to well-defined prior experiences with specific drugs, independently of any social or legal constraints regulating and defining drug use. In mice, one can readily control the order in which drugs are taken so that the order is the only determinant of outcome. Alternate specifications of the sequential order of drug presentation can help resolve the possibility that the ordered use between any two drugs is only determined by social factors related to availability of different substances.

Most drugs of abuse exert their addictive effects through effects on the striatum (Thomas et al., 2001). The nucleus accumbens (NAc) in the ventral striatum is critical for reward and addiction and is a site of convergence and integration of rewarding input from dopaminergic neurons in the ventral tegmental area (VTA) and glutamatergic input from the amygdala and the prefrontal cortex. The core of the NAc is made up primarily of GABAergic inhibitory spiny neurons. The NAc sends inhibitory feedback to the dopaminergic cells of the VTA. Reduction of excitatory input to the NAc is thought to decrease inhibitory output from the NAc to the VTA and thereby contribute, through disinhibition, to the increased reward and enhanced locomotion activation observed after cocaine administration (Kauer and Malenka, 2007).

We examined in mice how sequential administration of nicotine and cocaine alters locomotor sensitization and conditioned place preference, two addiction-related behaviors that are modulated by drugs of abuse, and three physiological and molecular markers in the nucleus accumbens of the striatum: synaptic plasticity; transcription of FosB, an immediate response gene implicated in addiction to many drugs of abuse

and in the response to other rewarding stimuli; and histone acetylation in chromatin (Levine et al., 2011).

Pretreatment of mice with nicotine for seven days increased the response to cocaine. Locomotor sensitization was increased by 98%, conditioned place preference by 78%, and cocaine-induced reduction in long-term potentiation (LTP) by 24%. Responses to cocaine were altered only when nicotine was administered first, and nicotine and cocaine were then administered concurrently. Reversing the order of drug administration was ineffective. Cocaine had no effect on nicotine-induced behaviors and synaptic plasticity. We found that nicotine by itself induced only a small increase in FosB expression in the striatum. However, nicotine also inhibited histone deacetylase (HDAC) activity, leading to a more widespread acetylation of histones at a larger number of genome locations in the striatum than did cocaine alone, thereby creating an environment that was primed for the induction of a number of genes. This ability of nicotine to hyperacetylate chromatin widely by inhibiting HDACs was not shared by cocaine, which caused a more local and transient acetylation. When a second drug of abuse, in this case cocaine, was given to animals after nicotine exposure, the higher histone acetylation levels led to greater activation of FosB and, likely, other genes.

Further, we found that a histone deacetylase inhibitor simulated the actions of nicotine by priming the response to cocaine and enhancing FosB gene expression and LTP depression in the nucleus accumbens. Conversely, in a genetic mouse model characterized by reduced histone acetylation, the effects of cocaine on LTP were diminished. We achieved a similar effect by infusing a low dose of theophylline, an activator of histone deacetylase, into the nucleus accumbens.

Cocaine must be administered to the animals while they are actively exposed to nicotine. These results from mice prompted an analysis of epidemiological data, which indicated that most cocaine users initiate cocaine use after the onset of smoking and while actively still smoking, and that initiating cocaine use after smoking increases the risk of becoming dependent on cocaine, consistent with our data from mice.

HDAC activators may be of potential clinical utility in the treatment of addiction because they could decrease FosB expression in response to cocaine. Modifying HDAC activators so that they target the striatum specifically would be particularly desirable because systemic treatments with HDAC activators or histone acetyltransferase inhibitors are likely to have cognitive and other deleterious effects.

DEVELOPMENTAL FACTORS: ADOLESCENCE AS A CRITICAL EXPOSURE PERIOD

“Normal developmental processes may result in higher risk for drug use at certain stages of the life cycle than others and experimentation with drugs at a particular stage of the life cycle may have lifelong consequences for subsequent extensiveness and chronicity of use. Epidemiological data on patterns of drug use in human populations as well as animal studies support

the notion of critical developmental periods for drug behavior (Purves et al., 2001). Experimentation most often starts in adolescence, as does addiction (Wagner and Anthony, 2002), a period when the brain is still undergoing significant developmental changes (Dahl and Spear, 2004).” (Koob et al., 2008: p. 363) The rates of drug use increase dramatically during adolescence. Rates of use of different substances double from early to late adolescence, as illustrated by *Monitoring the Future*, a national study of drug use among high school students. In 2011, lifetime rates of use in the 8th, 10th, and 12th grades for alcohol were 33.1%, 56.0%, and 70.0%, respectively; for cigarettes, 18.4%, 30.4%, and 40.0%; and for any illicit substances, 20.1%, 37.7%, and 49.9% (Johnston et al., 2011).

“Although the effects of drugs of abuse during this stage of development have not been adequately investigated, initial exposure in adolescence is associated with more chronic and intensive use, and greater risk of developing a substance use disorder (e.g., nicotine dependence, alcoholism, or dependence on illicit drugs) when cigarette smoking, drinking, or the use of illicit drugs starts early during adolescence compared with initiation at older ages (Hingson et al., 2006; Kandel, 2003; Kandel and Chen, 2000; Volkow, 2006).” (Koob et al., 2008: p. 363) In NESARC, 47% of those who reported having started drinking before age 14 became dependent on alcohol compared with 9% of those who started drinking at age 21 or older (Hingson et al., 2006). In NSDUH, 12.8% of those who had first started using marijuana before age 15 met criteria for last year dependence on an illicit drug within the last year compared with 2.6% of those who first started using marijuana at age 18 or older (SAMHSA, 2011: p. 72). As we described in the preceding, the rates of drug abuse or dependence among drug users are higher among adolescents than adults. “Normal adolescent-specific behaviors (such as risk-taking, novelty-seeking, response to peer pressure) increase the propensity of experimenting with legal and illegal drugs (Spear, 2000), which might reflect incomplete development of brain regions (e.g., myelination of frontal lobe regions) involved in the processes of executive control and motivation (Sowell et al., 2003).

The importance of adolescence as a critical developmental risk period for drug involvement and substance dependence is supported by work on rodents, which documents the greater vulnerability of adolescent than adult animals to various drugs. For example, in rats, exposure to nicotine during adolescence is associated with greater nicotine self-administration than first exposure in adulthood, a difference that persists when the adolescent rats reach adulthood (Levin et al., 2003). Adolescent rats appear to be more sensitive than adults to the rewarding actions of nicotine (Belluzzi et al., 2004).” (Koob et al., 2008: p. 363) Similarly, nicotine pretreatment leads to enhanced cocaine self-administration and locomotor activity in response to cocaine in adolescent but not adult rats (McQuown et al., 2007, 2009). Drug exposure during adolescence might result in different neuroadaptations from those during adulthood. In rodents, exposure to nicotine during the period corresponding to adolescence, but not adulthood, leads to alterations in cholinergic systems in the cerebral cortex, midbrain, and hippocampus

(Abreu-Villaca et al., 2003), including changes in nicotine receptors and enhancement of the reinforcing responses to nicotine (Adriani et al., 2003). “In addition, enhanced expression of plasticity-related genes following injection of nicotine in adolescent compared with adult rats has been observed throughout the brain, especially the forebrain (Schochet et al., 2005). Similar vulnerabilities in adolescence compared with adulthood have been reported for alcohol (Rezvani and Levin, 2004; Ristuccia and Spear, 2005)” (Koob et al., 2008: p. 363), amphetamines (McPherson and Lawrence, 2006), and morphine (White and Holtzman, 2005). Future research should allow clarification of whether neurobiological changes are the reason adolescents appear to become addicted to nicotine with lower nicotine exposure than adults (Kandel and Chen, 2000). Similarly, future research will allow us to determine if the increased neuroadaptations to alcohol during adolescence compared with adulthood (Slawecki and Roth, 2004) explains the greater vulnerability to alcoholism in individuals who start using alcohol early in life (Grant et al., 2001).

CONCLUSIONS

Data currently available to assess the extent of substance use disorders in the United States have many shortcomings and make comparison and replication across studies difficult. To overcome some of the limitations, we implemented secondary analyses of data from four surveys: NSDUH, NESARC, NCS-R, and NCS-A. The use of legal and illegal drugs in the United States is pervasive. In 2010, more than 90% of the adult population had ever used at least one substance and 45% of adolescents had done so (NSDUH). In 2001–2002, close to 40% of adult lifetime substance users met criteria for any lifetime substance use disorder, whether abuse or dependence on alcohol, nicotine, or an illicit drug. The highest lifetime rates of dependence were observed for nicotine dependence (17.7%), followed by alcohol (12.5%) and illicit drugs (2.6%) (NESARC). Adolescence appears to be a period of high risk for substance use disorders among those who have experimented with legal and illegal substances. Although the lifetime and last 12-month prevalence of use is lower among adolescents than adults, except for last 12-month use of illicit drugs, the rates of lifetime disorders among lifetime users are similar among adolescents and adults (NCS). The rates are even higher for last 12-month disorders among last 12-month adolescent users than adult users both in NCS and NSDUH, with the exception of dependence on nicotine among all cigarette users in NSDUH. Ages 18–25 represent the period of highest drug use prevalence for most substances. Whereas use of cigarettes and illicit drugs peaks in early adulthood at ages 18–25, the use of alcohol stabilizes through the late forties, when it starts its decline. The rates of dependence among users tend to remain flat for cigarette smokers and, as of age 18–25, to decline but slowly for users of other substances throughout adulthood.

Nicotine represents the most serious public health problem of the drugs that are used because not only does it affect almost a fifth of the population but it is also the most chronic

of the addictions, with more than 70% of adults who ever experienced symptoms of nicotine dependence reporting such symptoms within the last year. Furthermore, individuals who experiment with tobacco are more likely subsequently to experiment with illicit drugs, such as marijuana and cocaine. Recent work carried out using mice models identified molecular effects of nicotine on the brain that could explain its chronicity and its effects on other substances. Nicotine primes the response to cocaine by inhibiting histone deacetylase activity, causing global histone acetylation in the striatum, thereby inducing transcriptional activation of the *FosB* gene implicated in addiction. Understanding the pathways involved in this process may lead to the development of drugs that would impact in the addictive process.

Substance abuse and dependence are highly comorbid with other psychiatric disorders, especially among those who meet criteria for dependence on an illicit drug. In that group, close to 80% also meet criteria for a mood, anxiety, or antisocial personality disorder. The comorbidity between substance use disorders and psychiatric disorders is especially strong for antisocial personality disorder. Common biological and environment factors may underlie the observed associations between these two classes of disorder. Although much work remains to be done to understand the direction of causality between psychiatric and substance use disorders, it would appear that psychiatric disorders are more likely a cause of substance use disorders than substance use disorders are a cause of psychiatric disorders. Research on adolescents suggests that psychiatric disorders are more likely to precede and lead to substance use disorders than the reverse. Similarly, among adults, psychiatric disorders, in particular mood and anxiety disorders, predict persistence of substance use disorders but not the reverse.

Early onset of drug use during adolescence leads to more extensive and chronic use than later onset postadolescence, highlighting the importance of implementing prevention and educational efforts in that developmental period.

The use of animal models, imaging, and longitudinal epidemiological studies, in which individuals can be followed at relatively closely spaced intervals and for a long period of time, would help resolve some of the questions that are raised by the abuse of drugs in the population.

DISCLOSURES

No conflicts of interest to disclose for any of the authors. Support was provided by grant K05-DA0081 from the National Institute on Drug Abuse to Denise Kandel.

SECTION VII | DEMENTIA

DAVID M. HOLTZMAN

Although Alzheimer's disease (AD) was first described clinically and pathologically more than 100 years ago, it has only been over the last 30 years that clinicians and scientists have been able to unravel many of the scientific underpinnings of AD as well as several of the other causes of dementia. Because AD causes or contributes to dementia in about 30 million people worldwide and because of better overall medical care, we are facing a looming crisis. It is predicted that unless an effective therapy is developed, the prevalence of AD will triple over the next 30 to 40 years. An underlying principle that has emerged is that most neurodegenerative diseases, including AD, Parkinson disease, frontotemporal dementias, and prion diseases, appear to be disorders of protein aggregation in which normally soluble proteins become insoluble and accumulate in the brain, leading to neurotoxicity. Important clinical, genetic, and diagnostic advances, as well as a better understanding of pathophysiology, have led the field to the point where we are now poised to make important contributions to modify the course of different dementing diseases. There is even the possibility of delaying or preventing dementia.

Chapters 59 to 69 deal with various aspects of AD, which cause or contribute to approximately 70% to 75% of cases of dementia. In Chapter 59, Hassenstab, Burns, and Morris provide an update on the clinical and neuropsychological features of AD. They emphasize the importance of obtaining a history from a knowledgeable informant in determining whether an individual has developed cognitive impairment and if so, provide clinical and psychological methods to accurately quantify current cognitive and functional status. Utilizing purely clinical techniques, diagnosis of dementia caused by AD can be made quite accurately though imaging (see Chapter 62 by Brewer, Sepulcre, and Johnson) and fluid biomarker techniques (see Chapter 63 by Fagan) are proving to be very useful adjuncts. Structural and functional neuroimaging techniques are demonstrating the time course of changes in brain structure and function in relation to the clinical onset and progression of disease. Both measures appear to begin to become abnormal a few years before the onset of detectable cognitive change. Amyloid imaging as well as CSF measures of A β 42 appear to detect the onset of amyloid deposition in the brain as long as 10 to 15 years before cognitive decline and an increase in CSF tau, which occurs a few years before cognitive decline, marks the onset of neurodegeneration. These imaging and fluid biomarker techniques strongly add to both diagnostic and prognostic accuracy and will likely be very valuable in assisting in the enrollment of participants in both treatment and secondary prevention trials that are just beginning.

In Chapter 60, Tanzi describes how the discovery of different genes that cause dominantly inherited AD has revolutionized our understanding of AD by pointing us to which pathways are key in disease causation. These studies clearly point to the role of A β in instigating disease in that mutations in *PS1*, *PS2*, and *APP* almost all cause an increase in production in either all A β species or more commonly an increase in production of A β 42. Further, *APOE*, the most important genetic risk factor for AD, also influences A β metabolism, not by increasing synthesis but by influencing its aggregation and clearance. Additional new genetic risk factors have been uncovered and how they impact disease is still being sorted out. In Chapter 61, Morgan describes how researchers have taken advantage of the knowledge of the genes that cause or contribute to AD by creating many different genetic mouse models in which various pathological and behavioral phenotypes that mimic aspects of AD can be seen. This has been a colorful and productive area of research and is beginning to reap benefits, as disease modifying therapies are now being tested in humans based on promising data coming from these different models.

Although currently no therapies have been proved to delay the onset or slow the cognitive decline in AD, in Chapter 64 Sano and Neugroschl describe the current pharmacological therapies that have been shown to improve the symptoms of AD, including cholinesterase inhibitors and memantine, as well as results from a host of other studies. In Chapter 65, Grill and Cummings describe the very exciting work that is emerging on potential disease-modifying therapies for AD. Many different small molecules and biological therapies such as antibodies that target A β have shown promising preclinical data in animals. These treatments are in both early as well as later trials in AD. Additional targets such as tau and inflammation are also beginning to be tested now and in the near future.

A variety of other diseases contribute to or lead to dementia in addition to AD. The most common neurodegenerative diseases in individuals greater than age 65 outside of AD are dementia with Lewy bodies and dementia in Parkinson disease, described by Karantzoulis and Galvin in Chapter 66. These disorders feature the accumulation of synuclein in the brain. Many cases also feature A β accumulation. Another very common contributor to dementia either alone or more frequently in combination with AD is vascular dementia, described in Chapter 68 by Chui. Although not a frequent cause of dementia in the elderly, frontotemporal dementia (FTD) is a common cause of dementia in individuals less than 60 years of age. In Chapter 67, Naasan and Miller beautifully describe the varied clinical and neuroimaging features of FTD, which present with

either behavioral or language abnormalities. Importantly, the genetics and pathology of FTD clearly show it to be more than one disease, in which different genes and proteins can contribute. Improvements in diagnostic and biomarkers methods in this area should allow for promising treatment development as pathophysiological mechanisms emerge. Finally, although not a common cause of dementia, Chapter 70 by Watts and Geschwind describes diseases caused by prions. These diseases can cause rapidly progressive dementia in both humans and animals. Some of the major insights into a variety of neurodegenerative diseases have emerged from studies of prion disease, which can be both genetic and infectious.

It is clear that a major public health crisis is in the process of emerging because of the fact that lifespan is increasing and with that, dementing disorders, especially AD, are becoming more and more common. We have seen a clinical and scientific revolution in this area over the last 30 years in that the genetic and pathophysiological basis for these disorders is now much better understood. This is leading to the emergence of better diagnostic methods as well as promising disease-modifying therapies. It seems likely that over the next decades there will be a real chance that effective therapies for AD and other neurodegenerative diseases will become a reality. That day cannot come too soon.

59 | CLINICAL AND NEUROPSYCHOLOGICAL FEATURES OF ALZHEIMER'S DISEASE

JASON HASSENSTAB, JEFFREY BURNS, AND JOHN C. MORRIS

Allois Alzheimer reported in a meeting of German psychiatrists in 1906 his conclusion that a pathologic brain process, marked by microscopic lesions now recognized as amyloid plaques and neurofibrillary tangles, was responsible for the dementia and psychosis experienced for years by a woman before she died at age 55. His report generated little enthusiasm or interest from the audience and for many years thereafter what became known as Alzheimer's disease (AD) was considered to be an unusual presenile dementing disorder and garnered little attention. Studies in the 1960s, however, by Bernard Tomlinson, Gary Blessed, and Martin Roth in Great Britain (Tomlinson et al., 1968, 1970) showed conclusively that the neuropathology of the presenile disorder was identical to that of the far more numerous older cases of "senile dementia," thus establishing that AD is the same clinicopathologic disorder regardless of its age at onset. Based on this knowledge, Robert Katzman in 1976 correctly presaged the rapidly increasing prevalence and malignancy of AD (Katzman, 1976).

Alzheimer's disease is by far the most common cause of dementia and is present in 77% of demented individuals (Barker et al., 2002). It is strongly age-associated and thus typically is a disorder of older adulthood: 7% of persons affected by AD are age 65 to 74, 53% are 75 to 84, and 40% are 85 and older (Hebert et al., 2003). The prevalence of AD doubles every five years after the age of 65, affecting as many as 47% of people 85 years and older (Evans, 1987). Increased life expectancy in the United States and other developed countries has fueled an unprecedented growth in the elderly population that, in the absence of truly effective therapies, ensures continued dramatic increases in the prevalence of AD. In the United States alone, costs of caring for individuals with AD are estimated to be over \$200 billion annually (Alzheimer's Association, 2012). Although these figures very likely are underestimates given that AD is considerably underrecognized in clinical practice (Lavery et al., 2007) and on death certificates (Wachterman et al., 2008), the number of cases of AD, currently estimated to be 5.3 million in the United States, are expected to nearly triple over the next 50 years (Hebert, 2001).

This chapter reviews the clinical and neuropsychological characteristics and course of dementia caused by AD with a focus on its earliest symptomatic stages, because the typical person affected by AD is not profoundly demented (48% of individuals affected by AD are mildly demented, 31% are moderately

demented, and only 21% are severely demented [Hebert et al., 2003]). The chapter is written from the viewpoint of the clinician. It addresses the variability in current sets of clinical diagnostic criteria for AD and provides the rationale for the use of biological markers (biomarkers) to aid in moving the diagnostic process from a syndromic to a quantitative basis. Full discussions of biomarkers are found elsewhere in this section (imaging, Chapter 62; fluid, Chapter 63). Similarly, other illnesses that are considered in the differential diagnosis of AD dementia are addressed (dementia with Lewy bodies, Chapter 66; frontotemporal dementia, Chapter 67; vascular dementia, Chapter 68; prion disease, Chapter 69) and therapeutic approaches for AD dementia are the focus of Chapters 64 and 65. Genetic factors for AD are fully discussed in Chapter 60.

PATHOPHYSIOLOGY OF ALZHEIMER'S DISEASE

Alzheimer's disease is defined histopathologically by the presence of the hallmark lesions of plaques and neurofibrillary tangles (NFTs). Plaques are composed of extracellular beta-amyloid (A β) peptide deposited in the cerebral cortex as amorphous aggregates (diffuse plaques) and those with degenerating dendrites that contain hyperphosphorylated tau aggregates (neuritic plaques). NFTs are intracellular fibrillar aggregates of the hyperphosphorylated form of the microtubule-associated protein tau. NFTs are not specific for AD, suggesting that they may represent a secondary response to neuronal injury, at least in some instances. On the other hand, there is a strong association of A β plaques with AD. Down Syndrome and autosomal dominantly inherited AD, caused by deterministic mutations (or duplications) in the *amyloid precursor protein (APP)*, *presenilin 1 (PSEN1)*, and *presenilin 2 (PSEN2)* genes are rare but highly penetrant genetic causes of AD and are linked mechanistically by the overproduction of A β or an alteration in the ratio of the A β 42 isoform to A β 40. Hence, A β dysregulation (e.g., overproduction, reduced clearance, altered processing) is hypothesized as a critical "upstream" factor in the pathogenesis of AD (Hardy and Selkoe, 2002). When AD dementia is present, however, NFTs correlate more strongly with cognitive dysfunction than do plaques, perhaps because NFTs are more associated with synaptic and neuronal injury. The full-blown AD process involves many other pathologic factors, including

neuroinflammation, microglial activation, oxidative stress, and cell cycle abnormalities, that may contribute to disease progression. Although the precise cause(s) of AD remain unknown (Small and Duff, 2008), recent evidence of a gene mutation that results in inhibition of the proteolytic processing of APP into amyloidogenic peptides is associated with reduced incidence of cognitive decline and AD dementia in older adults, providing additional support for the amyloid hypothesis of AD (Jonsson et al., 2012).

Several sets of criteria for the neuropathological diagnosis of AD, based on the recognition of plaques and NFTs, have been developed but emphasize slightly different facets, such as whether diffuse and neuritic plaques or only neuritic plaques are considered (Nelson et al., 2012). A consensus panel now has recommended standard guidelines for the neuropathological assessment of AD and for its clinicopathologic correlations (Hyman et al., 2012). These new guidelines recognize a preclinical stage of AD, wherein A β deposits appear to accumulate over many years as plaques in the cerebral cortex in the absence of symptoms (Price and Morris, 1999). This preclinical stage is hypothesized as a clinically silent pathologic cascade resulting in increasing synaptic and neuronal loss that eventually produces the symptomatic stage (Jack et al., 2010; Perrin et al., 2009). This hypothesis also suggests that attempts to treat individuals with symptomatic AD may require a combination of drugs that target the multiple pathophysiologic mechanisms involved in the cascade. Because (presumably) irreversible neuronal loss already is substantial in medial temporal lobe structures by the time AD symptoms first appear (Price et al., 2001), detection of preclinical AD (before the brain is badly damaged) is desirable to enable possible “secondary prevention” strategies where therapeutic interventions aim to delay or possibly even prevent the appearance of symptomatic AD.

THE ALZHEIMER’S DISEASE CONTINUUM

Work groups convened by the National Institute on Aging (NIA) and the Alzheimer’s Association (AA) to revise clinical diagnostic criteria for symptomatic AD proposed a continuum that begins with the preclinical AD stage and then gradually manifests with subtle symptoms of mild cognitive impairment that then progresses to fully developed AD dementia. Compelling support for the AD continuum comes from a study of dominantly inherited AD. Representing less than 1% of all AD, individuals from families with autosomal dominant AD (ADAD) are at 50% risk of inheriting a causative mutation for AD (i.e., in the *PSEN1*, *PSEN2*, or *APP* genes) from their affected biological parent. Virtually all mutation carriers (MCs) will develop symptomatic AD, generally at the same age as their affected parent (the mean age of symptom onset in ADAD families is ~46 years), whereas their sibling non-carriers have no more risk for AD than the general population. The Dominantly Inherited Alzheimer Network (DIAN) has demonstrated that abnormal levels of A β 42 (the most pathogenic isoform of A β) measured in the cerebrospinal fluid (CSF) begin in asymptomatic MCs about 20–25 years prior to estimated age at onset (AAO) for symptomatic AD (Bateman et al., 2012). Cerebral

deposits of fibrillar A β are detected with molecular imaging about 15 years prior to estimated AAO, as are abnormalities in CSF levels of tau protein (and of its phosphorylated species); volumetric brain loss also is detected by magnetic resonance imaging (MRI) about 15 years prior to estimated AAO. Brain hypometabolism and deficits in episodic memory performance occur about 10 years before estimated AAO, and global cognitive impairment begins about 5 years before estimated AAO (Bateman et al., 2012). These findings are consistent with a continuous pathologic cascade in preclinical AD that ultimately manifests as symptomatic AD and suggest that abnormalities in A β metabolism begin more than two decades before symptomatic onset of AD. This provides a potential “window” for prevention therapies in asymptomatic individuals who are destined to develop symptomatic AD and further offers the opportunity to directly test the amyloid hypothesis with clinical trials of anti-A β monotherapies in asymptomatic MCs with preclinical AD. The extent to which these observations in DIAN extrapolate to the far more common “sporadic” form of late onset AD is unknown. Because abnormal biomarkers were present in DIAN only in MCs destined to develop symptomatic AD, however, it is likely that the same biomarker abnormalities in cognitively normal older adults also will predict symptomatic AD if the individuals continue to live.

CLINICAL DIAGNOSTIC CRITERIA FOR ALZHEIMER’S DISEASE

In 1984 uniform clinical diagnostic criteria were introduced by a Work Group convened by the National Institute on Neurological and Communicative Disorders and Stroke and the Alzheimer’s Disease and Related Disorders Association (NINCDS-ADRDA) (McKhann et al., 1984). These criteria provided the basis for the accurate recognition of the clinical disorder. The application of these clinical criteria firmly established AD as the dominant cause of dementia. The NINCDS-ADRDA criteria for the diagnosis of probable AD have been the underpinnings of AD clinical trials and research for over 25 years. To incorporate new knowledge resulting from this research, NIA-AA work groups recently updated these criteria. The new criteria recognize AD as a neuropathological entity that progresses from an asymptomatic stage (preclinical AD; Sperling et al., 2011) to a prodromal symptomatic stage (mild cognitive impairment; Albert et al., 2011) to the fully expressed AD dementia syndrome (McKhann et al., 2011). By definition, preclinical AD presently is detected solely by biomarkers, antecedent to symptomatic stages of AD. Only the clinical diagnosis of symptomatic AD, encompassing MCI and AD dementia, is addressed here.

MILD COGNITIVE IMPAIRMENT

The term mild cognitive impairment (MCI) was introduced to characterize the boundary of aging and dementia (Flicker et al., 1991). The earliest symptoms of AD are insidious and almost all patients with AD progress through a stage of subtle cognitive impairment that may not interfere importantly with daily

functioning. Clinical criteria for MCI were intended to characterize this prodromal stage, prior to the diagnosis of overt dementia (Petersen et al., 1995). Because MCI was not defined as a clinicopathologic entity, however, it can represent the earliest symptomatic stage of many underlying pathologies (not all of which necessarily progress to dementia) and thus MCI is heterogeneous in nature with highly variable outcomes.

The revised criteria for MCI move toward providing an etiologic diagnosis for this condition when it is considered to be a symptomatic prodementia phase of AD (Albert et al., 2011). These criteria nominally appear consistent with consensus criteria for MCI published in 2004 (Winblad et al., 2004) and require: (1) a change in cognition, self-reported or noted by an observer; (2) objective impairment in one or more cognitive domains; (3) independence in functional activities; and (4) absence of dementia (because functional independence is preserved). Unfortunately, the revised criteria for MCI broaden the definition of “independence in functional activities” to include “mild problems performing complex tasks... such as paying bills, preparing a meal, or shopping” and allow reliance on aids and assistance to accomplish these tasks to qualify

as “independent.” Because the differentiation of MCI from dementia rests solely on the criterion of functional independence (McKhann et al., 2011), this blurring of what represents “independence” leaves the diagnostic distinction entirely to the individual judgment of the clinician, resulting in nonstandard and arbitrary classifications (Morris, 2012). The “problematic” threshold for distinguishing the “essentially preserved” functional activities in MCI from the subtle functional deficits that accompany the milder stages of AD dementia (Petersen, 2004), combined with the heterogeneity of MCI, have left the field struggling to characterize this condition. In response, some investigators have recommended that the term “MCI” be replaced by etiological diagnoses, particularly when AD is believed to be the underlying causative disorder as determined by an appropriate clinical phenotype and/or by biomarker evidence (Dubois et al., 2010; Morris, 2012) (Table 59.1).

ALZHEIMER’S DISEASE DEMENTIA

Revised criteria for probable AD dementia include the presence of dementia and no evidence for other dementing conditions

TABLE 59.1. Current versions of lexicons and diagnostic criteria for Alzheimer’s disease

<p>1. Diagnostic and Statistical Manual of Mental Disorders, 4th Edition, Text Revision (DSM-IV-TR¹; 2000) <i>Criteria for AD:</i> the development of memory impairment and deficits in executive function, language, praxis, and/or perception that represent a decline from previous functioning, impair social or occupational activities, have a gradual onset and progression, and are not attributable to another disease</p>
<p>2. International Working Group for New Research Criteria for the Diagnosis of AD (Dubois et al., 2010) <i>Alzheimer’s disease:</i> use of this term is restricted to the clinical disorder, encompassing the full symptomatic spectrum from prodementia to dementia. The diagnosis is established by the presence of episodic memory loss and imaging or cerebrospinal fluid (CSF) biomarker evidence of AD. The term “AD” can be subdivided into “prodromal AD” (prodementia stage of AD) when instrumental activities of daily living (IADLs) are preserved and “AD dementia” when the cognitive loss interferes with IADLs <i>AD pathology:</i> the neurobiologic changes responsible for AD, regardless of whether the clinical disorder is present <i>Mild Cognitive Impairment (MCI):</i> cognitive impairment that is too mild to interfere with IADLs but for which no attributable disease can be discerned</p>
<p>3. National Institute on Aging-Alzheimer’s Association Workgroups on Diagnostic Guidelines for AD (Albert et al., 2011; McKhann et al., 2011; Sperling et al., 2011) <i>Dementia:</i> encompass the spectrum of dementia, from the mildest to most severe stages, and defined as cognitive deficits that represent a decline from previous levels of function and interfere with IADLs <i>AD dementia:</i> meets criteria for dementia, and cognitive decline is marked by insidious onset with progressive worsening and other illnesses that can explain or contribute to the cognitive loss are absent. Biomarker evidence for AD may enhance confidence in the clinical diagnosis, but such evidence is not presently ready to be incorporated into the routine diagnostic process <i>MCI due to AD:</i> concern about cognitive change (either self-reported or from an informant or observer), impaired performance in one or more cognitive domains, and independence in IADLs (distinguishing this condition from dementia). However, “independence” is expansively operationalized to include problems in performing IADLs and to include dependence on aids or assistance to function in daily life. AD biomarkers may be used to increase certainty that AD pathology is the cause of MCI, although currently there remain limitations in how biomarker evidence is interpreted. <i>Preclinical AD:</i> AD is defined as the underlying neuropathologic disorder and represents a continuum of pathophysiologic changes that eventually result in cognitive decline. Biomarkers of AD pathology provide hypothetical staging categories for preclinical AD (i.e., when cognitive symptoms and decline are undetectable by current clinical methods but AD lesions are present in the brain)</p>
<p>4. Washington University (Morris, 2012) <i>Alzheimer’s disease:</i> the neurodegenerative brain disorder, regardless of clinical status, that results in a continuous process of synaptic and neuronal deterioration</p> <ul style="list-style-type: none"> • AD is characterized by two major stages: <ul style="list-style-type: none"> – Preclinical (asymptomatic) – Symptomatic • Symptomatic AD is defined by intra-individual cognitive decline that interferes (from subtle to severe) with daily function. It can be subclassified on severity of symptoms: <ul style="list-style-type: none"> – Incipient (prodromal; MCI) – Dementia

¹DSM-5 is scheduled for publication in 2013.

(neurologic disorders or medical comorbidities) or medications that can substantively impair cognition (Table 59.1). When there is an atypical course or an etiologically mixed presentation, possible AD dementia is diagnosed. These criteria recognize advances in AD biomarkers and, when deemed appropriate by the clinician, encourage their use to enhance confidence that the etiology of the dementia syndrome is AD. Biomarkers reflect either the molecular pathology of AD or the presumed downstream effects of the underlying pathology (Table 59.2). The primary use of AD biomarkers currently remains in investigational studies but increasingly will become optional diagnostic tools. Indeed, the Food and Drug Administration in April 2012 approved the use of the ¹⁸F amyloid imaging tracer, florbetapir, for the indication of “brain imaging of amyloid plaques in patients... being evaluated for AD and other causes of cognitive decline” (“FDA Approves Amyvid®”; 2012). Nonetheless, much work is needed before the clinical utility of AD biomarkers for diagnostic considerations can be fully realized. A biomarker should detect a fundamental feature of AD neuropathology and should be validated using histopathologically confirmed AD cases. A biomarker should be precise in that it should detect AD early in its course and distinguish it from other dementias. Both the sensitivity and specificity of an AD biomarker should be at least 80%, with a positive predictive value approaching 90%. Biomarkers represent continuous biological processes, yet the cutpoints to define a “positive” or “negative” test impose an artificial dichotomous outcome on this continuum and will occasionally produce ambiguous or indeterminate results. There is a great need to standardize both the CSF and imaging biomarkers across laboratories. Practicing physicians have varying degrees of access to AD biomarkers, and reimbursement procedures have yet to be established. An ideal biomarker should be reliable, non-invasive, simple to perform, and inexpensive. The ultimate “test” will be to determine the utility of AD biomarkers in the clinic (Schoonenboom et al., 2012). Although the

revised criteria for AD dementia do not recommend the use of biomarkers for routine diagnostic purposes, other proposed criteria now require biomarker evidence for the diagnosis of AD (Dubois et al., 2010).

DIAGNOSTIC APPROACH TO ALZHEIMER'S DISEASE DEMENTIA

Because biomarkers have not yet been established for clinical practice, clinical methods currently provide the key information needed to diagnose AD dementia and create a differential diagnosis: history taking, mental status testing, and neurological examination. The diagnosis of AD dementia at present rests on the documentation of (1) intraindividual cognitive decline that (2) interferes with daily function.

HISTORY TAKING

Serial cognitive testing provides objective evidence of progressive cognitive decline but such data rarely are available in the acute patient care setting. Fortunately, the observations of a knowledgeable informant also are sensitive and reliable for detecting meaningful intraindividual cognitive decline that characterizes dementia (Carr et al., 2000). Whenever possible, therefore, a person who knows the patient well should be interviewed to assess whether the individual's current levels of cognitive function represent a decline from previously attained levels. In this way, the patient serves as his or her own control and mitigates the fact that specific cognitive strengths and weaknesses and activities of daily life vary widely among individuals. Factors that can influence cognitive test performance, such as literacy and educational attainment, native language, and cultural background, also are minimized. Even in the early stages of AD dementia, most patients lack insight into their cognitive problems. Patient self-report thus is less reliable than the report of an informant (Carr et al., 2000).

The Clinical Dementia Rating (CDR) is an informant-based clinical assessment and dementia staging instrument that is widely used in research settings to determine the presence of absence of dementia and, when present, its severity (Morris, 1993). Semistructured interviews are conducted by an experienced clinician independently with the informant and the patient to assess the patient's abilities in each of six domains: memory, orientation, judgment and problem solving, function in community affairs, home and hobbies, and personal care. Incorporated into the interviews are portions of the Dementia Scale (informant) and Information-Memory-Orientation test (patient) (Blessed et al., 1968), and also included are an aphasia battery, medical and psychiatric histories, and medication inventory. Using all information, the clinician rates each of the six CDR domains along five levels of impairment from none to maximal (rated as 0, 0.5, 1, 2, and 3). Combining the domain scores in accordance with a scoring algorithm produces a global CDR score, where 0 indicates cognitive normality and 0.5, 1, 2, and 3 indicate very mild, mild, moderate, and severe dementia.

The CDR is the primary global staging instrument for the Uniform Data Set (UDS; Morris et al., 2006; Weintraub

TABLE 59.2. Biomarkers for AD

BIOMARKERS FOR THE MOLECULAR PATHOLOGY OF AD

BIOMARKERS FOR THE CONSEQUENCES OF AD PATHOLOGY
PET Hypometabolism in temporoparietal cortex as demonstrated by decreased [¹⁸ F] fluorodeoxyglucose (FDG) uptake
Structural magnetic resonance imaging (MRI) Volume loss in: Hippocampus Medial, basal, lateral temporal lobe Medial parietal lobe Whole brain

et al., 2009), which, since 2005 has been the standard clinical and cognitive instrument for the evaluation of all cognitively normal control participants and individuals with MCI and AD dementia at the federally funded Alzheimer's Disease Centers (ADCs). Also included in the UDS are additional informant-based scales that capture other aspects of dementia, including neuropsychiatric features (Neuropsychiatric Inventory; Cummings et al., 1994), and functional abilities (Functional Assessment Questionnaire; Pfeffer et al., 1982). Mood and depression are assessed in the patient with the Geriatric Depression Scale (Yesavage et al., 1983). Few practitioners, however, have the training and expertise, much less the time, to administer the UDS or derive the CDR. A derivative of the informant portion of the semistructured interview used to score the CDR is the Ascertain Dementia 8 (AD8; Galvin et al., 2005), a brief eight-item questionnaire that can be used in practice settings as a dementia screening tool.

The AD8 can be completed in two to three minutes and can be administered in person or by telephone; it also can be self-administered by the informant. The eight questions (Table 59.3) ask whether there has been a change due to cognitive decline in the ability of the patient to perform daily tasks. Scores of 2 or more on the AD8 provide good discrimination between cognitive normality and even early-stage AD dementia with a positive predictive value of 87% (Galvin et al., 2005). Poor performance on the AD8 corresponds to biomarker evidence of AD dementia (Galvin et al., 2010). However, the AD8 is a screening, not a diagnostic, instrument and should be used to identify persons who would benefit from an evaluation for possible dementia.

NEUROPSYCHOLOGICAL TESTING

MENTAL STATUS TESTS

Standard cognitive testing can be very useful at the bedside. The ideal information for detecting dementia comes not from a comparison of an individual's cognitive performance with

TABLE 59.3. The AD8: dementia screening interview to differentiate aging and dementia

Is there repetition of questions, stories, or statements?
Are appointments forgotten?
Is there poor judgment (e.g., buys inappropriate items, poor driving decisions)?
Is there difficulty with financial affairs (e.g., paying bills, balancing checkbook)?
Is there difficulty in learning or operating appliances (e.g., television remote control, microwave oven)?
Is the correct month or year forgotten?
Is there decreased interest in hobbies and usual activities?
Is there overall a problem with thinking and/or memory?

Note: Report only a change caused by memory and thinking difficulties. (Source: Galvin et al., 2005.)

others (i.e., comparison of individual performance with normative values derived from age- and education-matched controls), but from whether an individual has declined from his/her past abilities. Such information is best captured at an initial evaluation by a careful history. Bedside cognitive testing is often accomplished using mental status tests, such as the Mini Mental State Examination (MMSE; Folstein et al., 1975). The MMSE is widely used and has modest sensitivity but fair specificity for detecting dementia (Galvin et al., 2005). The accuracy of the MMSE depends on the age, cultural background, and educational level of the individual. A standard cutpoint score of 23 or less as indicative of dementia has poor accuracy in individuals with education levels at the low and high end of the spectrum (Galvin et al., 2005). In addition, individuals who receive a clinical diagnosis of MCI often score in the normal range for elderly adults (Ismail et al., 2010). The Montreal Cognitive Assessment (MoCA; Nasreddine et al., 2005) is another popular bedside mental status examination that was designed to be more sensitive to frontal and subcortical pathology and to detect cognitive changes in individuals who score in the normal range on the MMSE. Like the MMSE, the MoCA has been validated in several languages and cultures. Some reports show the MoCA to be superior to the MMSE in sensitivity and specificity for detecting MCI and AD (Freitas et al., 2011).

NEUROPSYCHOLOGICAL EVALUATION

Although mental status tests can be useful to screen for the presence of global cognitive difficulties, they are not designed to detect the subtle cognitive changes seen in early symptomatic AD and can be strongly affected by the demographic characteristics of the patient. Mental status tests also cannot provide a comprehensive assessment of specific domains of cognitive functioning, which can be critical for differential diagnosis, tracking change over time, and for treatment planning. A full neuropsychological evaluation is useful when there is a question of more subtle cognitive impairment, or when a more thorough assessment of cognitive strengths and weaknesses is necessary. Neuropsychological evaluations are also indicated when attempting to establish the cognitive fitness or competency of an individual with dementia to perform activities of daily living, including working and driving, and their capacity to make medical, legal, and financial decisions (Moberg and Kniele, 2006). In moderate to severe AD (CDR 2–3), neuropsychological assessment becomes less useful, because patients with advanced AD have pronounced global cognitive deficits that preclude testing. A typical neuropsychology referral involves history taking with the patient and often an informant, and several hours of testing using standardized measures of cognitive functioning. The neuropsychologist then compares the cognitive profile of the individual to normative data (see section on normative data in neuropsychological assessment for more information) and generates a report describing the cognitive profile and the most likely contributing factors, and may include recommendations for treatment. Tests administered usually include an estimate of premorbid functioning and assessments of fluid and crystallized intelligence, attention, working memory, processing speed, visuospatial skills, language, executive functioning, and several aspects of

memory. Mood and personality assessments may also be completed. Neuropsychologists are typically Ph.D. level clinical psychologists who, in addition to training in psychopathology and psychotherapy, have completed specialized internship and fellowship training in neuropsychological assessment. As such, they are well suited for assessment of mood and personality and can play a valuable role in differential diagnosis.

NEUROLOGICAL EXAMINATION

The neurological examination is a standard part of the assessment of a patient with dementia to detect neurological deficits and signs that may suggest possible causes of dementia. In typical AD dementia, the neurological examination is nonfocal and generally unremarkable, particularly in the mild-moderate stages. In more advanced AD dementia, the apparent inability to cooperate may result in *gegenhalten* (oppositional resistance) when limb muscles are passively stretched. Cortical release signs (suck and grasp reflexes) may be elicited in late-stage AD dementia, and not infrequently there are mild extrapyramidal signs (usually bradykinesia and gait and tone abnormalities) and occasionally myoclonus. The risk of seizures is increased in advanced AD dementia (Romanelli et al., 1990) but seizures are uncommon in the mild-moderate stages (Irizarry et al., 2012).

Aphasia (language dysfunction), apraxia (disordered purposeful movement, distinct from paresis), and agnosia (disordered perception) may develop in later stages of AD dementia. For individuals with milder stages of dementia, deficits in these areas usually are limited to word-finding difficulty for names of people and objects (dysnomia) and perhaps constructional apraxia (i.e., visuospatial impairment as manifested by poor clock drawing performance). Occasionally, AD dementia presents as an asymmetric (“focal”) cortical syndrome. Unexplained language dysfunction with relative sparing of memory may indicate the presence of a variant of frontotemporal lobar degeneration, such as nonfluent progressive aphasia or semantic dementia, but atypical AD also can cause progressive aphasia. AD also can present as posterior cortical dysfunction (Renner et al., 2004). The dysfunction can include partial or full examples of the disconnection syndrome, alexia without agraphia (generally involving pathology in the left occipital lobe and splenium of the corpus callosum) and Gerstmann syndrome (dyscalculia, agraphia, right-left disorientation, and finger agnosia), implicating pathology in the left parietal lobe. In one series of 100 “focal” cortical syndrome cases that were examined postmortem, 34 of 100 were attributed to histopathological AD and close to one-half (12 of 26) of the cases with progressive aphasia had neuropathologic AD (Alladi et al., 2007). Visual agnosias include Balint syndrome, where there is failure to properly synthesize all components in the visual field (simultanagnosia) owing to bilateral occipitoparietal pathology that occasionally can be AD (Graff-Radford et al., 1993).

LABORATORY EVALUATION

Depression, B12 deficiency, polypharmacy, and hypothyroidism are not infrequent disorders in older adults and have been associated with cognitive impairment. Screening for

these treatable disorders is recommended in the evaluation of possible contributors to dementia (Knopman et al., 2001). Treatment of these disorders is unlikely to completely reverse cognitive deficits. Nevertheless, the high frequency of these co-morbidities and the potential for at least partial amelioration of cognitive symptoms justifies screening.

RADIOLOGICAL EVALUATION

STRUCTURAL IMAGING

Structural neuroimaging, either MRI or non-contrast computed tomography, is recommended to evaluate potential causes of dementia (Knopman et al., 2001). Up to 5% of patients with dementia have imaging evidence for brain neoplasms, subdural hematomas, communicating hydrocephalus, or other structural lesions that may contribute to the cognitive symptoms. Although not specific for AD, neuroanatomic changes consistently have been linked with AD brain pathology and MRI volumetrics are increasingly being used as a “downstream” biomarker for AD dementia that indirectly detects cell loss and AD neuropathological burden (Du et al., 2003; Jack et al., 2002). Cerebral atrophy also is associated with normal aging (Foteno et al., 2005). Programs have been developed to indicate whether the degree of quantitative volumetric loss (either regional, such as for the hippocampus, or whole brain) falls in the range of “normal” or “pathologic” atrophy.

PHENOMENOLOGY OF ALZHEIMER'S DISEASE DEMENTIA

COURSE

Alzheimer's disease is a uniformly fatal disorder. The duration of AD dementia, from initial appearance of symptoms until death, averages 7 to 10 years, although shorter and longer periods of survival are not uncommon. Staging of dementia generally describes three levels of severity: very mild/mild (corresponding to CDR 0.5 and CDR 1), moderate (CDR 2), and advanced (CDR 3). Although an inevitably progressive disorder, the rate of progression of AD dementia is stage-dependent such that the less the dementia severity, the slower the rate of progression. For example, the median time to progression to a higher CDR score was 3.07 years for CDR 0.5 individuals with AD dementia versus 2.41 years for CDR 1 individuals (Williams et al., 2012). Older age and the presence of the $\epsilon 4$ allele of *apolipoprotein E* (*APOE*) are associated with more rapid progression (Cosentino et al., 2008; Williams et al., 2012).

FEATURES OF VERY MILD/MILD ALZHEIMER'S DISEASE DEMENTIA

The evaluation seldom is sought by the patient, who typically is unaware that there is a “problem,” but most often by family or friends. The clinical hallmark of AD dementia is impairment in the learning and retention of new knowledge, such that details of events and conversations are not recalled and questions and statements often are repeated. Performance

for autobiographical memory, where the individual's ability to correctly recall events (independently related by the family) in which s/he had recently participated is assessed, is at least as informative for memory function as brief memory tests (Dreyfus et al., 2010). Patients may have difficulty in remembering appointments or to take their medications and often demonstrate misplacement of items without independent retrieval. Temporal and geographical disorientation may result in forgetting the date or day of the week and difficulty in navigating unfamiliar areas. Executive dysfunction is manifested by less facility in organizing information and in impaired decision-making. There is less ability to perform cognitively demanding behaviors, such as operating a motor vehicle or managing the household finances (Table 59.4). Although language skills generally are preserved, difficulties with word retrieval are common and may result in slow, hesitant speech. Personality generally is maintained, although family and friends may note that the affected individual is "quieter" or withdrawn, especially in social settings. Many activities in the community (shopping; attending religious services) and at home (cooking; laundry) still may be performed, if less well than previously, without assistance from others and self-care tasks (dressing, grooming, bathing, toileting) generally are completed independently. Hence, to the casual observer the affected person looks and acts normally, and it is only those who know the person well who are aware of the decline from previously attained levels of cognition and function.

TABLE 59.4. Alzheimer's disease dementia clinical phenotype: mild stage

Gradual onset and progression
Informant report Frequent repetition, misplaced items, difficulty recalling names Functional impairment Driving (failure to maintain lane; minor accidents; poor navigation) Operation of appliances (e.g., remote controlled devices) Household finances; cooking; shopping
Affected individual Impaired insight Impaired recall of recent events Poor judgment
Keys Decline from prior levels Consistency of problems Interference with daily function
Probe for intraindividual cognitive decline Ask if a "problem" represents a change from prior abilities
Obtain concrete examples of how cognitive problems interfere with everyday function
Use judgment Discordance of informant report vs. individual performance Alzheimer dementia phenotype can be present in high-functioning persons who still perform well on tests Individual's self-report of whether or not there are cognitive problems often is unreliable

FEATURES OF MODERATE ALZHEIMER'S DISEASE DEMENTIA

Progressive decline in cognitive and functional abilities now necessitates supervision for almost all aspects of the individual's daily life, and the dementia is obvious even to people who do not know the patient well. New information quickly is forgotten, and recall of even highly learned information may be impaired. Attention also is impaired and the patient is more distractible, with the consequence that attempted tasks are not completed. Disorientation for even familiar settings may result in the individual failing to recognize a home they have visited many times. Elopement is a serious risk as the patient cannot find the way home nor communicate appropriately to others where they live or with whom. Judgment and problem solving abilities are notably impaired, such that it is unsafe for the individual to be home alone because of safety and security concerns (e.g., leaving the doors unlocked; inviting strangers into the house; failing to turn off the stove burners; acquiesce to solicitations for money). The affected individual also must be accompanied in all activities outside of the home. Although the individual may engage in some basic tasks, including cooking, cleaning, and self-care, these generally require supervision. Although patients may continue to dress themselves, supervision may be needed to ensure that the patient does not repeatedly wear the same soiled clothes or put them on improperly; prompting often is needed to have them bathe. Medications must be administered to the patient. The increased dependence of the patient often results in considerable burden for the primary caregiver, who most often is the spouse or adult child of the patient, and negatively affects the caregiver's health. Additional care often is sought from unpaid (family and friends) and paid caregivers. Institutionalization also may be considered, particularly when there is frequent incontinence, wandering, or behavioral abnormalities.

ADVANCED ALZHEIMER'S DISEASE DEMENTIA

Patients in the advanced stages of AD dementia lack comprehension, may no longer remember loved ones, and fail to recognize their home or other familiar surroundings. They lose the ability to perform even simple activities of daily living. Night and day are confused. Eventually patients become near-mute and nonambulatory and require total care for dressing, hygiene, eating, and toilet functions as sphincter control is lost. The patient ultimately succumbs to medical complications such as inanition, aspiration, pneumonia, and sepsis arising from urinary tract infections or decubitus ulcers.

NEUROPSYCHIATRIC FEATURES

Neuropsychiatric and behavioral symptoms are common in AD dementia and contribute to the clinical profile of the disease. Neuropsychiatric problems do not occur in all persons with AD dementia, but generally emerge during the moderate stage of dementia. Neuropsychiatric symptoms can be subclassified as mood disturbances, psychosis (delusions and hallucinations), and personality changes and are observed

in a majority of patients with dementia (Sink et al., 2005). Neuroimaging and pathological studies have demonstrated that neuropsychiatric and behavioral symptoms reflect associations with regional pathology as indicated by discrete areas of atrophy, hypometabolism or decreased blood flow (Bruen et al., 2008). For instance, patients with apathy are more likely to have disproportionate dysfunction in the medial frontal and anterior cingulate regions, whereas agitation is higher in those with increased NFT burden in the left orbitofrontal cortex.

The relationship of AD and depression is complicated, but 30% or more of individuals with AD dementia will have at least some depressive features, although the percent meeting criteria for major affective disorder is much lower (Olin et al., 2002). Depressive symptoms in individuals with AD may be a manifestation of pathology in the locus ceruleus and the substantia nigra and thus may be an early symptom of AD pathology (Bruen et al., 2008). Importantly, effectively treating depression can have an impact on the severity of cognitive-related disability, and a low threshold for treatment of depressive symptoms in patients with cognitive impairment is important as some associated cognitive impairments may be improved (McNeil, 1999).

Agitation and aggression are particularly difficult to manage. Agitation represents disruptive psychomotor activity. Hallucinations and delusions occur in about 30% of cases at some point during the course of the illness (Lyketsos et al., 2002). Visual hallucinations are a key feature of dementia with Lewy bodies but are less common in AD and, when present, generally occur in the later stages. Delusions of spousal infidelity and theft are common. Misidentification syndromes such as the Capgras syndrome or reduplicative paramnesia can also occur. Capgras syndrome is the belief that a family member or friend has been replaced by an identical appearing impostor. Reduplicative paramnesia is the delusion that a place (such as one's house) has been duplicated in and exists in two or more places. For instance, the patient may believe their house is somewhere else and that the house they are in is identical to their own. Treating these distressing neuropsychiatric symptoms should first seek to identify the possible physical, social, and environmental precipitants and to remove or reverse them. When non-pharmacologic interventions fail, atypical antipsychotics may provide some relief from agitation or psychosis but randomized clinical trials generally fail to demonstrate benefit (Sink et al., 2005). Metaanalyses indicate that the use of antipsychotics in elderly patients with dementia is associated with increased mortality, primarily related to cardiovascular events.

BIOMARKERS FOR ALZHEIMER'S DISEASE

An autopsy study of 919 individuals with a clinical diagnosis of AD dementia at federally-funded ADCs found that the clinical diagnosis was relatively inaccurate, with mismatches between the clinical and neuropathologic diagnoses in 16.7% of cases (Beach et al., 2012). Although it is possible that the ADCs were referred more complicated cases than are encountered in routine practice, the expertise of these tertiary care centers might

be expected to compensate and yield more accurate diagnoses. Hence, diagnostic misclassification is not inconsiderable for cases of presumed AD dementia. The advent of biomarkers of the molecular pathology of AD is anticipated to improve clinical diagnostic accuracy. Biomarkers also may provide more precise and sensitive measures of disease progression and may allow shorter trials with smaller sample sizes by using biomarkers as surrogate end points. For example, in early symptomatic AD, individuals who were most likely to cognitively decline rapidly were identified by CSF markers for AD (Snider et al., 2009), potentially helping to reduce the number of participants needed to demonstrate a drug effect in trials of MCI and early-stage AD individuals.

Despite promising results, biomarkers must be shown to be at least as accurate as clinical diagnosis alone before their role in the routine assessment in patients with cognitive impairment can be determined. It is likely that a panel of biomarkers rather than a single test will have the most utility for the diagnosis of AD and, in cognitively normal persons, for predicting who will progress to symptomatic AD (de Leon et al., 2001). A major remaining problem for the field is the lack of standardization of the analytic techniques to determine CSF biomarkers. Even the time of collection of CSF is important as CSF A β 42 levels have diurnal fluctuations (Batemen et al., 2007). Different assay platforms also introduce variability. Harmonization of laboratory measurements are needed to minimize current intercenter variations in CSF assays (Mattsson et al., 2011).

Although there remains some uncertainty as to precisely how biomarkers will ultimately be incorporated into the standard evaluation of cognitive impairment, a variety of biomarker measures are currently available for the practicing physician and may provide clinically relevant information in specific circumstances. Measures of amyloid and tau in CSF are commercially available. Although the PET radioligand ^{11}C Pittsburgh Compound B (PIB; Klunk et al., 2004) has dominated amyloid imaging research because it enters the human brain rapidly and has very high selectivity and nanomolar affinity for A β plaques, it has a half-life of only 20 minutes. Its use is thus limited to medical centers with on-site cyclotrons and ^{11}C radiochemistry expertise. Tracers labeled with ^{18}F have a longer half-life (close to two hours) and allow for wider distribution from commercial producers.

Amyloid imaging with ^{18}F florbetapir now is commercially available for detecting the presence of cerebral amyloid deposits in individuals with cognitive decline and additional ^{18}F amyloid tracers are in development. Structural neuroimaging techniques are becoming readily available for volumetric quantification. The use of biomarkers to aid the clinical evaluation of individuals with cognitive impairment is likely to accelerate in coming years. Early recognition of disease will be increasingly important if disease modifying therapies are developed, in particular because those therapies are likely to have greatest efficacy early in the course of disease before major neurodegeneration has occurred.

Alzheimer's disease is associated with a number of modifiable risk factors. Cardiovascular risk factors such as diabetes, hypertension, and hypercholesterolemia are associated with a higher risk of developing AD, whereas lifestyle factors such as

physical activity, diet (low fat consumption, moderate alcohol consumption, Mediterranean diet), and cognitive engagement are associated with a lower risk of developing AD. These observations suggest that interventions designed to modify these factors may influence AD risk. The observational nature of the data and methodological limitations of the studies, however, limit the scientific quality of the data and make them insufficient for drawing firm conclusions on the association of any modifiable risk factor with cognitive decline or AD. Further studies are necessary, including long-term population-based studies and randomized controlled trials to further investigate these strategies. Intriguing but nonsignificant data from a population-cohort study suggests that age-adjusted dementia incidence may be declining (Schrijvers et al., 2012). This observation would be consistent with a concept that risk of dementia may be modifiable by trends in social (increased years of education) and medical (better treatment of cardiovascular disease) factors; it also is inconsistent with dementia as an inevitable consequence of aging (Larson and Langa, 2012).

NEUROPSYCHOLOGICAL FEATURES OF ALZHEIMER'S DISEASE

The limbic structures, including the hippocampus and entorhinal cortex, are among the brain regions involved in the earliest stage of symptomatic AD, with increasing involvement of frontal, temporal, and parietal cortices as the disease progresses (e.g., Bondi et al., 2008; Braak and Braak, 1991). In line with this, numerous studies have shown that episodic memory tasks typically are the first to evidence change in symptomatic AD and the structures underlying episodic memory function (medial temporal lobe, precuneus, and other limbic areas) are the first to show changes in volume, connectivity, and task-related brain activity (Bondi et al., 2008; Buckner et al., 2009). These changes also are excellent predictors of disease state (Putcha et al., 2011; Yassa et al., 2011). The AD dementia syndrome is thus characterized by prominent episodic memory deficits with rapid forgetting of material, executive dysfunction, and additional deficits in certain aspects of language, visuospatial abilities, and attention.

Subtle declines in episodic memory in older adults may precede the recognition of symptomatic AD (see Bondi et al., 2008 for review). The traditional view that the first cognitive change is represented by episodic memory deficits may not always be the case. As Storandt (2008) notes, a circularity bias exists when group designations such as MCI are based on neuropsychological status. For example, if a diagnosis of MCI is contingent on episodic memory deficits, it is not surprising that affected individuals most often exhibit significant differences in episodic memory. Longitudinal cognitive and clinical assessments over several years in individuals who subsequently had AD confirmed that deficits occur in non-episodic memory domains in over one-third of cases (Storandt, 2008; Storandt et al., 2006). Personality changes, difficulties with executive or visuospatial functions, slowing of psychomotor speed, or combinations of these appeared to mark initial cognitive decline in some persons (Johnson et al., 2009; Storandt, 2008). Information about

intraindividual changes that is gathered from collateral sources also detected subtle cognitive decline that was so minimal it did not meet the cutoffs used to classify MCI. Similarly, others have reported that persons without dementia but with notable personality changes were much more likely to develop dementia two years later (see Storandt, 2008, for review).

Difficulties with attention and executive functioning commonly occur in patients at early stages of AD, and continue to worsen with the progression of the disease. It may be the case that early episodic memory deficits are a result of multiple factors, including difficulty with attention and executive functioning mechanisms. Attention and executive functioning represent somewhat overlapping constructs with many aspects, but the processes of inhibitory control and maintenance of task sets appear to play a critical role in early AD (Buckner, 2004; Storandt, 2008). Neuropsychological tasks that emphasize these processes are very sensitive indicators of the early stage of symptomatic AD. For example, the Stroop test (Stroop, 1935) and the Trail Making test (Reitan, 1992) are good examples of measures that assess these processes. The incongruent condition of the Stroop test requires the patient to inhibit a more salient overlearned response (reading a word) in favor of a less salient response (naming the contrasting ink color). Patients with symptomatic AD, even at early stages, will perform much more slowly and make more errors on this task compared with the baseline conditions where they are asked to simply read words or name color blotches (Amieva et al., 2004). Similarly, individuals with symptomatic AD will have considerable difficulty on the Trail Making B test, which requires them to switch between one overlearned task to another overlearned task to connect a series of numbers and letters (Albert, 2008).

NORMATIVE DATA IN NEUROPSYCHOLOGICAL ASSESSMENT

Clinical assessment of an individual can be understood as having two distinct forms. An idiographic approach considers the individual as a unique agent with characteristics that set him or her apart from other individuals and refers to theories that are applicable to that specific case. In contrast, the nomothetic approach describes general laws of functioning that apply to all individuals and groups of individuals (Persons and Tompkins, 1997). Neuropsychological assessment emphasizes the nomothetic approach, in that a patient's score on a cognitive test is compared to the average performance of a larger group of demographically similar individuals who are typically free from disease. This larger group is referred to as a normative data set and may include individuals with a wide range of demographics (e.g., ages, educational achievement) and linguistic and ethnic backgrounds. In addition to healthy normative data sets, a patient's score can be compared to disease- (e.g., MCI or dementia) or cohort- (e.g., inpatients, on/off medications, age-groups) specific normative data sets. Normative data often are provided by the authors or publishers of a particular test or by other investigators attempting to validate an instrument in a particular clinical population. Attending carefully to the selection of normative data sets for clinical application is critical for interpretation of raw test scores. Normative data can be quite heterogeneous in

terms of the size and demographics of the sample, and the time at which the data were collected may introduce cohort effects. Normative data sets are not consistent in accounting for potential moderator variables such as education, gender, or cultural and linguistic backgrounds (Manly, 2008). Also, generalizability may be compromised by geographic limitations, because the samples may be representative of a certain region or collection of disparate regions in the United States or elsewhere (Kalechstein et al., 1998). Differences between these normative samples can significantly alter interpretation of test results. Kalechstein, van Gorp, and Rapport (1998) applied different sets of normative data to scores on commonly used cognitive tests for a group of individuals of various ages and education levels. Interpretation of performance was drastically affected depending on which set of normative data were used for comparison. In the most extreme cases, a score from a single test could span as many as four clinical classifications (e.g., Average, Low Average, Borderline, and Impaired). In other words, the percentile rank for a score on a single test could range from greater than the 25th percentile (Average) to less than the 2nd percentile (Impaired), depending on which normative data set was used for comparison.

Several studies have noted that many individuals continue to perform well on cognitive tests despite having substantial neuropathological abnormalities that ultimately lead to symptomatic AD (Knopman et al., 2003; Price et al., 2009; Schmitt et al., 2000). These individuals tend to be more educated, have larger brain volumes, and may be more socially engaged (James et al., 2011; Roe et al., 2011; Scarmeas and Stern, 2003). This phenomenon has been described as a reserve capacity that may prolong the prodromal period of AD (Roe et al., 2011). However, others have noted that an overreliance on insensitive cognitive tests and the relatively few studies that track intraindividual change may fail to detect subtle cognitive decline in these individuals. Although serial neuropsychological evaluation is ideal for assessment of intraindividual change, this may be impractical for a number of reasons. Thus, most referrals for neuropsychological assessment provide a cross-sectional

view of cognitive functioning. Without a careful history taking, which should include the patient and a reliable informant, it is possible that an apparently normal-looking cognitive profile may actually represent a significant decline from a former level of cognitive functioning (Fig. 59.1). This is often the case for high-functioning individuals.

Storandt and Morris (2010) describe an ascertainment bias, which highlights methodological issues related to determining the clinical diagnosis of dementia. They point out that many studies of so-called “cognitive reserve” have used insensitive mental status examinations as the only outcome measures. They also note that individuals who already have early cognitive impairment are included in normative samples, thereby lowering the group mean and reducing the sensitivity to detect impairment (Fig. 59.2). In a carefully assessed sample that was followed through autopsy confirmation of AD, application of commonly used standard deviation cutoffs of -1.0 or -1.5 on episodic memory tests detected only 23% and 44%, respectively, of patients who later developed AD. When this same sample was compared with a robust control group composed of individuals who never progressed to CDR greater than 0, sensitivity and specificity increased greatly but still was inaccurate in over 30% of cases (Storandt and Morris, 2010). These findings underscore the need for development of robust normative data, and also emphasize that an approach that uses standard deviation cutoff scores for classification may not be ideal, even with very robust normative data.

One potential solution is the development of a single comprehensive set of normative data that would include a large, demographically and geographically diverse sample with complete biomarker and neuroimaging data. Cerebrospinal fluid analytes and neuroimaging markers (including structural and functional MRI, amyloid imaging, and white matter imaging) could be used to identify individuals most likely to develop AD and classify them appropriately in the normative data set. An individual’s cognitive profile could then be compared with the normative group that is free of detectable AD neuropathology

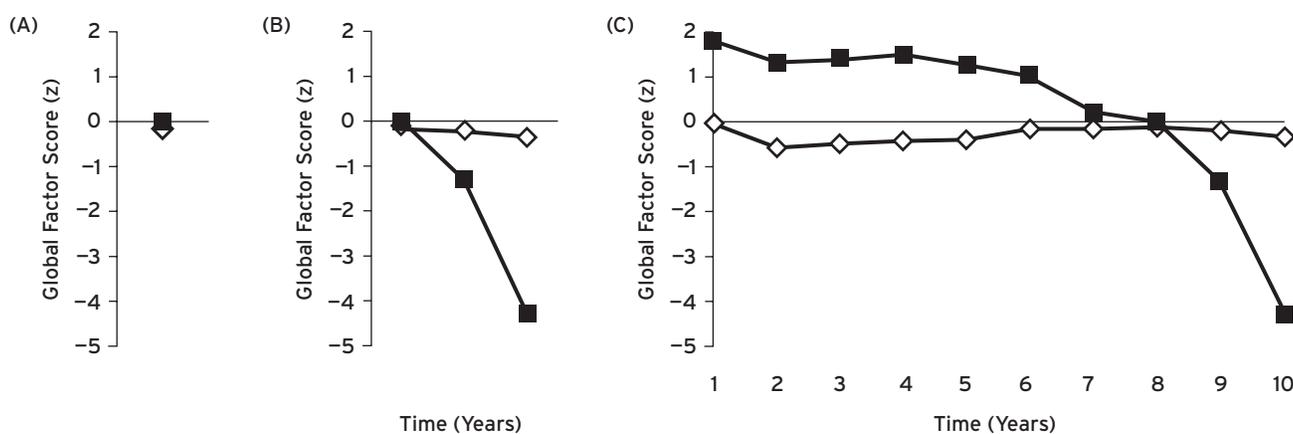

Figure 59.1 Global factor Z-score cognitive trajectories for two individuals seen over 10 annual follow-up visits. (A) At follow-up visit 8, both individuals score very close to the mean of the reference sample, indicating “normal” cognitive performance. (B) In subsequent assessments, one individual (filled black squares) declined at visit 9 to approximately 1.5 standard deviations below the mean performance of the reference sample and at visit 10 to over four standard deviations below the mean of the reference sample. (C), Cognitive performance at assessments prior to visit 8 for the same individual (filled black squares) reveal that decline had begun well before visit 8. Based on visit-specific neuropsychological performance alone, this individual might be considered as “cognitively normal” (visit 8) or “mild cognitive impairment” (visit 9), but neither of these considerations can be supported once intraindividual decline is taken into account. (Courtesy of Storandt, M.)

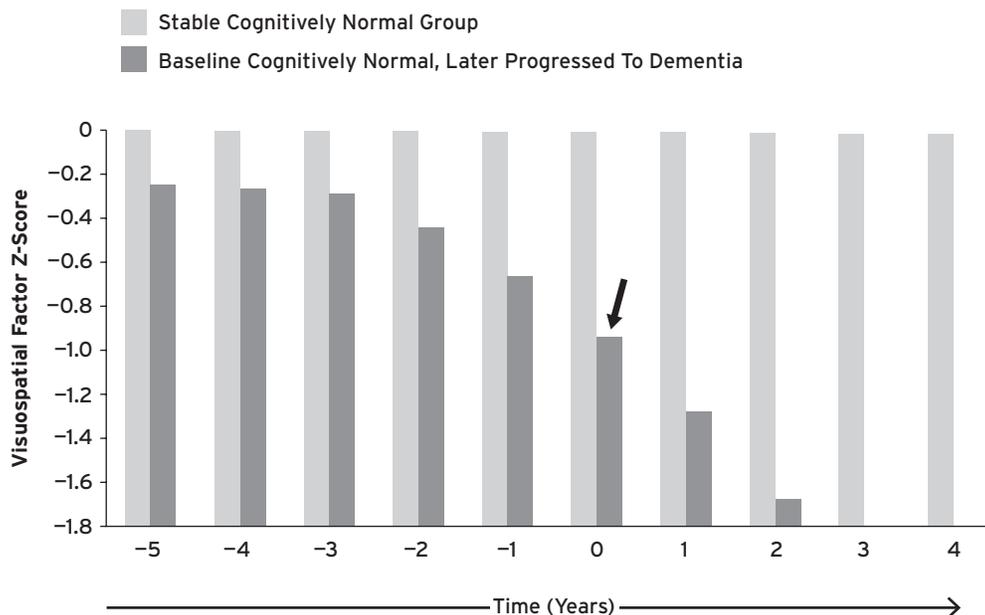

Figure 59.2 Longitudinal change in visuospatial domain factor scores in older adults who were cognitively normal at entry. The stable cognitively normal group never progressed to a CDR > 0. The autopsy-confirmed group began to decline 3 years prior to receiving a clinical diagnosis of dementia at year 0 (black arrow). Please note that the x-axis (time in years) is only applicable to the Stable group. Including asymptomatic persons with preclinical AD artificially lowers normative values. As a result, means and cutpoints used to detect impairment are too low. (Johnson et al., 2009.)

and could also be compared with a group with AD neuropathology but who show no clinical symptoms. However, this would be a costly and likely impractical endeavor making a set of “local norms” an appealing option (Kalechstein et al., 1998). Local norms would have the advantage of being ideally similar to the group to which each individual would be compared.

NEUROPSYCHOLOGICAL ASSESSMENT OF ALZHEIMER’S DISEASE IN DIVERSE POPULATIONS

The tremendous growth of ethnic minorities in the United States and Western Europe places increasing emphasis on the need for cognitive measures and normative data that are appropriate to adequately assess individuals of different ethnic, cultural, and linguistic backgrounds. Neuropsychology is in a position to benefit from advances in psychometric methods that move beyond the scrutinizing of between-group test score discrepancies, yet the vast majority of traditional neuropsychological measures commonly in use have not been properly validated for use in minority populations (Manly, 2008; Pedraza and Mungas, 2008). Thus, making diagnostic decisions using neuropsychological tests can be problematic when used on individuals who are not white, have at least two years of college education, are native English speakers, and from at least the midlevels of socioeconomic status (see Manly, 2008 for review). There have been large-scale efforts to develop normative data sets (see Pedraza and Mungas, 2008 for review), but there is still insufficient normative data for the two largest ethnic minorities groups in the United States, blacks and Hispanics. As such, classification accuracy rates for ethnic minorities using traditional normative data sets, especially for difficult diagnoses like prodromal AD, are unacceptable. Pedraza and Mungas (2008)

found that using traditional cutoff values of -1.0 standard deviations below the mean for a primarily white sample resulted in classification of 24% to 56% of cognitively normal blacks as cognitively impaired. Results were dramatically improved when using ethnically-specific normative data from Mayo’s Older African American Normative Studies (MOAANS; Lucas et al., 2005). Even when the most likely moderator variables such as age, gender, education, and ethnic backgrounds are taken into account either statistically as covariates or through use of specific normative data sets, other factors can significantly influence cognitive test performance. In a seminal manuscript, Manly and colleagues (Manly et al., 2002) found that using reading level as a proxy for quality of educational attainment largely attenuated differences in neuropsychological test performance between older blacks and whites. These findings appear to extend to blacks with AD. Chin and colleagues (Chin et al., 2012) found that controlling for quality of education using a reading level score, even after including reported years of education as a covariate, attenuated observed differences between blacks and white Non-Hispanics with AD on every neuropsychological test included in the analyses, as well as performance on mental status examinations. Interestingly, the attenuating effect remained after consideration of differences in functional impairment and disease duration, suggesting that use of reading level as a proxy for quality of education is a powerful predictor of neuropsychological performance even in patients with substantial clinical symptoms of AD.

Normative data sets that include mixed ethnicities may provide more accurate performance estimates for ethnic minorities than norms based exclusively on whites. However, grouping people of diverse ethnic backgrounds together may diminish the impact of cultural variables that are unique to particular ethnicities (Lucas et al., 2005). Persons of different ethnic

backgrounds may approach the testing situation with different experiences and attitudes that can significantly affect performance. Participants may not be accustomed to the emphasis on speeded performance or have limited familiarity with the wording used in test instructions or test questions (Lucas et al., 2005). Thus, there have been several large-scale attempts to create racially and ethnicity-specific normative data sets in efforts to circumvent these issues; however, this approach has not been without some controversy. Pedraza and Mungas (2008) summarize several arguments against race- or ethnicity-specific normative data sets. Some argue that use of separate norms may ignore underlying factors that contribute to between group differences, such as educational quality. Others argue that use of separate norms reinforces the assumption that race is a biological rather than a socially constructed distinction; another position is that use of separate norms promotes a fundamental misunderstanding about why the discrepancies exist.

DISCLOSURES

Dr. Jason Hassenstab reports that neither he nor his family owns stock or has equity interest (outside of mutual funds or other externally directed accounts) in any pharmaceutical or biotechnology company. Research support from the Charles F. and Joanne Knight Alzheimer's Disease Research Center and the National Institutes of Health (K23DK094982).

Dr. Jeffrey Burns reports research support from the National Institutes of Health (R01AG034614, R01AG03367, P30AG035982, U10NS077356, UL1TR000001). Dr. Burns also receives research support for clinical trials from Janssen, Wyeth, Danone, Pfizer, Baxter, Avid Radiopharmaceuticals, and Merck. Dr. Burns serves as a consultant for PRA International, has served as an expert witness for legal cases involving decision-making capacity, and has received royalties from publishing *Early Diagnosis and Treatment of Mild Cognitive Impairment* (Wiley Press, 2008) and *Dementia: An Atlas of Investigation and Diagnosis* (Clinical Publishing, Oxford, England, 2007).

Dr. John C. Morris reports that neither he nor his family owns stock or has equity interest (outside of mutual funds or other externally directed accounts) in any pharmaceutical or biotechnology company. Dr. Morris has participated or is currently participating in clinical trials of antidementia drugs sponsored by the following companies: Janssen Immunotherapy, and Pfizer. Dr. Morris has served as a consultant for the following companies: Eisai, Esteve, Janssen Alzheimer Immunotherapy Program, Glaxo-Smith-Kline, Novartis, and Pfizer; and receives research support from Eli Lilly/Avid Radiopharmaceuticals.

RUDOLPH E. TANZI

Over the past three decades, considerable progress has been made in the identification of genetic risk factors for Alzheimer's disease (AD). However, the challenges have been immense. First, although one of the key features of AD is familial aggregation and family history is the second greatest risk factor for AD, the genetics of AD are complex and heterogeneous (reviewed in Bertram et al., 2009; Bertram et al., 2010; Tanzi and Bertram, 2005). Second, a definitive diagnosis of AD requires a postmortem neuropathological examination of the brain. The quality of any genetic study depends on the validity and reliability of the phenotypes used. In considering "affection status" as a phenotype, it needs to be emphasized that any AD cohort consisting of living patients may be "contaminated" with non-AD cases of dementia (e.g., frontotemporal lobar dementia). A third challenge is that AD strikes late in life, usually after the age of 70 years. Thus, in family-based genetic studies, parental DNA is rarely if ever available. Moreover, family history, as related by family members may not be accurate. Despite these challenges, genetic discoveries in AD have provided the first and most vital clues regarding the causes of AD. For decades after Alois Alzheimer described the disease in the autopsied brain of a demented female patient in her 50s, our understanding of the etiology and pathogenesis was limited to what could be garnered from the pathological aftermath of the disease. The advent of the first AD genes in the 1980s and 1990s provided us with the first solid clues regarding the etiology and pathogenic events of AD along with strategies for treating and preventing this devastating disease.

EARLY-ONSET FAMILIAL ALZHEIMER'S DISEASE

Based on twin and family studies, approximately 80% of AD includes the inheritance of specific genetic factors as part of its etiology (Gatz et al., 2006). The existence of relatively large multigenerational early-onset familial Alzheimer's disease (EO-FAD) families helped to make the EO-FAD genes the "low hanging fruit" in AD gene discovery. Roughly 5% of AD is EO-FAD, which can be caused by well over 200 rare, fully penetrant mutations in three different genes. In 1987, we and others isolated the gene encoding the amyloid β (A β) protein precursor (*APP*), (Goldgaber et al., 1987; Kang et al., 1987; Tanzi et al., 1987a; Tanzi et al., 1988a), and physically and genetically mapped it to chromosome 21 (Tanzi et al., 1987a). The cloning of *APP* was made possible by the publication of the amino acid sequence of the amyloid β -protein by Glenner and

Wong (1984) and Masters et al (1985). In their paper, Glenner and Wong predicted that the gene responsible for making the " β -protein," as they called it, would be on chromosome 21 and carry mutations causing AD. More importantly, Glenner first proposed that AD is a cerebral form of amyloidosis, in which the accumulation of cerebral amyloid β -protein drives all subsequent pathology. Glenner's β -protein hypothesis was subsequently reinterpreted and reported eight years later as the "amyloid cascade hypothesis" of AD (Hardy and Higgins, 1992), and was further refined in later years (Hardy and Selkoe, 2002; Tanzi and Bertram, 2005).

When we and others used the A β amino acid sequence (Glenner's β -protein and Masters' A4) to clone the *APP* gene (Goldgaber et al., 1987; Kang et al., 1987, Tanzi et al., 1987a, Tanzi et al., 1988), the first AD candidate gene had been identified. Concurrent with the isolation of the *APP* gene, we also reported in that same issue of *Science*, evidence for genetic linkage of EO-FAD to genetic markers on chromosome 21 in the vicinity of *APP* (St George-Hyslop et al., 1987). From 1982 to 1987, Paul Watkins and I had been working in the laboratory of James Gusella at MGH to isolate the first single nucleotide polymorphisms (SNP) on chromosome 21, called restriction fragment length polymorphisms (RFLPs). These were used to build a complete genetic map of this chromosome (Tanzi et al., 1988b). At that same time, we had been collecting some of the largest, multi-generational EO-FAD families and started testing them for genetic linkage to chromosome 21 in 1983.

After testing the first two EO-FAD families (of Canadian and Italian descent), no genetic linkage of AD was observed for the SNPs on our genetic linkage map of chromosome 21. Later, two more EO-FAD families (of German and Russian descent) were added to the study, and Peter St George-Hyslop and Jonathan Haines had taken over the project as I turned my own efforts to cloning the first AD candidate gene, *APP*. At the same time that we and others had reported the identification and characterization of the *APP* gene, St George-Hyslop and Haines claimed to find linkage to chromosome 21 in the vicinity of the *APP* gene near marker *D21S1* (St George-Hyslop et al., 1987). Disappointingly, soon after, we showed that the same four large EO-FAD families apparently linked to markers on chromosome 21 near *APP* exhibited absolutely no genetic linkage to *APP* (Tanzi et al., 1987b). Van Broeckhoven et al. also reported lack of linkage of EO-FAD to *APP* in other EO-FAD families (Van Broeckhoven et al., 1987). Importantly, in both of papers, *APP* was ruled from linkage in the specific EO-FAD families tested, however, we did not rule out *APP* as a candidate gene for other cases of AD. Later the four EO-FAD

families reported to be linked to chromosome 21 were shown to actually be linked to an EO-FAD locus on chromosome 14q24 and were ultimately demonstrated to carry mutations in the presenilin 1 (*PSEN1*) gene (Sherrington et al., 1995).

So, although the original genetic linkage of EO-FAD to chromosome 21 (St George-Hyslop et al., 1987) was spurious, ironically, it prompted other groups, including that of John Hardy, to test other EO-FAD families for genetic linkage of EO-FAD to our DNA markers (RFLPs) on chromosome 21. And some of those families exhibited genuine linkage to our chromosome 21 map RFLP markers that we had shared with John Hardy. In 1991, the first EO-FAD mutation was found in *APP* by re-sequencing those independent chromosome 21-linked EO-FAD families (Goate et al., 1991). However, this was not the first disease mutation reported in *APP*. Prior to the Goate et al. (1991) paper, Frangione et al. had already reported the first pathogenic mutation in *APP* (Levy et al., 1990). Levy et al. (1990) sequenced exons 16 and 17 of *APP*, which encode the A β domain, and uncovered the first pathogenic mutation in *APP*, which was responsible for Dutch hereditary cerebral hemorrhage with amyloidosis, sometimes referred to as a vascular form of AD. Goate et al. (1991) took a similar approach on their chromosome 21-linked families by resequencing the same two *APP* exons, to find the first EO-FAD mutation (London mutation; V717I) in *APP*.

Less than a year after the elucidation of the first *APP* mutations, it became clear that mutations in *APP* accounted for a very tiny proportion of EO-FAD (Tanzi et al., 1992). In 1995, several EO-FAD mutations were found in *PSEN1* (Sherrington et al., 1995) on chromosome 14. Shortly afterward, we reported a homolog of *PSEN1* called presenilin (*PSEN2*) (Levy-Lahad et al., 1995) on chromosome 1 and showed that it contained the N141I mutation in Volga-German EO-FAD families. This was subsequently confirmed by Rogaev et al. (1995). To date, 30 mutations (plus duplications) have been reported for *APP*, 185 for *PSEN1*, and 14 for *PSEN2* (Alzheimer's Disease & Frontotemporal Dementia Mutation Database; <http://www.molgen.ua.ac.be/ADMutations>). Generally, the EO-FAD mutations in *APP*, *PSEN1*, and *PSEN2* and duplication of *APP* are fully penetrant for causing AD (Table 60.1). However, we recently reported the first case of non-penetrant *APP* duplication (Hooli et al., 2012).

The vast majority of the more than 200 EO-FAD mutations in *APP*, *PSEN1*, and *PSEN2* lead to increase in the ratio of A β ₄₂:A β ₄₀ (Scheuner et al., 1996; Tanzi and Bertram, 2005). The increase in relative levels of A β ₄₂ then promotes

the aggregation of the peptide into β -amyloid (Jarrett et al., 1993). Three years after the discovery of the presenilins in 1995, they were shown to act as aspartyl proteases that carry out γ -secretase cleavage of *APP* in its transmembrane domain to produce A β (reviewed in Tanzi and Bertram, 2005). Based on these collective findings, we have been collaborating with Steve Wagner (UCSD) to develop a class of highly promising AD drugs known as γ -secretase modulators, which are aimed at reversing this ratio. (Kounnas et al., 2010).

GENETICS OF LATE-ONSET ALZHEIMER'S DISEASE

The most common form of the disease is defined by onset after 65 years and is referred to as LOAD. Unlike EO-FAD, which is characterized by classic Mendelian inheritance most often in an autosomal dominant manner, LOAD exhibits a genetically complex pattern of inheritance. Risk for most cases of LOAD involve the influence of both genetic and life exposure factors. The most highly confirmed risk factor for LOAD is the ϵ 4 variant of the apolipoprotein E gene (*APOE*) (Strittmatter et al., 1993) on chromosome 19. The three major variants of *APOE* are based on combinations of amino acids 112 and 158 (ϵ 2: Cys₁₁₂/Cys₁₅₈; ϵ 3: Cys₁₁₂/Arg₁₅₈; ϵ 4: Arg₁₁₂/Arg₁₅₈). A single copy of the ϵ 4-allele increases AD risk by about four-fold, whereas two copies increase risk by greater than 10-fold. In contrast, the ϵ 2-allele of *APOE* is protective (Corder et al., 1994). Functionally, *APOE* is believed to play a role in the clearance of A β from the brain (reviewed in Kim et al., 2009).

For a decade or more after the report of association of LOAD with *APOE*, hundreds of genes were tested for association with AD leading to endless series of replications and refutations. Lars Bertram, colleagues, and I started an online database called AlzGene.org (<http://www.alzgene.org>) (Bertram and Tanzi, 2008; Bertram et al., 2007) to summarize and display these findings in a systematic and objective manner. In addition, AlzGene.org presents metaanalysis results for AD candidate genes that have been tested in at least four independent case-control samples. The strongest association with LOAD on AlzGene is obtained with *APOE*. Roses et al. (2010) recently proposed that additional genes near *APOE* might also influence risk for AD. One of these is a poly-T variant in the gene for the translocase of outer mitochondrial membrane 40 homolog (*TOMM40*), which is in strong linkage disequilibrium with *APOE*, mapping only ~2,000 basepairs away. The "long"

TABLE 60.1. Early-onset familial Alzheimer's disease genes

GENE	PROTEIN	CHROMOSOME	MUTATIONS	CONSEQUENCE
<i>APP</i>	Amyloid β (A4) Protein Precursor	21q21	30 (duplication)	Elevated A β ₄₂ /A β ₄₀ ratio Increased A β production Enhanced A β aggregation
<i>PSEN1</i>	Presenilin 1	14q24	185	Elevated A β ₄₂ /A β ₄₀ ratio
<i>PSEN2</i>	Presenilin 2	1q31	14	Elevated A β ₄₂ /A β ₄₀ ratio

poly-T repeats were reported to be associated with earlier onset of AD. This creates a conundrum because it is highly unlikely that both *APOE* and *TOMM40*, sitting right next door to each other, both contribute to AD risk. Given the choice of whether the real AD gene there is *APOE* or *TOMM40*, functional studies strongly support *APOE* as the actual AD gene in this region based on its ability to affect cerebral A β clearance (reviewed in Kim et al., 2009). Moreover, in our own family-based studies of AD, the statistical signal strength of the association of *APOE* with AD is 15 orders of magnitude higher than that observed for any of other genes in the *APOE* region, including *TOMM40* (unpublished data).

Although most studies searching for novel AD genes after the report of the association with *APOE* employed candidate gene searches, more genome-wide association studies (GWAS) have become more common. In GWAS, up to one million SNPs (along with single copy probes to detect copy number variants) are tested for genetic association with disease risk and phenotypes including age-of-onset, biomarkers, imaging results, and neuropathological endpoints. The first genome-wide significant GWAS finding of a gene associated with LOAD was with the gene encoding GRB2-associated binding protein 2 (*GAB2*; Reiman et al., 2007). However, the association was only deemed “genome-wide significant” following post hoc stratification by *APOE*. The association was followed by a series of replications and refutations. Functionally, *GAB2* has been proposed to affect both tau phosphorylation (Reiman et al., 2007) and A β production (Nizzari et al., 2007).

A year after the *GAB2*, we reported the first genes to exhibit genome-wide significant association with AD without stratification on *APOE*. To achieve this, we employed family-based GWAS (Bertram et al., 2008) and reported three AD genes candidates containing SNPs that exhibited genome-wide significance for association AD. These included *ATXN1* (ataxin 1), *CD33* (siglec 3), and an uncharacterized locus on chromosome 14 (*GWA_14q31.2*). *ATXN1* can carry an expanded poly-glutamine repeat that causes spinocerebellar ataxia type 1. *ATXN1* also affects A β levels by regulating levels of β -secretase, the rate-limiting enzyme for A β production (Zhang et al., 2010). *CD33* is a sialic acid-binding, immunoglobulin-like lectin that regulates the innate immune system (Crocker et al., 2007), including inflammation. We recently showed that A β has the microbiological properties of an antimicrobial peptide, used in the brain’s innate immune system (Soscia et al., 2010). Thus, control of the brain’s innate immune system by molecules like *CD33*, might also regulate A β levels via clearance by microglial cells.

In 2009, two of the largest case-control GWAS carried out to date (Harold et al., 2009; Lambert et al., 2009) led to three novel AD genes: *CLU* (clusterin; apolipoprotein J), *CR1* (complement component [3b/4b] receptor 1), and *PICALM* (phosphatidylinositol binding clathrin assembly protein). However, the effect sizes of the AD-associated SNPs in these genes are tiny (i.e. increasing or decreasing risk by ~1.15-fold). In contrast, *APOE*- ϵ 4 increases risk for AD by ~4-fold and 15-fold, for one or two alleles, respectively. Functionally, *CLU* is likely involved in importing A β from plasma back into the brain (DeMattos et al., 2004; Nuutinen et al., 2009). In contrast, *APOE* exports the peptide out of the brain into the plasma. *PICALM*

is involved in clathrin-mediated endocytosis (Tebar et al., 1999; Treusch et al., 2011), and *CR1*, like *CD33*, plays a role in the innate immune system (Khera and Das, 2009). In 2010, another case-control GWAS (Seshadri et al., 2010) reported association with the gene for bridging integrator 1 (*BIN1*), which had actually been reported to be associated with AD in an earlier study (Lambert et al., 2009). The AD-associated SNP in *BIN1* also has a very small effect size on AD risk with an allelic odds ratio of ~1.15. *BIN1* is expressed in the CNS and like *PICALM*, plays a role in receptor-mediated endocytosis (Pant et al., 2009).

In 2011, two more case-control GWAS reported four more AD candidate genes including *CD2AP*, *MS4A6A/MS4A4E*, *EPHA1*, and *ABCA7* (Hollingworth et al., 2011; Naj et al., 2011). These studies also identified a second AD-associated SNP in *CD33* providing strong support for our previously reported genome-wide significant association of *CD33* with AD three years earlier (Bertram et al., 2008). Thus, in addition to the four original AD genes, *APP*, *PSEN1*, *PSEN2*, and *APOE*, 11 more AD genes (*CD33*, *GWA_14q31.2*, *ATXN1*, *CLU*, *PICALM*, *CR1*, *BIN1*, *ABCA7*, *MS4A6E/MS4A4E*, *CD2AP*, and *EPHA1*) harbor SNPs that exhibit genome-wide significance for association with LOAD (Table 60.2).

The predicted and known functions of the AD genes fall into four basic categories: A β metabolism, lipid metabolism, innate immunity, and cellular signaling. With the identification of the original 4 and 11 novel confirmed AD genes, we hope to answer some key remaining questions regarding the etiology and pathogenesis of AD. First, which genes besides *APP*, *PSEN1* and *PSEN2* affect the production of A β ? Based on our own data these would minimally include *ATXN1* (Zhang et al., 2010). Second, which genes besides *APOE* affect the clearance of A β in the brain? These would likely include *CLU* and according to our own unpublished preliminary data, *CD33*, based on its ability to activate microglial degradation of A β . Other AD candidate genes that activate microglia to clear A β may also be involved (e.g. *CR1*).

The excessive accumulation of A β in the brain is believed to trigger tauopathy and tangles, followed by neurodegeneration and inflammation. The ability of excess accumulation of

TABLE 60.2. Late-onset Alzheimer’s disease genes

cerebral A β to trigger tauopathy likely involves aberrant signaling and could therefore involve *PICALM*, *BIN1*, *CD2AP* (Treusch et al., 2011). Neurodegeneration accompanied by tauopathy and excess A β accumulation must also induce inflammatory pathways to complete the course of neuronal cell death and synapse loss initially triggered by excessive A β accumulation in the brain. It is likely that AD genes involved in the innate immune system (e.g. *CD33*, *CLU*, *MS4A6E/MS4A4E*, and *EPHA1*) play a role here. Thus, so far, the known AD genes and newly confirmed AD gene candidates from GWAS fit fairly nearly into an overall pathogenic pathway in which excessive accumulation of A β leads to tauopathy and neurodegeneration followed by inflammation ultimately resulting in catastrophic loss of neurons and synapses leading to dementia (Tanzi and Bertram, 2005).

ADAM10: FIRST LOAD GENE WITH RARE PATHOGENIC MISSENSE MUTATIONS

Late-onset AD has been associated with common genetic variants, which, with the exception of *APOE*, exert small effects on risk. However, our laboratory recently reported two rare, highly penetrant mutations for LOAD (Kim et al., 2008), located in the *ADAM10* gene. *ADAM10* encodes the major α -secretase in the brain, which cleaves within the A β domain of APP to preclude β -amyloid formation. We reported two rare (7 of 1000 LOAD families) LOAD mutations in *ADAM10*: Q170H and R181G. Both are located in the prodomain region and lead to AD at roughly 70 years old. Both mutations severely impair *ADAM10*'s ability to cleave at the α -secretase site of APP *in vitro* (Kim et al., 2008) and these effects have now been confirmed *in vivo* (unpublished observations). To date, these are the first and only highly penetrant, rare mutations reported for LOAD. These findings underscore the critical need for whole genome or whole exome sequencing to identify other rare functional DNA variants causing LOAD, perhaps with high penetrance as we have observed for the novel LOAD mutations in *ADAM10*.

CONCLUSIONS

Over the past three decades, the identification and characterization of the AD genes have elucidated the etiology and pathogenesis of AD. Studies of these genes have also provided valuable clues regarding treatment and prevention of AD (reviewed in Bertram and Tanzi, 2010; Tanzi and Bertram, 2005). Following the initial discovery of the first four established AD genes, *APP*, *PSEN1*, *PSEN2*, and *APOE*, AD GWAS aimed at identifying additional AD genes (reviewed in Bertram et al., 2009, 2010) have introduced a new era of AD genetics. However, the new LOAD genes coming out of GWAS carry SNPs that generally have only small effect sizes. It is almost certain that in most, if not all cases, these SNPs are not the functional variants affecting risk for AD. Fortunately, the development of powerful sequencing technologies such as whole genome sequencing should allow us to identify the actual functional variants in the

novel AD genes emerging from GWAS, as well as in the original AD genes. The eventual elucidation of the actual functional variants in these genes (as we have found in *ADAM10*) will allow for more meaningful biological and translational studies as well as novel animal models for AD. In this way, genetic studies of AD will continue to inform and guide new treatment strategies for preventing and treating this terrible disease.

DISCLOSURES

Dr. Tanzi serves as a consultant to Prana Biotechnology, Eisai, Genomind, Probio Drug, Abide, and EcoEos. He also has a financial interest in Prana Biotechnology, Neurogenetic Pharmaceuticals, Evolutionary Genomics, Neuroptix, Abide, and Genomind.

61 | EXPERIMENTAL ANIMAL MODELS OF ALZHEIMER'S DISEASE

DAVE MORGAN

This meta-review will summarize the history and current state of the science in the use of animals to glean insights into the causes and to assist in identifying meaningful treatments for Alzheimer's disease (AD). As such it will refer readers to more detailed reviews on specific topics as needed and not to the original works to any great extent. Moreover this review will focus on experimental models of Alzheimer's disease that are based on the pathology of that disease and not merely the symptoms (e.g., memory loss).

PURPOSE OF ANIMAL MODELS

For virtually every known human malady there have been attempts to understand the disease better using systems that can be manipulated either more conveniently, more precisely, or more ethically than similar manipulations in human subjects. There are two primary goals of the animal models. The first is to provide a platform in which to study the basic mechanisms underlying the disease. This more detailed understanding can occur at molecular, cellular, tissue, organs, or systems level within the organism. Rarely do the models mimic all aspects of the human disorder. This is particularly true for AD. However, because of our capacity to manipulate the animal models, we can test hypotheses regarding the causes and processes generating the disorder.

A second rationale for animal models is to use them to identify treatments, often pharmacological, to consider for evaluation in the human disease. Importantly, these two roles do not require the same types of models. For example drugs designed to have symptomatic benefit may be tested quite readily in models that have the same physiological changes as the disorder in question, irrespective of how those changes developed. Streptozocin induced diabetes is one example. This toxin is not a pathogenic mechanism normally causing the disease in man, yet can create a model to evaluate certain types of drugs intended to benefit diabetics.

In the field of Parkinson disease the use of animal models reflecting the pathology of the disease has been a mainstay of investigations since the 1960s. The 6-hydroxydopamine lesion model mimics the dopaminergic deficit that is found in Parkinson disease. This has facilitated the development of the number of dopamine enhancing medications and surgical interventions (cells, electrical stimulation, lesions) that have proven beneficial in the treatment of Parkinson disease. In

the 1980s the MPTP model was developed as a possible explanation of the pathogenic mechanisms involved in Parkinson disease. This model also has permitted the development of medications of benefit in treating Parkinson. However more recently the identification that synuclein is a key component in the pathophysiology of Parkinson disease has led to the conclusion that the MPTP model probably only is mechanistically valid for the few individuals inadvertently exposed to this toxin. Instead it is now the case that a number of new models based on the rare genetic causes of parkinsonism are providing a valuable adjunct to the symptomatic models. The hope is these new models may be recapitulating some of the pathogenic mechanisms of the sporadic disease.

ANIMAL MODELS OF ALZHEIMER'S DEMENTIA BASED ON THE CHOLINERGIC HYPOTHESIS

In the middle 1970s two groups of British neurochemists led by David Bowen and Peter Davies independently identified a decrease in markers of the cholinergic system in Alzheimer's disease (AD) postmortem tissue. Importantly, the brain regions that were most affected by AD were the regions of the neocortex and the perirhinal area including the hippocampus (Mesulam, 2004). Other regions of the brain such as the striatum and the thalamus were relatively unaffected in AD patients compared to age-matched controls. This was the first indication that the cholinergic system played a role in the symptoms of Alzheimer's disease analogous, in some ways, to the role of the dopaminergic system in Parkinson disease. These neurochemical observations were followed shortly by anatomical measurements within the forebrain nuclei known to contain the cholinergic neurons. These include the nucleus basalis magnocellularis, the medial septum, and the diagonal band of Broca. These cholinergic nuclei are the regions known to project to the neocortex and the perirhinal regions including the hippocampus.

There is a large and extensive literature relating the acetylcholine system in the central nervous system to learning and memory function. In the 1970s David Drachman and his collaborators demonstrated that cholinergic antagonists such as scopolamine were capable of decreasing learning and memory performance in rats (Hasselmo, 2006). One important control used by this group was to test methylscopolamine and

demonstrate that there were no learning and memory performance deficits caused by this drug. Methylscopolamine fails to cross the blood-brain barrier. Thus it has all of the autonomic nervous system effects that scopolamine has, yet lacks central cholinergic blockade. These groups also reported that the effects of scopolamine could be reversed by coadministration of cholinergic agonists such as carbachol or cholinesterase inhibitors. More recent work has shown that selective muscarinic antagonists, selective nicotinic antagonists, and drugs that block choline uptake into the nerve terminal also can impair learning and memory function in animals. Another important feature of anticholinergic drugs is that the memory deficits observed are qualitatively similar to those that are observed with AD. That is, the drugs tend to disrupt the acquisition of new information while sparing the recollection of previously learned information. This is similar to early-stage Alzheimer patients who show impairment of short term or working forms of memory yet have intact recollection of events that occurred many years prior to the onset of their memory deficits. Moreover, there is a correlation between the degree of cholinergic marker reduction and cognitive dysfunction in Alzheimer patients at autopsy (Mesulam, 2004).

Consistent with the psychopharmacology studies, lesions of the cholinergic neurons in the basal forebrain generally lead to impairments of learning and memory functions. Cholinergic neuron lesions have been achieved by electrocoagulation, excitotoxin injections, fimbria-fornix transections, and more selective cholinergic lesions using 192-IgG saponin (Casamenti et al., 1998; Yamada and Nabeshima, 2000). This latter agent is a conjugate of an immunoglobulin and a toxin. The antibody binds the p75 nerve growth factor receptor that exists largely on cholinergic neurons. The saponin is internalized and released to cause the death of the cholinergic neurons in the basal forebrain. These lesions cause memory deficits that can be reversed by cholinomimetic drugs or treatments that promote cholinergic neuron survival such as nerve growth factor (Yamada and Nabeshima, 2000). Somewhat surprisingly, the more selective the lesion is for the cholinergic neurons within these basal forebrain nuclei the less impact this has on learning and memory function in the rats or other animals in which these lesions are performed. Instead it appears that the major impact of these cholinergic selective lesions is on attentional processes rather than learning and memory per se (Blokland, 1995). It should be noted that sufficient attention is essential for the acquisition of new information and this may underlie a large component of the deficits observed both in the animal models as well as in Alzheimer patients when testing learning and memory performance.

The evidence provided by the pharmacology experiments combined with the results observed in the lesion studies led to the *cholinergic hypothesis* of the memory dysfunction in AD. In the early 1980s this was proposed most clearly by Ray Bartus, arguing that the cholinergic model of geriatric memory dysfunction would provide a convenient system in which to identify drugs that could later be used to treat Alzheimer's disease.

Based largely on the evidence detailed in the preceding, the first cholinesterase inhibitor was tested in human Alzheimer patients by Summers. This initial drug, Tacrine, showed a

modest cognitive benefit but was approved as the first available agent to treat AD. However, liver toxicity in a substantial number of patients has led to it being replaced by newer agents. The second-generation cholinesterase inhibitors, donepezil, rivastigmine, and galantamine have become the primary approach to treating Alzheimer's disease. Although these drugs have frustratingly modest impact on disease symptoms, unlike the dopaminergic drugs in Parkinson, they do provide some benefit and have been argued to delay institutionalization by up to two years. There also remain opportunities to improve the use of these medications using a personalized medicine approach to identify those individuals who will respond to each cholinesterase inhibitor optimally. This is based on the observation that although only one-third of patients respond to the first cholinesterase inhibitor they are administered, approximately one-half of those non-responders will respond to one of the other cholinesterase inhibitors that are available (Auriacombe et al., 2002).

AMYLOID INJECTION MODELS

Early studies on cultured primary neurons found that incubation with A β could kill these cultured cells at μ M concentrations. This rapidly led to attempts in the early 1990s to generate a model of A β neurotoxicity *in vivo* by injecting A β into the brain. The first attempts had very mixed results (Harkany et al., 1999; Yamada and Nabeshima, 2000). Several groups reported some apparent toxicity and occasional neuron loss, whereas others reported only minimal effects. Some of these early studies examined the effects of A β 25–35 peptide or A β 1–40. This was largely because of the early challenges in synthesizing the 1–42 peptide, and the greater costs of the longer synthetic peptides. A β 25–35 was a low cost means of rapidly generating amyloid fibrils, although it is not found *in vivo* at meaningful concentrations. Nonetheless, parsing the studies on the basis of the A β sequence does not resolve the diverse outcomes. One suggestion was that effects of A β 25–35 were only transient, compared with A β 1–42 (Harkany et al., 1999). Another general observation was that infusions of A β using osmotic pumps generally caused larger effects that endured longer than acute bolus injections (Harkany et al., 1999). Our own work in this area identified that the heparan sulfate proteoglycan, perlecan, promoted the formation of A β -conophilic deposits when infused into the hippocampus of young rats. This was associated with dramatic activation of astrocytes and microglia. However, after several years of experience in evaluating this preparation, we finally concluded that these deposits did not cause significant neurotoxicity (Holcomb et al., 2000). Parallel, but unpublished work concluded the same for combinations of A β with apolipoprotein E or alpha-1 antichymotrypsin. Instead, these infusions resulted in large congophilic aggregates (several hundred μ m), which would then gradually be cleared by microglia leaving a vacuole at the site of the infusion.

In studies that did report an impact of intracranial A β , the most common observations were memory deficits in mice or rats. The groups led by Giancarlo Pepeu and Tibor Harkany found that the most sensitive neurons to the toxicity

of infused A β were the cholinergic neurons (Chambon et al., 2011). Reasonably consistent declines in rat cholinergic markers in cerebral cortex and hippocampus were found following either direct injections into cholinergic nuclei or infusions into the ventricles. Some studies also found that ventricular infusions of A β peptides *in vivo* would lead to defective long-term potentiation in *ex vivo* slices from these mice (Yamada and Nabeshima, 2000). Finally, the age of the organism appears to be a meaningful consideration. Bruce Yankner's group found that of aged rats, aged rhesus, and young rhesus, only the aged rhesus monkeys demonstrated neuronal loss after injections of fibrillar (but not soluble) A β into the cortex (Geula et al., 1998).

The introduction of the transgenic mouse models in the mid-1990s, coupled with frustrations in identifying a consistent means of producing toxicity with A β application, led many to abandon these direct injection approaches. Although the precise reasons for the inconsistency between and often within a research team are not resolved, Pat May and others commented on the lot to lot inconsistency for most synthetic A β preparations (Yamada and Nabeshima, 2000). Moreover, we are now increasingly aware that there are different aggregations states of A β , with the intermediate sized aggregates, oligomers, likely being more toxic to neurons than the monomers or the fibrils. As indicated in Table 61.1, there are some distinct advantages of the direct administration approach. Given the advances in peptide synthesis, and availability of recombinant peptides, some of the lot to lot variability plaguing early studies may be avoided. Moreover, we now have reasonably well characterized means of producing stable aggregated forms of A β intermediates that may produce more reliable impacts on neuronal activity. Certainly, for drug targets designed to interfere with events downstream of A β action, the intracranial injections may be more useful screening systems than transgenic mice.

TRANSGENIC MOUSE MODELS OF AMYLOIDOGENESIS

AMYLOID PRECURSOR PROTEIN TRANSGENIC MICE

Probably the most studied models relevant to Alzheimer's disease are those which overproduce the A β peptide. These mice derive from oocyte injection of a construct containing multiple

copies of the human amyloid precursor protein (APP) gene (often as concatemers). Overexpression of human APP leads to overproduction of A β via the processing of the APP protein. The excess A β leads to a variety of changes, some of which are consistent with observations in AD. These models have proven very useful in (1) understanding the mechanisms leading to the production and clearance of the A β peptide *in vivo* and (2) screening agents suggested as potential amyloid lowering therapeutics.

George Glenner's publication of the amino acid sequence of vascular amyloid led within a year to the identification by four independent groups that the sequence was contained within the APP gene. This launched a number of campaigns to produce transgenic mice overexpressing this protein in hopes of creating a mouse model of AD. The seminal observation by John Hardy and Alison Goate that mutations in APP could lead to familial Alzheimer's disease provided further impetus to this effort, and suggested modifications that could increase the likelihood of success.

However, obtaining a successful mouse model proved exceedingly challenging. Some early approaches employed constructs directly expressing the A β sequence. One of these was first described in a paper in *Science*. These mice had low levels of transgene expression, but as they aged developed some punctate staining seen with anti-A β antisera, which were interpreted as amyloid deposits. However, neuropathologists noted these did not resemble amyloid plaques in AD, but instead appeared to be artifacts typically observed in the C57BL6 mice (used as background strain) as they aged (Greenberg et al., 1996). Additional scrutiny revealed the control mice for the published study were considerably younger than the transgenic mice. Subsequent work revealed that the non-transgenic mice of this background also developed these histological artifacts. This paper was later retracted.

Another approach was to express the C terminal 100 amino acids of the APP sequence. This essentially provided a peptide that has the N terminus produced by the beta secretase cleavage. Subsequent processing by gamma secretase would result in release of the A β peptide. A paper was published in *Nature* that presented micrographs that recapitulated all of the histological changes found in AD: amyloid plaques and neurofibrillary tangles. However, shortly after publication, neuropathologists noticed that the micrographs shown were not from mouse brain, but appeared to be AD brain tissue. Subsequent evaluation of

TABLE 61.1. Advantages and disadvantages of direct A β administration models

ADVANTAGES	DISADVANTAGES
<ul style="list-style-type: none"> • Can examine multiple species • Studies can be conducted rapidly with minimal colony maintenance expense • Have known time when toxicity initiates. Can measure time course to determine if there is spontaneous recovery or permanent damage • Can use different variants of Aβ • Can measure the physical state of the administered material (monomer, oligomer, fibril) • Can control dose • Can evaluate the effects of host age 	<ul style="list-style-type: none"> • Doses used are likely in excess of those found <i>in vivo</i> • Requires surgical intervention/anesthesia • Injected material can be cleared quickly • Aβ will form a concentration gradient from the site of administration (nonuniform dose) • Aβ largely extrasynaptic as opposed to synaptically released <i>in vivo</i> • Problems with consistency of lots/preparations of Aβ

the sections by Don Price revealed they were indeed human in origin, and the paper was retracted (Greenberg et al., 1996). This series of events led one of the coauthors, Gerry Higgins, a coauthor of the original amyloid cascade hypothesis manuscript with John Hardy, to stop working in the Alzheimer field. As a personal anecdote, the author of this chapter recalls a casual conversation with Dr Higgins about this mouse shortly after publication. His enthusiasm for its use as a model and willingness to share it suggests he was unaware that the data published in *Nature* were not genuinely from the transgenic mice he had collected.

Another early mouse used full length APP with a neuron-specific enolase promoter. These mice, developed at the biotechnology firm Scios-Nova, expressed some A β , but the histology did not resemble the amyloid deposits found in the AD brain. The author of this chapter recalls having to be “educated” regarding what a plaque was on tissue sections we had stained with anti-A β antisera in tissue from these mice. It was a faint cloud of staining which might easily be taken as artifact. Nonetheless, these mice did exhibit memory deficits, a point of relevance to be discussed later. There are a number of other transgenic mice that were reported in the early 1990s that were attempts to model the amyloid pathology of AD, but none of these produced the plaque pathology found in the postmortem AD tissue. These are summarized nicely in Greenberg et al. (1996). There were probably thousands more oocytes injected and progeny born without phenotypes that were never reported in publications.

The first mouse to demonstrate amyloid deposition that resembled that found in AD was reported by Games et al. (1995). These mice used a minigene construct to produce multiply spliced forms of APP and the platelet derived growth factor promoter (which, in spite of its name, drives high expression in neurons). The APP sequence included the Indiana mutation near the gamma secretase site, which increased the production of A β ending at residue 42 relative to residue 40. These mice produced APP at almost ten-fold excess over endogenous levels. These mice also developed both diffuse and compact fibrillar amyloid deposits as they aged. Furthermore, there was a characteristic activation of microglial cells near the compacted deposits and activation of astrocytes surrounding the deposits. They also induced dystrophic neurite formation near the compacted plaques, all of which were similar to the pathology found in AD. This so called “PDAPP” mouse has been used extensively by Athena/Elan, Lilly, and their collaborators for evaluating potential treatments for AD. An interesting back story on this mouse, to this author’s understanding, is that it was originally generated at a small biotech in Worcester, Massachusetts called Exemplar by Sam Wadsworth and colleagues. Shortly after the production of the line, the company’s deteriorating finances led to attempts to license the mouse, but they did not yet have any histopathology demonstrating their success. Given the history of APP transgenics up to that time, a number of companies offered the opportunity refused to license or purchase the mouse until Athena neuroscience (now Elan) obtained the line. Another important component of this episode is that before the paper was published in *Nature*, histological sections were sent to Don Price, a neuropathologist

who played a role in debunking the two earlier transgenic mouse claims that were retracted. His verification that these amyloid deposits were authentic was crucial to the acceptance of the conclusions.

Shortly after the publication of the Games et al., 1995 paper, additional transgenic models came to light that had remarkably similar forms of amyloid pathology. The mouse described by Karen Hsiao (now Karen Hsiao Ashe) and her group expressed APP with a Swedish mutation under the control of the prion promoter (Hsiao et al., 1996). The Swedish mutation increases beta secretase cleavage, increasing both C terminal length variants of A β . This mouse also deposited both diffuse and compacted amyloid, but most importantly, also demonstrated impaired learning and memory. Dr. Ashe has been exceedingly generous in making these mice available for academic research, and through licensing via the Mayo clinic, for pharmaceutical company research, even as she has weathered legal challenges. At this time they are probably the most frequently investigated model of amyloid deposition (Elder et al., 2010).

A report on a third mouse was published in 1997 (Sturchler-Pierrat et al., 1997) that used an APP construct with a Swedish mutation driven by the Thy-1 promoter. This mouse has been largely used extensively by Novartis and their collaborators. A fourth mouse model from David Borchelt used a construct very similar to that used by Karen Ashe (Borchelt et al., 1996). Although it is certainly the case that one can find differences among these different models, they all share some striking features. First, they all have both diffuse and compact fibrillar amyloid (although the ratios vary, discussed later). They all have a strong microglial reaction within the plaque core for the compacted deposits (but not the diffuse). They all have astrocytic activation in the periphery of the compacted deposits. They all have dystrophic neurites that stain for many of the same markers as dystrophic neurites in AD (including phospho-tau, although they do not have paired helical filaments of tau). Also somewhat surprising is they all, at least initially, deposit amyloid in those regions most associated with pathology in AD; the hippocampus and the neocortex. Again, the relative distributions may be different, but they do not show compacted deposits in cerebellum or brainstem until the animals age considerably. Interestingly, another mouse with the Thy-1 promoter that expresses only A β with a truncation at amino acid 3 (glutamine; p3E A β ; TBA2 mouse) initially produces pathology in the cerebellum, rather than forebrain (Crews et al., 2010). This would imply that it is not the promoter, but the processing of APP that directs the initial forebrain pathology in these models.

Some other useful mice soon followed. The TgCRND8 mouse from Peter St George-Hyslop’s group is a very aggressive model. This mouse carries the Swedish and Indiana mutations driven by the prion promoter. These mice develop plaques by 3 months of age and have a 50% lethality by 12 months (Balducci and Forloni, 2011; Kobayashi and Chen, 2005). A pair of mice generated by Lennart Mucke’s group, called J9 and J20, also have some useful properties. These two lines share the same construct, a combined Swedish and Indiana mutant driven by the PDGF promoter. These two lines vary considerably in expression and one can be used to study the phenotypes

associated with low expression (and delayed onset of deposition) and the other to study the phenotype of an aggressively depositing mouse model. Although a number of reviewers believe that the promoter is important in the differences among different lines, there are many other factors influencing expression. These include insertion site and copy number. In our own work with the Tg2576 line, we encountered a sudden appearance of mice in studies that had little amyloid deposition relative to the other mice in the same experimental group. This was outside the range of variability over the prior five years. Fortunately, we had information on transgene copy number collected at genotyping and necropsy and were able to determine that all these mice with reduced phenotype had reduced copy number. Through our genealogy records for the colony, we were able to trace this back to a single male mouse who was, unfortunately, exceptionally fertile. We then walked forward and culled all mice derived from this sire to minimize the influence of this low copy number on the variance in the colony phenotype.

In some lines, the first deposits are stained by Thioflavin S or Congo red, have dystrophic neurites and activated glial in their vicinity. Later these mice develop the less intensely stained diffuse deposits. These lines include the PDAPP and Tg2576 lines (Bloom et al., 2005; Gordon et al., 2002). Conversely, there are some lines such as the J20, that develop the diffuse deposits first, then later establish the compacted plaques (Kobayashi and Chen, 2005). The diffuse deposits stain with anti-A β antisera but not Thioflavin S and Congo red. They also lack the reactive glial cells. In some lines (Tg2576), there are some brain regions that only develop diffuse deposits (striatum). Additionally, many of the mice also develop cerebral amyloid angiopathy. These deposits are along the arterioles and arteries penetrating the parenchyma of the neocortex from the meninges. These deposits follow the ring-like contours of smooth muscle around the arterioles and can be stained by Congo red and Thioflavin S (Duyckaerts et al., 2008).

The C terminus of A β ends predominantly at amino acid 40 and, to a lesser extent, 42. The longer form of A β has a greater propensity to form aggregates *in vitro* (Greenberg et al., 1996). When antisera specific for A β 40 or A β 42 are used to stain brain sections from transgenic lines, the diffuse deposits are labeled exclusively by A β 42 and not A β 40. The compacted deposits are stained by both A β 40 and A β 42 specific antibodies, whereas the cerebral amyloid angiopathy stains almost exclusively with the A β 40 antisera. This pattern is very similar to that in Alzheimer cases at autopsy (Duyckaerts et al., 2008).

Different mutations affect the ratio of A β 42/40. Most mutations in the C terminus of A β (London, Indiana) bias the gamma secretase cleavage towards the long form of the A β peptide. As such they alter the ratio without altering the total amount of A β produced. The N terminal Swedish double mutation increases beta secretase cleavage relative to alpha secretase. This leads to increases in both A β 40 and A β 42, with no change in the ratio in newborn mice. This can modify the subsequent extent of A β deposition into the various compartments of the brain. For example, the PDAPP mouse, which only carries the Indiana mutation, at maturity, has a large amount of diffuse deposits, but relatively few compacted deposits (Bloom et al., 2005). Further

there is very little amyloid angiopathy in this mouse. The Tg2576 mouse, which only expresses the Swedish mutation, has a large compacted plaque load relative to diffuse, and develops amyloid angiopathy. The APP23 mouse, which carries the Swedish mutation also has a very large number of compacted plaques and severe amyloid angiopathy, often with spontaneous cerebrovascular hemorrhage (Hock and Lamb, 2001).

One mutation of APP in the mid-domain region, known as the Dutch mutation, causes hereditary cerebral amyloidosis with hemorrhage characterized by severe cerebral amyloid angiopathy. This mutation does not alter amyloid processing, but appears to have a higher rate of fibril formation and possibly reduced clearance rates relative to wild type A β . Mice generated by Mathias Jucker's group carrying this mutation driven by the Thy1 promoter develop primarily amyloid angiopathy, presumably owing to the preserved ratio of A β 42/40, replicating the human disease (Balducci and Forloni, 2011). However, when crossed with a mouse containing a mutation in presenilin 1 (PS1), which increased the amount of A β 42, these mice now deposited amyloid in compacted and diffuse deposits; therefore, one can argue it is the 40/42 ratio, not the Dutch mutation leading to the excess vascular pathology in these mice (relative to parenchymal) (McGowan et al., 2006).

In order to address the question of the relative importance of A β 40 versus A β 42 in amyloid deposition, Mike Hutton and Todd Golde's group developed two mouse lines using the BRI fusion proteins which only overproduced 40 or 42. The BRI construct is cleaved after synthesis to release the A β molecule, so one caveat is this peptide is not generated through normal APP processing. The mice overproducing A β 42 developed deposits in all three loci; compacted, diffuse and vascular. The mice overproducing A β 40 developed no deposits. This argues that all forms of deposition still require A β 42 to seed the formation of fibrils found in compacted and vascular amyloid. Interestingly, when the BRI-40 and BRI-42 mice are crossed, the expression of A β 40 in the crossed mice reduces the overall amount of pathology seen in the BRI-42 mouse line, arguing that A β 40 can inhibit fibril formation to some extent (Elder et al., 2010).

The great majority of mouse lines modeling amyloidogenesis have found it necessary to have considerable APP overexpression (greater than fivefold over endogenous). This has been achieved by insertion of multiple copies of the transgenes (concatamers) and use of heterologous promoters to drive high levels of expression. However, these promoters do not mimic the spatial and temporal pattern of expression of endogenous APP. Two models have been developed to avoid the heterologous promoter issue. One is the production of a yeast artificial chromosome mouse containing the entire 300 kb human APP gene. The wild type version of this mouse produced human APP but failed to result in deposition. However, introduction of the Swedish mutation produced the R1-40 mouse line, which does develop many of the same deposits as the cDNA or minigene based transgenics. These mice have the advantage of proper APP cellular, regional and developmental regulation of expression and RNA splicing, permitting the same mRNA variants as found in the human brain (Hock and Lamb, 2001). These mice also develop memory deficits as they age.

Another approach at generating amyloid depositing mice has used gene targeting technology to knock-in the human A β sequence with a Swedish mutation into the mouse APP gene. Alone, this APP knock-in model does not result in amyloid deposits, but when crossed with a mouse containing a knocked-in PS1 mutation, these mice develop robust plaque pathology (Hock and Lamb, 2001). These mice were developed at Cephalon, and have not been widely disseminated. However, the absence of APP over expression and the appropriate regulation of the modified gene provide important information and reduce the caveats associated with transgenic models in exploring the regulation of APP and PS1 expression by AD-like pathology (Crews et al., 2010).

AMYLOID PRECURSOR PROTEIN TRANSGENIC LINES CROSSED WITH OTHER LINES

In October of 1996, Karen Ashe published her paper in *Science* regarding the Tg2576 APP transgenic mouse line (Hsiao et al., 1996) and Karen Duff and John Hardy published their paper on a PS1 transgenic mouse line that overproduced mouse A β 42, yet failed to develop amyloid deposits (Duff et al., 1996). Although most PS1 mutant mice have minimal phenotype (Kobayashi and Chen, 2005), there are reports of increased sensitivity to neurotoxic insults (Elder et al., 2010). Within a month of these two publications, Dr. Ashe had shared her mouse with Hardy and Duff at the University of South Florida (USF) and a cross between these mice was initiated. Before the first progeny were mature, Dr. Hardy was recruited to the Mayo Clinic in Jacksonville with Dr. Duff, yet the mice remained at USF. Our research team at USF then characterized these crossed APP+PS1 mice, and identified a considerable synergy of the combined mouse (termed by us as APP+PS1) with respect to amyloid deposition, with first deposits moved to three to four months of age from nine to eleven months in the APP only mice (Holcomb et al., 1998). A parallel observation was made by David Borchelt's group at Hopkins (Borchelt et al., 1997) with largely the same outcomes. These crosses demonstrated that the mutation in APP and the mutations in PS1 appeared to both be active through the processing of APP with the final common outcome the generation of more A β 42. Interestingly, these crossed mice have been designated with a variety of arithmetic operators (APP-PS1; APP/PS1; APPxPS1; PSAPP) We remained convinced because the two transgenes are added together, not subtracted, divided or multiplied, that APP+PS1 is the appropriate designation, but recognize this convention is unlikely to hold sway. These doubly transgenic lines have also become widely disseminated through the Mayo Clinic and USF. The Borchelt group generously provided their mice to the Jackson Laboratories where they can be purchased commercially. The Tg2576 mouse is also now commercially available through Taconic. Of further interest is the fact that the widely used Swedish mutation was sequenced in Tampa in laboratories rented by USF. In a recent court decision, ownership of the Swedish mutation patent was transferred from the Alzheimer's Institute of America with Michael Mullan as sole inventor, to

USF and the University of London, with John Hardy named as coinventor (this ruling is under appeal). Thus USF, although a minor player overall, has had significant impact in the area of mouse models for amyloid deposition.

Another informative cross was to breed the APP mice onto a BACE1 (beta secretase) null condition. By deleting the BACE1 gene, A β was not produced. Thus one could discern those aspects of the APP mouse phenotype which were due to A β deposition from those due to APP overexpression, or the presence of the mutation. The APPxBACE1^{-/-} mice fail to develop amyloid deposits, as expected, and also fail to develop memory impairments. There are some effects of the BACE1 null condition, such as impaired myelination during development, but the general absence of phenotype implies that BACE1 inhibition could be relatively free of adverse events (PS1 null mice are embryonic lethal; Kobayashi and Chen, 2005). Conversely, crossing APP mice with a line overexpressing BACE1 leads to accelerated amyloid deposition (Kobayashi and Chen, 2005). Crossing an APP mouse line with mice overexpressing ADAM-10, an enzyme capable of alpha-secretase cleavage, leads to reduced amyloid pathology and diminished phenotype, presumably due to increased competition with endogenous BACE1 for APP substrate (Duyckaerts et al., 2008).

BEHAVIORAL CHANGES IN AMYLOID PRECURSOR PROTEIN TRANSGENIC MICE

The Tg2576 mouse was the first line to develop memory deficits associated with amyloid deposits similar to those in Alzheimer patients (Hsiao et al., 1996). The PDAPP mouse, develops an early atrophy of the hippocampus and corpus callosum prior to any amyloid deposits (Bloom et al., 2005), which made observation of amyloid-associated behavioral changes challenging, although ultimately these could be discerned on top of the developmental atrophy using a working memory approach (Chen et al., 2000). In our own research, the Tg2576 or APP+PS1 lines have been shown in multiple studies to have decreased performance on spatial navigation tasks that was correlated with the amount of amyloid deposition (mostly Congophilic plaques in cortex and or hippocampus; Gordon et al., 2001). Hence, this impairment of learning, often found in early stage Alzheimer cases, is an important component of the amyloid depositing mouse phenotype.

MORRIS WATER MAZE

The most common method of evaluating memory in APP mice has been the Morris water maze. This task involves use of a pool in which a hidden platform is submerged that mice are expected to find in order to escape the need to swim. The task takes place in a room with salient extramaze cues (probably the most critical one being the investigator) and the mouse is expected to use these extramaze cues to determine the location of the hidden platform. The task is performed with multiple trials per day (four consecutive trials are common) over multiple days (10 is common). At the end or on intermediate days, the mice are administered a "probe" trial, in which the

platform is removed and the specificity with which the mouse attempts to find the platform in its prior location is measured. Typically, mice will decrease the time required to find the hidden platform with increased training (decreased latency) until reaching some minimum time (typically 10–15 seconds). One potential concern with the latency measure is that it can be confounded by swim speed of the mouse. To rule this out, distance traveled can also be measured with computerized equipment. A common measure of retention on the probe trial is percent of time spent swimming in the pool quadrant previously containing the probe. However, there are many other measures developed with computerized tracking equipment (e.g. platform crossings, learning index) that can be used to assess performance on the probe trial. One factor rarely mentioned is that the probe trial is really an extinction trial (no reward is administered). Some animals, not finding the platform where it previously was located, might logically decide to search elsewhere, yet this would be scored as failure to learn. Another problem with this task is that the mice are expected to apply a spatial hypothesis to solving the problem (which the vast majority do). However, some mice might instead learn to swim in a circle a certain distance from the edge of the pool and stumble upon the platform by chance. Although this works equally well for the mouse, it again is judged as failure to learn. Intriguingly, mice with hippocampal lesions, or blind mice, do reduce latency over trials on this task. However, they do poorly on the probe trials because they are not applying a spatial hypothesis to solving the problem.

OBJECT RECOGNITION

Another oft used task is the object recognition task. Advantages of this task are that it requires little specialized equipment (the Morris maze often uses computerized equipment to measure learning) and can be performed in a much shorter time than the Morris water maze task. This task involves placing the mouse into a new environment in which there are one or two objects within the environment. During the exploration of this novel environment the mouse will encounter and presumably learn about these objects. Sometime later (usually the same day, but sometimes 24 hours later) the mouse is reintroduced to the same novel environment but this time with one object being from the previous encounter and another object for which the mouse lacks prior exposure. The assumption is that the mouse wishes to seek novelty and will spend more time exploring the novel object than time spent exploring the previously encountered object. The ratio of time attending to novel versus old object is called the recognition index. Periods of exposure run from 60 to 300 seconds for these sessions in the novel environment. One problem with this approach is the assumption that the APP mouse seeks novelty to the same extent as non-APP mice. However, there are indications that APP mice develop neophobia (Duyckaerts et al., 2008). If the mice are scared of the novel object, they may not show increased attention toward it and be deemed memory deficient. However, the difference is really one of motivation. This confound can be easily addressed by an independent measure of neophobia. One such measure is to water deprive mice for 12 hours and

administer two water bottles, one with standard water and the other with water sweetened with 0.1% saccharin. Noting the relative consumption from the two bottles over 60 minutes is an independent measure of neophobia (which in the form of bait shyness is a great asset to a mouse in the wild). If mice lack neophobia, yet demonstrate no preference for the new object, then one can more safely infer a true memory deficiency. A final comment from our experience: the amount of time mice spend attending to objects in total is relatively small (less than 20% of the time in the environment). Our work found that the difference between six seconds and eight seconds was often all that separated the APP and non-transgenic littermates in this task. As “attending to the object” is a very subjective measure, it is essential that the rater be blind to the identity of the mice being evaluated (preferably via videotape with multiple raters). Variants of this task include use of spatial location as the difference between the first and second exposures to the new environment (one object moves and the other remains in place) or use of other mice as the objects (social recognition). This latter task has a great deal of ethological validity, and mice do spend more time attending to other mice than they do to inanimate objects.

FEAR CONDITIONING

Another task often used to determine memory loss in APP mice is fear conditioning. This task has the advantage of being relatively rapid to perform (three five-minute sessions), but does require expensive equipment. In this task mice are introduced to a novel environment with a grid floor that can be electrified. After two minutes they are administered first a tone followed by a foot shock. Often this is repeated a second time within the same session. The environment has sensors that can detect if the mouse is “freezing” (not moving, a typical response to threat in a mouse). Usually the next day mice are once again introduced to the novel environment in which they were shocked the day before. Once again freezing is measured and mice that learned the task well are expected to freeze for the majority of the five-minute session, or at least during the first few minutes. This is called contextual fear conditioning. Typically the day after testing for context mice are placed in a completely different environment and administered the tone. Again, freezing is measured in response to this cue, referred to as cued conditioning. Lesion studies in rats have demonstrated that the contextual conditioning is a hippocampal-dependent task, whereas the cued conditioning is dependent on the amygdala. Often the APP mice are shown to be deficient in the contextual component of this task, leading investigators to conclude there is a memory deficit. However, the majority of APP mouse lines show excessive activity in open field tasks and increased numbers of arm choices in Y-maze alternation testing. They skitter. Thus one would like to have some independent measure of the capacity for freezing to be convinced that the deficit is truly failure to recognize the context in the fear conditioning recall test. One means of achieving this is to see no difference in response to the cued conditioning trial between the APP mice and non-transgenic littermates. However, rarely is this critical control presented in publications, and on some occasions

APP mice are deficient in this response as well as the response to the context. Drugs which increase or decrease the propensity towards immobility will have impact on the readout for this task without requiring an impact on the learning process. Rarely are these potential confounds considered.

RADIAL ARM WATER MAZE

When our group began working in earnest with APP and APP+PS1 mice in the late 1990s, we were fortunate to have in the Psychology department at USF David Diamond. Diamond had developed a variant of the Morris maze using rats, which overcame some of the caveats regarding the task. Essentially he superimposed the radial arm maze, used often in dry form for learning in rats, onto the water maze pool. This provided swim alleys within the pool which mice could enter. The hidden platform was placed near the end of one of these arms and the number of incorrect arm entries (errors) could be used to evaluate the degree to which mice have learned the platform location. An advantage over the traditional Morris maze is that mice are forced to use a spatial strategy to solve the problem so long as the starting location for each trial is varied (swimming in a circle does not solve the problem). The number of errors (incorrect arm entries) is relatively independent of swim speed; moreover, the task has a broad dynamic range. In the Morris maze probe trial, a well learned mouse may swim 60% in the target quadrant versus 25% for the clueless mouse. In the radial arm water maze, chance performance is four–five errors, whereas a well-learned mouse performs at less than one error (on average). Intermediate performance (two to three errors) can be resolved statistically with reasonable sample sizes ($N = 10$), and rate of learning (trials to criterion) can also be assessed. When we first used this task with APP mice, we developed a working memory version of the task, with four massed trials followed 30 minutes later by a fifth “probe” trial (although the platform remained in the pool). The idea was to measure registration of learning in the first four with failure of recall on the fifth trial. We have yet to see this occur (memory impaired mice never learn on the first four trials). This was a working memory task because each day the platform location was moved. Mice had to find the new location on trial 1, and recall that during the succeeding trials that day.

One drawback of this working memory approach was the need for 10–14 consecutive days of training to obtain criterion learning (less than one error on trials four and five). The labor involved in 70 trials per mouse was extensive. Towards reducing this burden, we have developed a two-day variant of the procedure that is a reference memory version of task (the original Morris maze is a reference memory task). A detailed methods paper has been published describing the testing procedures (Alamed et al., 2006). In this version of the task mice are run in cohorts of four mice (counterbalanced amongst treatment and genotype groups). Mice are given 15 trials on day one and another 15 on day two. However, mice are rested in between each trial as other cohort mates perform, and a second cohort is interspersed every five trials to decrease fatigue and permit consolidation. These changes to a spaced practice format have permitted us to identify criterion learning (less

than one error) by midway through the second day of training (about 22 trials) in non-transgenic mice. If additional challenge is needed to resolve subtle memory differences, mice can be administered reversal training on a third day (new platform location). Finally, mice are given a series of trials in an open pool with a visible platform, just to confirm that mice are capable of performing the task.

This task also has confounds. One confound is mice that fail to swim, or do so slowly. A mouse that swims in circles in the center of the pool, fails to make errors. But, this does not mean it has learned. To overcome this confound, we “charge” mice one error for every 15 seconds (out of 60 total seconds) they fail to make an arm entry. This admittedly contrived correction would give a non-performing mouse four errors (dead mice do not perform perfectly). Mice that consistently fail to swim (25% of trials) are culled from further analysis. Hence, this approach is an alternative to the other widely used tasks mentioned previously. It measures spatial navigation, imposes a use of a spatial strategy, can permit independent verification of performance capability, requires minimal equipment (small pool, flowerpot platforms, and aluminum or plexiglass inserts to form alleys). It is intermediate in the number of trials and short in the number of consecutive days required to commit to testing. Still, it is a single measure of behavioral performance and should be included in the context of a behavioral test battery with sensory and motor function tasks. There are a number of other behavioral tasks that can be used in assessing memory in APP mice (conditioned food aversion; passive avoidance, Barnes maze, among others), but none of them is a perfect test of memory independent of performance or motivational confounds. Given the range of such tasks, it is remarkable how consistently APP mice perform poorly on these tasks (Kobayashi and Chen, 2005).

One of the surprising findings in the APP mice is that the memory deficits do not appear to be directly caused by the amyloid deposits visible histologically. There are several building lines of evidence that suggest the cognitive deficits in these mice are due to some variant of A β that is present, likely in soluble form, before the first deposits have developed. One is that for many of the lines, impaired memory can be found at ages prior to observable deposits (Kobayashi and Chen, 2005), including an early mouse line from Scios-Nova, that never developed traditional amyloid deposits (Greenberg et al., 1996).

A second observation, pioneered by Karen Ashe’s group, is that although individual mouse memory performance correlates with amyloid deposits within an age group, the memory loss does not grow increasingly worse as the mice age. This is consistent with there being a variable rate of A β production in each mouse that affects multiple pools of A β . Thus mice overproducing oligomeric A β would also be expected to deposit more amyloid, but the oligomer level could remain stable with age, resulting in a constant level of memory disturbance. One 56 kDa oligomer of A β (predicted to be a 12 mer) shows a strong correlation with Morris maze performance over a range of ages (Elder et al., 2010). In addition, injection of extracts enriched for this 12 mer cause memory impairments in rats.

A third observation is treatments that rescue memory function without any further reductions in amyloid deposition.

Antibodies against the A β peptide can be administered for short durations and rescue memory without impacting the number of amyloid deposits (in young and middle aged mice; our work in 20-month-old and greater mice has not found this to be true). Presumably, these soluble forms of A β will be the first ones accessible to the antibodies, permitting a rapid reversal of the memory impairment caused by these variants (Kobayashi and Chen, 2005). Treatment with BDNF similarly can lead to reversal of memory deficits, with no impact on the amyloid loads (Gotz et al., 2011). All of this has led to a hypothesis that A β when produced in excess overloads synapses, impairing their function (Jaworski et al., 2010). Thus, modest reduction in soluble A β steady-state levels could have profound impact on memory performance by relieving this overload.

There are a number of physiological changes observed in APP mouse brain. In general, long-term potentiation (LTP) is reduced and/or basal synaptic transmission is impaired, but this is not true for all models studied thus far (Balducci and Forloni, 2011). Interestingly, extracts of APP mouse brains containing dimeric forms of A β can induce LTP loss in non-transgenic mice. Most mice have minimal brain atrophy. In PDAPP mice there is some atrophy very early in development, but this does not progress as the mice age and develop memory problems (Bloom et al., 2005). The vast majority of mice have minimal neuron loss. However a few lines are reported to have considerable loss in hippocampus, or select cortical regions, but not the widespread atrophy and loss of brain volume found in AD (Elder et al., 2010). Synapse loss in selected brain regions is common in APP mice. The Tg2576 mouse has minimal loss of synaptic markers, but others show losses of synaptophysin, MAP2, and synaptic spines (Duyckaerts et al., 2008). In a number of models, this can be detected before the first deposits of A β appear. Often this is in association with a transient increase in intracellular A β , although some still question if this is instead APP (Balducci and Forloni, 2011). Given the data that the memory loss in these mice precedes deposition, it would seem plausible to propose that some soluble form of A β impacts synaptic function leading to impaired learning and memory. However, this inhibition appears reversible and can be overcome by a variety of treatments, without requiring concomitant reductions in the total amount of amyloid deposited in the brain.

TAU DEPOSITING MICE

Although more appropriately considered models of frontotemporal dementia or other tauopathies than Alzheimer's disease, the co-occurrence of both amyloid and tau pathology in Alzheimer victims makes brief consideration of these models appropriate here. Like APP mice, early models of tau overexpression failed to reproduce a number of the histological features of tauopathies, especially neurofibrillary tangles (NFTs). However, Mike Hutton's observation that mutations in tau were responsible for some cases of frontotemporal dementia led to development of transgenic lines expressing mutated forms of tau. These produced the first models of tauopathy with development of a full spectrum of abnormal tau aggregates and neurodegeneration (Gotz et al., 2011). Surprisingly,

a large number of these mice caused neuropathology in the spinal cord and brain stem, with minimal involvement of the forebrain (Elder et al., 2010).

A major step in sequencing the pathology of Alzheimer's disease came from studies increasing amyloid deposition in tau transgenic lines either by direct injection or crosses with APP mice. This led to increases in forebrain tau pathology in association with amyloid deposits (Gotz et al., 2011; McGowan et al., 2006). Mathias Jucker's group showed that extracts from APP mouse brains could perform similarly (Gotz et al., 2011). Studies with anti-A β antibodies in the 3x Tg mouse of Frank LaFerla (APP, PS1, and tau mutations) observed that reductions of A β were paralleled by reduction in early stage tau pathology (but not later-stage tau pathology), inferring that in this mouse the tau pathology was being driven by A β . Moreover, Mucke's group has shown that breeding the APP mouse onto a tau null background leads to intact learning and memory, in spite of a full spectrum of amyloid pathology (Elder et al., 2010). This would suggest that even the APP phenotype is mediated through effects on tau.

One mouse that has aggressive tauopathy is the Tg4510, developed by Jada Lewis and Karen Ashe. This mouse drives mutant tau expression with a regulatable promoter. The transcription factor for the regulator is driven by the CaM kinase 2 promoter, thus producing tau overexpression largely in forebrain neurons (where CaM kinase 2 is expressed) and delaying production until after birth. These mice develop abnormal tau pathology within neurons by three months, memory loss and neuron loss by six months, and continued brain atrophy to nine months (Santacruz et al., 2005). Interestingly, turning off the overexpression of tau with doxycycline at five months can reverse the memory loss and atrophy, but does not arrest the further development of NFTs, implying these are not responsible for these aspects of the phenotype. There have been oligomeric forms of tau identified that may be related to this memory loss (Gotz et al., 2011). Our own work with this mouse has reproduced the severe atrophy that develops such that stereotaxic coordinates need to be adjusted for the age of the mouse. Upon removal the brain is obviously smaller, and ultimately the mice become moribund and cannot be tested behaviorally, even though they can continue to survive for several months.

COMPARISONS OF TRANSGENIC MOUSE MODELS TO ALZHEIMER'S DISEASE

Few argue that the mutant APP overexpression mouse models fully mirror the pathology found in Alzheimer's disease. At least superficially, there is no abnormal tau pathology (without adding tau mutations), there is no neuron loss, nor is there brain atrophy (Table 61.2). There is synapse loss, but this is modest compared to AD and is apparently reversible. There is no substantial loss of forebrain cholinergic neurons that seems characteristic of AD. Still, the physiological appearance of amyloid deposits, the distribution of different A β length variants into vascular, diffuse, and compacted deposits appears qualitatively similar. The activation of microglia, centered within the plaques, and the activated astrocytes surrounding the plaques

TABLE 61.2. Advantages and disadvantages of transgenic models of amyloidogenesis

ADVANTAGES	DISADVANTAGES
<ul style="list-style-type: none"> • Resembles AD histopathologically • Utilizes the normal APP processing machinery to synthesize, release, and degrade Aβ • Progressive development of the phenotype with age • Observe deficits in learning and memory which resemble those in early AD • Models are reasonably consistent across individual mice 	<ul style="list-style-type: none"> • Requires use of mutations; may not be relevant to sporadic AD • Requires overexpression of APP. May overload cellular compartments • Cognitive deficits precede amyloid deposition in mice. In AD, amyloid deposits precede cognitive changes • Incomplete pathology; no neuron loss, no NFT, no atrophy • No deficits in the cholinergic neurotransmitter system

are very similar to Alzheimer cases. Moreover, the first appearance is in the hippocampus and cortical structures, as opposed to brainstem, spinal cord, and cerebellum as found for tau transgenic mice.

However, there are differences even in those structures that appear similar. Roher has pointed out that the plaques in APP mice are “soft.” They are soluble in strong detergents, unlike those from Alzheimer postmortem cases. This results in only small amounts of racemized, isomerized, and cross-linked A β within the APP mouse plaques. Some of these changes require the simple passage of time (not dependent upon biological age) and mice are not sufficiently long lived. Furthermore, Roher claims the transgenic mice have minimal quantities of oligomeric forms of A β (Kokjohn and Roher, 2009).

Perhaps the most concerning issue regards the mismatches between timing of pathology and memory dysfunction. Data clearly show that that humans develop considerable amyloid deposition years before the first detectable symptoms of the disease become manifest. However, the data in mice argue that the memory deficits appear before the deposits. Moreover, at least in the APP mice, these memory deficits do not progress like human AD to involve all neuronal functions. Our experience with Tg2576 mice is that there is modest attrition in the transgenic offspring until 15 months of age (about 25%). However after that time they lead a normal lifespan. We have studies demonstrating antibody reversal of memory loss as late as 28 months of age in this line (Wilcock et al., 2004b). At this point, we have not found treatments reversing memory loss in AD cases, ever.

In the opinion of this author, these mice are rightfully studied as models of amyloidogenesis (first denoted by Price). If one’s scientific question regards amyloid deposition, perhaps even the relative deposition into specific compartments, the models would seem to be adequate. They have predicted well the outcomes of immunotherapy studies, with increased vascular amyloid and microhemorrhage associated with clearance of parenchymal deposits (Boche and Nicoll, 2008; Wilcock et al., 2004a). Importantly, this would not have been observed had we evaluated middle-aged mice instead of aged mice (Li et al., 2012). However, it is likely that the severe cognitive dysfunction in AD results from more degeneration than found in the APP mice. The relentless progressive decline from short-term memory to profound dementia, is considerably more dramatic than anything found in APP mice (even those with added tau transgenes). Some have argued the APP mice to be possibly models of the earliest stages of mild cognitive impairment, or

perhaps models of accelerated aging in mice (Ashe and Zahs, 2010).

The tau mice may be better as models of later stages of the disease. There is profound neuron loss and brain atrophy in these models. It is likely the later features in AD result from consequences of tauopathy rather than amyloid. Thus, the tau models may be better for predicting the outcomes of therapeutic trials directed at reducing the rate of atrophy, or protecting neurons and synapses, than the APP mice.

The emerging view is that mouse models can duplicate certain aspects of Alzheimer’s disease. The processing of APP is likely very similar in mouse and man. Drugs intended to attack this target are likely to find the APP models good predictors of hitting that target. However, they are not models of Alzheimer’s disease. As such it is folly to predict, in the absence of human data, that amyloid reductions will benefit patients or that drugs benefitting APP mice will benefit patients. That is a question being addressed by the multitude of trials with anti-amyloid agents. It is likely that one or more of these will successfully lower amyloid and we can ascertain at what disease stage, if any, this approach can be used to slow disease course. Other models represent other components of the AD pathogenesis. The tau models are emerging as the next line of investigation, and development of therapeutics to attack this pathology are in the early phases. Undoubtedly, the mouse models of tauopathy will have benefit in this regard, but will need to be interpreted with the same caveats as for amyloid depositing animals.

Time will tell.

62 | STRUCTURAL, FUNCTIONAL, AND MOLECULAR NEUROIMAGING BIOMARKERS FOR ALZHEIMER'S DISEASE

JAMES B. BREWER, JORGE SEPULCRE, AND KEITH A. JOHNSON

Alzheimer disease (AD) is currently a major public health challenge and one that poses an even greater threat for the future as the population ages. The role of neuroimaging in AD diagnosis and in the general assessment of cognitive impairment in the elderly has greatly evolved over the past two decades. In the past, structural neuroimaging was used merely to support the physical exam in the exclusion of focal lesions that could contribute to a patient's cognitive impairment. In most cases, any such discrete lesion sufficient to impair cognition would also be detectable through a careful examination, so the majority of clinical neuroimaging interpretations were negative and unhelpful. In fact, the added benefit of neuroimaging used in this manner was, and continues to be, controversial, as evidenced by variation in professional society guidelines regarding the use of neuroimaging in this setting (Knopman et al., 2001; Rabins et al., 2007). However, the development of magnetic resonance imaging (MRI) and positron emission tomography (PET) biomarkers that directly assess the degree of regional neurodegeneration or dysfunction and, more recently, neuroimaging biomarkers that assess pathological hallmarks of AD have brought transformative change to the field and shifted interest to earlier pathophysiological events. While much effort remains focused on the study of AD dementia and mild cognitive impairment (MCI), now preclinical stages have become a major focus. The move toward expanding the scope of inquiry into preclinical stages and younger age groups is motivated in part by the recognition that the presymptomatic phase of the illness is of 10–20 years duration and in part by the related need to enable earlier disease modifying intervention. The evolving view of AD pathophysiology has recently been fueled by rapid developments in amyloid-beta ($A\beta$) imaging and fluid biomarkers; however, simultaneous advances have been realized in other types of AD biomarkers. Neuroimaging biomarkers are now routinely incorporated into AD clinical trials and are increasingly used in clinical practice. This chapter will broadly describe the development and use of these biomarkers as they relate to AD.

ESTIMATES OF NEURODEGENERATION IN ALZHEIMER'S DISEASE

QUANTITATIVE MAGNETIC RESONANCE IMAGING BIOMARKERS

VOLUMETRIC MAGNETIC RESONANCE IMAGING

The slowly progressive neurodegeneration of AD is reflected in brain structural changes that can be appreciated at the macroscopic level. Medial temporal regions, such as the entorhinal cortex and hippocampus, are typically affected earliest, consistent with the hallmark memory problems that usually accompany disease onset. Macroscopic structural change broadly mirrors the pathological spread of the disease, with atrophy subsequently apparent in lateral temporal as well as medial and lateral parietal association cortex followed by frontal regions and, finally, primary sensorimotor cortices (McDonald et al., 2009). Though the changes are slow, over time the accumulation of atrophy is readily apparent to visual inspection (Fox et al., 1996; Scheltens et al., 1992).

Thus, in the absence of a suitable biofluid marker of neural damage and the unacceptable invasiveness of brain biopsy, a great deal of research has focused on the promise of neuroimaging and direct visualization of brain structure to assess the likelihood of neurodegeneration in individual patients. Typically, such approaches have leveraged the improvements in image quality afforded by MRI, though the quantitative nature of computed tomography (CT), including high spatial fidelity, and recent advances in achievable image spatial resolution, tissue contrast, and overall quality might suggest future promise for CT in quantitative assessment of neurodegeneration. The discussion that follows regarding structural neuroimaging will nonetheless focus on approaches using MRI.

Direct assessment of putative brain atrophy can make use of semiquantitative approaches to rate severity of volume loss or employ tools for quantification of brain structure volumes, volumetric MRI (vMRI), to provide measurements that could be tracked over time or compared to a normative database

(for review, see Jack, 2011). In clinical practice, volumetrics may inform the clinical assessment by either supporting or calling into question the impression, previously based solely on clinical history and examination, that neurodegenerative disease is present and possibly causing the complaint (Fig. 62.1).

It is not surprising that the hippocampus has been targeted as the structure most likely to provide a reliable volumetric biomarker of neurodegeneration in AD. Damage to hippocampal tissue is severe early in the disease and, owing to its somewhat cylindrical structure, hippocampal borders are relatively easy to delineate for volume measurement. However, it should be noted that hippocampal atrophy is not specific to AD, nor is all AD associated with severe hippocampal atrophy (for review of focal variants of AD, see Kramer and Miller, 2000). Some degree of hippocampal volume loss is expected even in healthy aging, and the structure's volume is further correlated with overall intracranial volume. Thus, the effects of age and intracranial volume, and possibly gender and race, must be accounted for. An individual's prior history of brain trauma, alcoholism, drug abuse, and vascular risk factors such as hypertension and smoking, would also likely influence the measure, so it is unlikely that a distinct "cutoff" in hippocampal volume could be identified that will reliably predict AD risk across patients.

Instead, hippocampal volume is more likely to be useful as a measure that helps assess the likelihood that neurodegeneration is present rather than a diagnostic for AD. As such, the measure should be seen by treating physicians as one additional data point to assist in their clinical impression. Most clinicians are familiar with tests that shape, rather than define,

a clinical impression, and such tests are valuable nonetheless. An example might be the measurement of hemoglobin in the setting of a patient complaint of fatigue. A normal hemoglobin directs attention to etiologies other than anemia, and a finding of low hemoglobin supports, but does not assure, that anemia is causing the fatigue. The assessment and management depend heavily on the clinical setting and ancillary factors associated with the measurement. In practical terms, this means that the relevance of a vMRI finding to a particular case will be determined by the treating physician, rather than by the radiologist. However, the radiologist can provide additional qualitative information from the images that lend further value to the quantitative information.

Despite intense focus on translation of hippocampal volumetry to the clinical realm for AD assessment, ancillary measures of atrophy may be critical to improve interpretability of hippocampal volume. Several research groups have examined the value of combining regional volumetric measures across cortical and subcortical structures to more completely describe the spatial pattern of changes associated with AD (Davatzikos et al., 2008; Dickerson et al., 2009; McEvoy et al., 2009; Vemuri et al., 2011). A pattern with broad consistency across techniques emerges, where atrophy is prominent in medial and lateral temporal and parietal regions, moderate in frontal regions, and minimal in primary sensorimotor regions. The combination of regions, naturally, improves classifier sensitivity and specificity beyond that achieved through the use of a single region. However, the ability to translate such advanced approaches to the clinical environment has

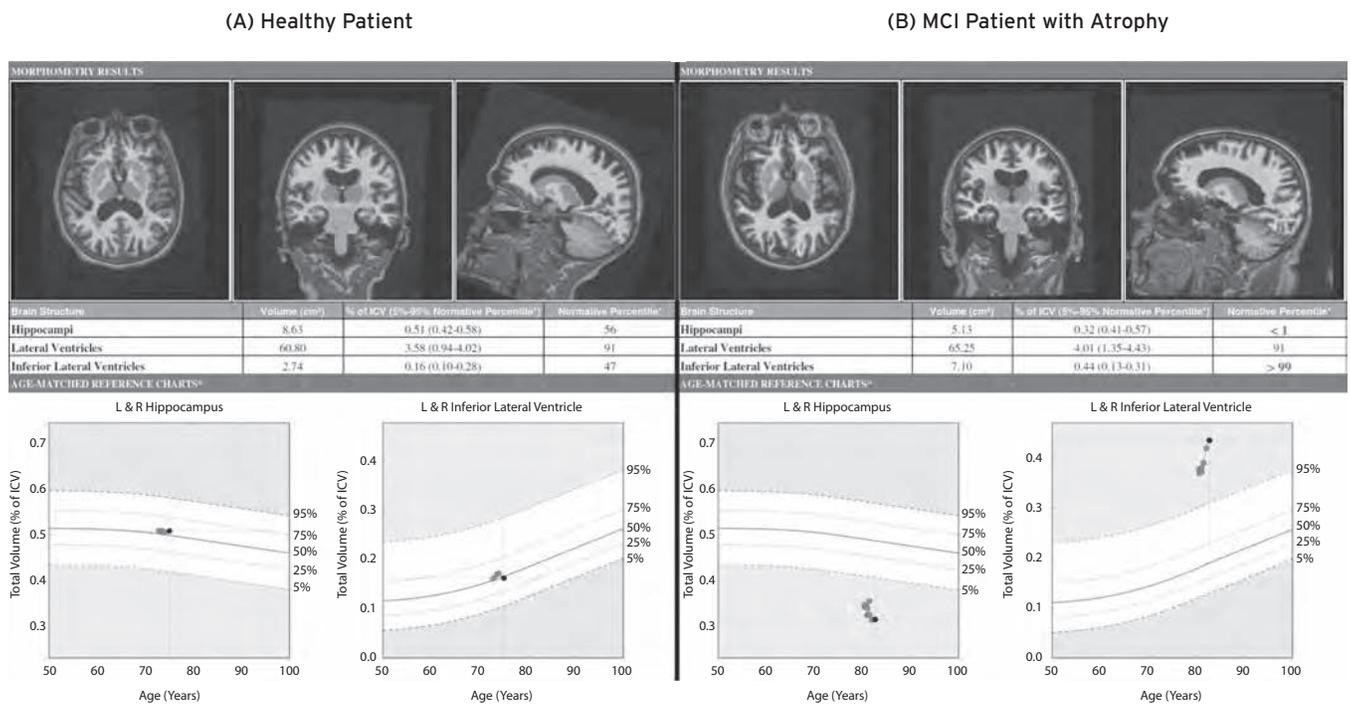

Figure 62.1 Example volumetric reports for two subjects enrolled in a longitudinal quantitative imaging study. (A) A 75-year-old healthy subject who remained stable and was without evidence of hippocampal neurodegeneration or temporal horn enlargement during scanning over two years. (B) An 82-year-old, cognitively impaired subject who progressed from MCI to AD at the third year of follow-up. This patient was a non-carrier of APOE4 genotype who, by CSF testing, had elevated phospho-tau and reduced levels of amyloid beta 42 in cerebrospinal fluid. vMRI shows evidence of hippocampal neurodegeneration and ex vacuo dilatation of the temporal horns during scanning over two years. (See color insert.)

not yet been demonstrated and may not be practical. In particular, those that rely on support vector machines to obtain data-derived regions with highest classifier performance might be overly reliant on features of the data set used to train the classifier, and so performance may not necessarily generalize to the wider population seen in clinical practice. Further, given anatomical variation in cortical folding, derivation of regional cortical volume or thickness is more challenging and computationally expensive than derivation of volumes for most subcortical structures, such as the hippocampus and ventricular subregions.

Indeed, some contextual information about a hippocampal volume measurement can be provided by additionally assessing temporal horn volume. Hippocampal and wider medial temporal lobe (MTL) degeneration is often associated with *ex vacuo* expansion of the temporal horn of the lateral ventricle. Therefore, temporal horn volumetry with comparison to normative values can provide complementary evidence of concurrent *ex vacuo* dilatation of this ventricular structure. Such a finding could support that the individual's hippocampus was previously larger and had undergone degeneration, as opposed to having been congenitally small. Further, measurement of the entire ventricular system and its relationship to norms can assist interpretation of the temporal horn volume. The combination of measures would inform assessment of likelihood that the temporal horn enlargement is more specifically due to regional *ex vacuo* changes (if, along with low hippocampal volume, only the temporal horn is abnormally large), rather than due to general ventricular system expansion (if both temporal horn and the entire ventricular system are abnormally large). Evidence of MTL-focused atrophy might provide an early sign of neurodegenerative disease, including AD, which typically affects these structures first. Table 62.1 provides examples of possible clinical interpretations when hippocampal, temporal horn, and overall lateral ventricle volumes are examined in combination.

Finally, it should be noted that, even when a typical pattern is noted or when markedly out of the normal range, a single measurement in time cannot definitively point to a neurodegenerative etiology, since many of the aforementioned traumatic or congenital factors are associated with low volumes of structures not seen to progressively deteriorate. Therefore, the most powerful evidence for ongoing neurodegeneration might be demonstration of accelerated progressive deterioration in structure volumes through longitudinal imaging. Thus, beyond comparing a patient's brain to a normative database, a patient's brain volumes would be quantitatively compared to those measured for that individual at a prior time. Differences in scanner hardware and software adds significant variability to measures of very subtle volume change across time, and, even at a single site, equipment changes are frequent in clinical practice, so this remains a significant challenge to obtaining accurate measurement of change across time. To be most relevant to clinical practice, meaningful information would need to be obtained across a relatively brief period of follow-up, preferably around one year. This would require highly robust methods, including correction for subtle scanner-specific distortions that could assess anatomical changes with high enough precision to

reliably distinguish across individual subjects miniscule differences in rate of atrophy (e.g., hippocampal volume loss ranges from 1–5% across healthy elderly, MCI, and AD). Such precision is a significant challenge, particularly if the equipment changes between scans. Nevertheless, equipment manufacturers are becoming more aware of the potential value of quantitative neuroimaging, which lends hope that procedures could be standardized to improve accuracy of measurements despite equipment and software variability.

Though several caveats remain to be considered, working groups gathered through efforts of the Alzheimer's Association and the National Institute on Aging recently published guidelines for revised diagnostic criteria for AD and MCI that incorporate vMRI and other biomarkers (Albert et al., 2011; McKhann et al., 2011). Tools for vMRI have already been established in large radiological practices to assess the degree to which an individual's brain structure volumes fit within the normative range adjusted for age, sex, and intracranial volume. Relatively recent Food and Drug Administration approval of an automated vMRI tool has permitted further research of its applicability in unselected clinical cohorts encountered through everyday practice as well as in the highly selected cohorts studied in AD clinical trials.

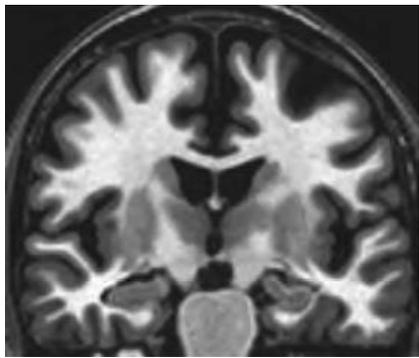

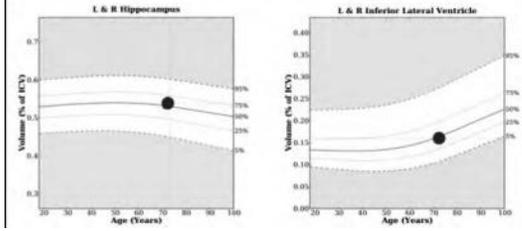

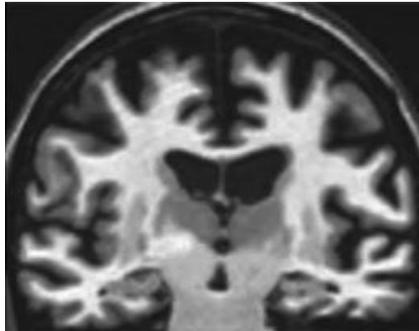

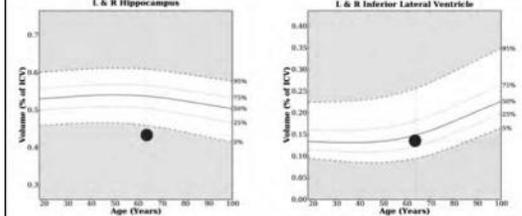

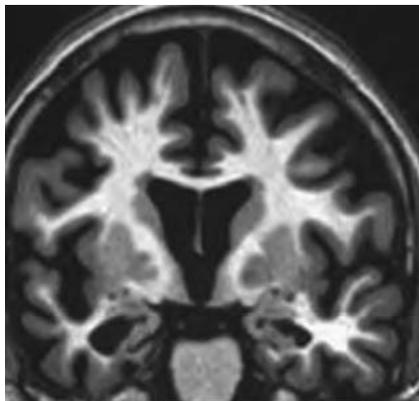

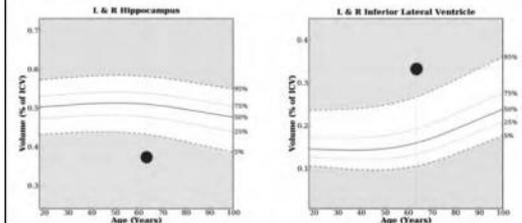

DIFFUSION-WEIGHTED IMAGING

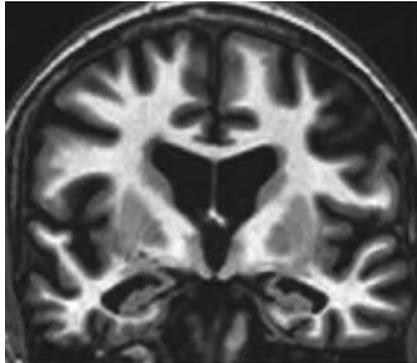

Magnetic resonance physics allows flexible approaches to examine water molecule behavior within tissue. Structural neuroimaging may focus on achieving high anatomical detail through examining magnetic contrast related to tissue content, itself, or it may focus on measuring more general effects on contrast due to surrounding tissue structure or magnetic properties. In diffusion-weighted imaging, the effect that surrounding tissue structure has on water movement is paramount. MRI contrast can be achieved by examining the degree of water movement within the region; water movement is restricted by surrounding anatomy, and the more restricted, the greater the signal. In directional diffusion weighted imaging, such as diffusion tensor imaging or diffusion spectrum imaging, both the magnitude and direction of water movement is collected, informing whether water movement is more hindered in one direction versus another.

As white matter tracts in the brain are one of the major anatomical features that might direct water to diffuse in one direction (parallel the white matter) relative to another (perpendicular to the white matter), directional diffusion weighted imaging has become a favored research tool with which to examine white matter integrity in neurodegenerative diseases such as AD (for review, see Oishi et al., 2011). Indeed prior cognitive research has described AD as a disease of "disconnection" between disparate cortical brain areas, so the ability to examine fiber tract disruption is a compelling reason to examine the effects of AD on white matter tracts as evidenced by changes in diffusion-weighted signal.

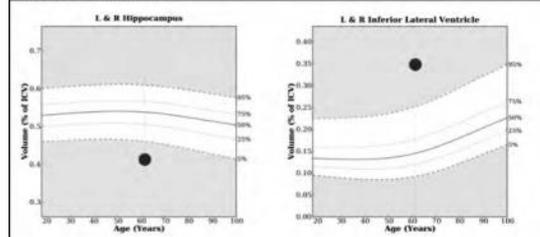

However, it remains to be seen whether degeneration of fiber tracts is best measured through changes in directionality, as opposed to magnitude, of diffusion. When comparing impaired patients to healthy controls, studies have found regional group differences in fractional anisotropy, a measure

of directional diffusion, yet some studies have found even more robust differences in mean diffusivity, a directionless measure of diffusion magnitude. Neurodegeneration in AD seems more likely to cause loss of fibers within defined tracts rather than a shift in direction of those tracts. Thus directional measures, though useful for identifying tract location, might be less powerful for detecting tract degeneration than simpler measures of diffusion magnitude. Further, the directional diffusion signal can be influenced by a number of subtle factors, so export of this tool to the clinical realm will face a number of challenges, not least of which will be the development of normative ranges for determining whether a patient's scan is normal or abnormal when placed in context with the general healthy population. Nevertheless, the approach shows promise as a technique that shows a complementary anatomy not seen in conventional structural imaging.

FUNCTIONAL MAGNETIC RESONANCE IMAGING

Though other approaches exist, most functional MRI is based on the Blood Oxygen Level-Dependent (BOLD) effect, which allows MRI sensitivity to variations in relative levels of oxyhemoglobin and deoxyhemoglobin that vary in association with regional brain activity (for review, see Brown, Perthen, Liu, & Buxton, 2007). Given the probability that changes in neural function precede frank neurodegeneration and changes in structure, functional MRI (fMRI) has been studied extensively as a potential biomarker to identify the earliest brain changes associated with AD. Broadly, methods applied to fMRI can be divided into two categories: task-dependent fMRI and task-free, or "resting-state," fMRI (rsfMRI).

In task-dependent fMRI, subjects in the scanner might be asked to perform a defined "activation" task that alternates with or occurs separately from a "control" task while BOLD signal is recorded. The control task differs from the activation task in a way that is designed to isolate and identify the brain activity linked to a targeted cognitive function, which is a cognitive function used during the activation task, but not during the control task. This "cognitive subtraction" technique suffers from a number of factors that limit interpretation, particularly when applied to a diseased population. For example, an observed signal difference between AD and controls might be related to uncontrolled variation in task difficulty or attentional resources that must be dedicated to performing the task, despite matched performance across groups. This adds to more general concerns about factors of subject motion and brain atrophy that must be accounted for in all neuroimaging biomarkers of AD. Such factors might be particularly problematic for fMRI biomarkers, because the effect of confounders can be amplified by the analysis approach (Seibert and Brewer, 2011).

In rsfMRI, subjects are instructed to simply lie still in the scanner, perhaps with guidance to keep their eyes open throughout the session, but functional data are nonetheless collected without regard to any specific mental activity. Instead, it is the interregional correlation in BOLD signal fluctuations that provides the marker of interest. The pattern of interregional correlation is remarkably consistent, in that signal from a particular brain region tends to be tightly linked

with signal from other regions that show relatively stable correlations across subjects and scanning sessions. These stable interregional correlations have been termed "functional connectivity" and the phrase "functional network" is often used to refer to regions linked by their covariance in BOLD signal. Several distinct functional networks have been described, including the attentional/salience network of bilateral frontal regions and anterior cingulate gyrus, the sensorimotor network of bilateral primary motor and sensory cortex, and the default mode network of medial and lateral parietal, medial and lateral temporal, and medial frontal cortex.

The latter default network is the most studied and, owing to its remarkable overlap with the spatial distribution of amyloid deposition and atrophy in AD (Buckner et al., 2009; Greicius et al., 2004; Raichle et al., 2001; Sepulcre et al., 2010), has garnered the most interest for its potential as an early biomarker of the disease. A consistent finding is that interregional correlations in the default network are reduced in AD. However, concerns remain about the general effects of atrophy and motion on the ability to identify functional correlations themselves. A more compelling finding is the identification of default network reductions in amyloid positive individuals who are asymptomatic, who would not be expected to exhibit large differences in atrophy or motion from those who are amyloid negative (Sperling et al., 2009). Default network correlations have been noted even to be reduced in individuals gene positive for autosomal dominant AD before symptoms have begun (Sperling et al., 2012). Such findings suggest the tremendous potential for fMRI as an early biomarker of AD, though its translation to use in the clinical setting will require a great deal more research.

MAGNETIC RESONANCE SPECTROSCOPY

Magnetic resonance spectroscopy (MRS) has long showed promise for detection of regional chemical changes associated with neurodegeneration, inflammation, or gliosis, and so it has been a technique of interest for detecting such changes in AD. It provides information about relative concentrations of key chemicals, such as *N*-acetylaspartate, creatinine, and myoinositol, and there is strong evidence that the regional concentration of these chemicals varies with the neurodegeneration seen in AD (for review, see Tran et al., 2009). While specialized research laboratories have consistently demonstrated robust discrimination between clinical groups, suggesting potential value in assessment of individual cases, improved standardization of approach is needed before MRS can be widely applied in multisite clinical trials or generally in the clinical setting.

POSITRON EMISSION TOMOGRAPHY FLUORODEOXYGLUCOSE IMAGING

CLINICAL USE OF FLUORODEOXYGLUCOSE PET

Fluorodeoxyglucose (FDG) PET is a marker of brain metabolism with limited but established utility in differentiating AD from other brain pathologies that manifest as cognitive

impairment. Under normal circumstances, the physiological level of glucose use reflected by FDG PET is due primarily to regional synaptic activity, and FDG uptake in nonhuman primates has been correlated with levels of synaptophysin in histological studies (Rocher et al., 2003). Since glucose consumption is by far the major contributor to the brain's energy budget, FDG uptake reflects the full range of brain energy requirements, including protein and lipid synthesis, as well as maintenance of electrochemical gradients used in neural activity (Raichle et al., 2001). Alterations in synaptic activity detectable with FDG reflect chronic synaptic dysfunction (or loss) as well as perturbed functional status observed within shorter time intervals, such as during specific cognitive or motor task performance.

Fluorodeoxyglucose metabolism is assessed regionally with PET so that anatomic patterns of relative hypometabolism may be both visually evident and expressed quantitatively; quantification may involve arterial blood sampling or may alternatively use internal tissue reference standards. No single pathognomonic FDG PET finding specifies the presence of the clinical syndrome of AD dementia or the presence of AD pathology. However, the anatomic pattern of relative FDG hypometabolism in AD is characteristic and is considered to be an endophenotype of AD, that is, a consistently affected hypometabolic group of brain structures that has been strongly associated with both the clinical syndrome of AD dementia and the postmortem finding of definite AD (Jagust et al., 2007). The AD endophenotype of FDG hypometabolism comprises the posterior midline cortices of the parietal (precuneus) and posterior cingulate, the inferior parietal lobule, posterolateral portions of the temporal lobe, hippocampus, and medial temporal cortices (Foster et al., 1983; Minoshima et al., 1997). This pattern is present in AD, is linearly related to dementia severity, and is associated with subsequent clinical decline and conversion to AD (Chetelat et al., 2003; Jagust et al., 2007). It is seen less severely or consistently in MCI, and to some extent, in A β positive normal elderly (Caselli et al., 2008; Cohen et al., 2009; Langbaum et al., 2009). Because the AD-like pattern of FDG hypometabolism is associated both with the clinical features of established AD dementia, and with AD pathology at postmortem (Jagust et al., 2007), it may be used to differentiate AD from frontotemporal lobar degeneration (FTLD) and to some extent from dementia with Lewy bodies (DLB). Specifically, it is typical to find frontotemporal hypometabolism in FTLD, and occipital—in addition to the AD-like temporoparietal—hypometabolism, in DLB. Other applications have been proposed for FDG PET, particularly to detect individuals who are likely to develop AD dementia in the future (Chetelat et al., 2003); however, this has not yet been successfully implemented in clinical practice.

UNDERSTANDING THE ALZHEIMER'S DISEASE BRAIN WITH FLUORODEOXYGLUCOSE

In recent years neuroimaging techniques such as FDG PET and fMRI that are capable of revealing different aspects of the brain function have provided key insights about functional organization and its spatial distribution in AD. For instance, the

metabolic-anatomic endophenotype of AD described earlier is sometimes asymmetric and predominantly temporoparietal in the early stages, but later progresses to involve prefrontal and heteromodal areas largely overlapping with the aforementioned default mode network.

As AD progresses from presymptomatic to established AD dementia, regional glucose metabolism gradually worsens (Bateman et al., 2012; Jack, 2011) and the spatial pattern of progression may be conditioned by anatomic interconnectivity, in parallel with the progression of pathological processes (Arnold et al., 1991; Pearson and Powell, 1989). AD neurodegeneration involves specific functional networks of the human brain (Greicius et al., 2004; Seeley et al., 2009), and this feature has led to a new reformulation of the old hebbian principal: “not only neurons that fire together wire together, but also neurons that wire together die together” (Sepulcre et al., 2012). It may be possible to track FDG metabolic changes along specific anatomic pathways that relate to underlying pathologic progression, and also to relate these findings to evidence of regional atrophy (Villain et al., 2010).

Some investigators have reported that FDG hypometabolism is detectable along the AD trajectory prior to the appearance of cognitive symptoms and signs of neurodegeneration in individuals at increased risk for AD (Jack et al., 2010; Jagust et al., 2006). Thus, the AD-like pattern of hypometabolism or hypoperfusion predicts cognitive decline in subjects that eventually convert to AD (Jagust et al., 2006) and in carriers of autosomal dominant AD mutations (Bateman et al., 2012; Johnson et al., 2012). It is also associated with the progression of the clinical dementia rating scale sum-of-boxes in both AD and MCI subjects (Chen et al., 2010). Importantly, several studies have found that glucose alterations are not merely caused by concurrent atrophy, and therefore regional FDG reduction is an independent piece of information in AD (Johnson et al., 2012). Moreover, FDG metabolism continues to decline even in advanced stages of the disease when other pathological factors reach a plateau (Engler et al., 2006; Jack et al., 2010). It is likely that these declines reflect the combined effects of several potentially overlapping processes; these include specific genetic effects, mitochondrial dysfunction, oxidative stress, excitotoxicity, synaptic and neuronal failure triggered by A β , neurofibrillary tangle accumulation, and/or other factors, together with other downstream degenerative processes. It is likely that FDG PET is sensitive to several components of the neurodegenerative process, and thus separate biomarker representation may be required to track specific processes.

Finally, several studies have shown that FDG hypometabolism matches, to some extent, the brain distribution of amyloid deposits, particularly in the default mode network (Cohen et al., 2009; Engler et al., 2006; Klunk et al., 2004). However, this relationship is not settled and other groups have not found meaningful or strong associations particularly at later stages of the disease (Furst et al., 2012; Rabinovici et al., 2010). In general, glucose hypometabolism in frontal regions is less evident than in temporoparietal cortex, whereas amyloid uptake is usually somewhat greater in frontal regions (Klunk et al., 2004).

Therefore, the association of amyloid deposition with reductions of glucose utilization remains unclear. Many important challenges remain unsolved in AD research and one of them is the integration of structural, functional, and molecular neuroimaging findings.

SUMMARY AND LIMITATIONS OF FLUORODEOXYGLUCOSE PET

FDG PET is a widely available technology that may help diagnostic accuracy in neurodegenerative illnesses, particularly when earlier stages of cognitive impairment are possibly due to AD pathology or to FTLD. However, further work is needed to determine the diagnostic value of FDG when assessing pre-clinical stages of AD. Like other imaging biomarkers, FDG does not indicate clear spatial patterns that distinguish between normal aging and MCI or AD (Caselli et al., 2008; Chetelat et al., 2003; Langbaum et al., 2009). As with these other modalities, the observed heterogeneity in FDG patterns of metabolism may be the result of individual differences, particularly in cognitive reserve, or comorbid conditions of aging such as vascular disease, as well as to idiosyncratic factors. Neural dysfunction likely precedes neurodegenerative changes, and so FDG PET holds great promise for monitoring cognitive transition from preclinical to established AD (Furst et al., 2012; Jack et al., 2010). Nevertheless, the sensitivity of FDG PET relative to that of vMRI remains to be established despite the existence of head-to-head comparisons performed in the same patients (Karow et al., 2010). Sensitivity of a biomarker depends not only on acquisition modality, but also on analysis techniques, which continue to evolve. Therefore, it is still unknown which variable will best be associated with cognitive symptoms for continued translation into clinical use in the earliest stages of disease. Although the availability of FDG PET has increased dramatically over the past decade and the standardization of methods has improved substantially, costs of PET technology remain high, and cost effectiveness in dementia diagnosis has been difficult to demonstrate.

AMYLOID IMAGING

CLINICAL USE OF AMYLOID IMAGING

Amyloid- β (A β) dysmetabolism and subsequent deposition is a defining neuropathological feature of AD (Braak and Braak, 1991; Selkoe, 2006), and the ability to detect brain A β deposits during life has revolutionized clinical research in AD (Klunk et al., 2004). The *in vivo* visualization of brain A β deposition with amyloid PET is virtually equivalent to demonstration of the pathology at autopsy, as has been repeatedly demonstrated (Bacskai et al., 2003; Ikonovic et al., 2008; Klunk et al., 2004; Sojkova et al., 2011) for rare exceptions, see Klunk, 2011. Amyloid PET detects fibrillar amyloid because PET tracers bind to the beta-sheet protein structure that forms when A β polymerizes (Ikonovic et al., 2008). Amyloid PET can thus detect the A β that is a major component of the damage occurring in patients with cognitive impairment caused by AD and is always seen in AD dementia patients at autopsy. A negative amyloid PET scan generally indicates very few or no amyloid deposits and greatly reduces the likelihood that any cognitive

impairment is caused by AD. A positive scan indicates that moderately to severely elevated numbers of β -amyloid deposits are present. A fundamental concept of amyloid PET is that the images indicate presence of A β deposits, but do not reliably distinguish between normal, MCI, and AD dementia, and thus do not relate directly to these traditional clinical diagnostic categories (Johnson et al., 2012). In other words, it is critically important to note that a positive amyloid PET scan does not by itself establish any clinical diagnosis, including that of AD dementia. The test may be positive in normal older individuals as well as in other clinical entities such as DLB.

The highly stereotyped anatomic pattern of amyloid PET ligand binding to areas of high connectivity forms the basis for the amyloid PET endophenotype of AD (Arnold et al., 1991; Braak and Braak, 1991; Buckner et al., 2009). Thus, areas that are highly interconnected, such as precuneus, posterior cingulate, inferior parietal and lateral temporal cortices (i.e., portions of the DMN), are typically affected, but the earliest and most heavily involved is often the middle frontal cortex, which is part of the cognitive control network. The time course of amyloid deposition typically involves these vulnerable regions; however, there is substantial variability in regional deposition at early stages, and at later stages, additional brain regions including primary cortices are also affected.

Most published reports to date involve the C-11-labeled agent *N*-methyl 11C-2-(4-methylaminophenyl)-6-hydroxybenzothiazole, also known as Pittsburgh Compound-B (PIB; half-life 20 minutes) (Klunk et al., 2004). Other compounds made with the more convenient F-18 radio-label (half-life 110 minutes) are increasingly available for research and even clinical use (Johnson et al., 2012).

The reported correspondence of amyloid positivity with traditional clinical diagnoses is as follows: more than 90% of clinically diagnosed AD patients and approximately 60% of MCI patients are classified as amyloid positive with PET (Johnson et al., 2012). Similar proportions have been reported using CSF biomarkers of A β (Fagan et al., 2007).

Longitudinal studies are just now emerging, but when MCI subjects have been followed over one to three years after PET, approximately one-half of those who were amyloid positive at baseline converted to AD dementia and approximately 10% of the amyloid negative subjects converted to AD dementia. These studies are ongoing, and continued clinical and histopathological follow-up will be required because it is possible that the clinical diagnoses would not be confirmed at autopsy.

A substantial fraction of apparently healthy, elderly cognitively normal subjects have A β deposits detected by PET (10% to 50%) (Jack et al., 2010; Johnson et al., 2012), and such individuals are termed preclinical AD based on the hypothesis that the progressive accumulation of amyloid places them at higher risk for developing clinical syndrome of AD dementia (Jack et al., 2010). The magnitude and timing of such risk remains the subject of active investigation; however, several AD prevention clinical trials are proceeding on the basis of AD risk defined in this way. The analysis of early changes and preclinical stages of AD is critical to understand the transition to symptomatic forms of the disease. Recent data have shown a continuum of accumulation of *in vivo* amyloid protein from

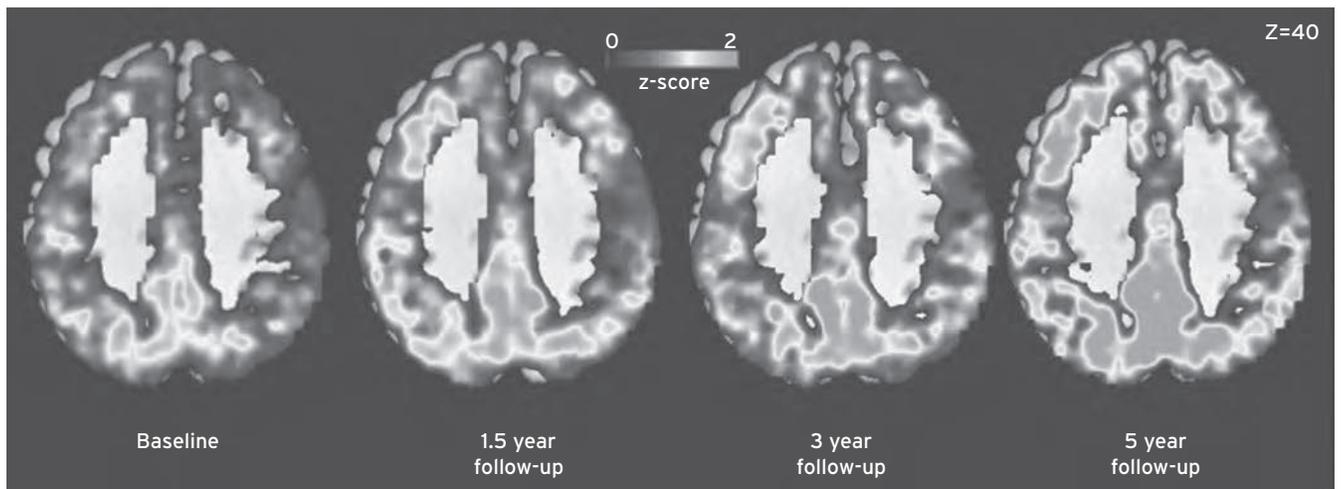

Figure 62.2 Longitudinal PET amyloid imaging of an individual subject who progressed from healthy to dementia. (See color insert.)

early stages (i.e., elderly cognitively normal controls) to symptomatic phases of the disease (Jack et al., 2010; Villain et al., 2012; Villemagne et al., 2011) (see Fig. 62.2).

Amyloid PET may have substantial clinical utility in differential diagnosis of established dementia, particularly in younger individuals in whom the prognosis and clinical management would differ depending on the underlying pathology. For example, the underlying pathology of FTLD does not involve A β , and amyloid PET is reported to be negative in clinical FTLD that has been confirmed at autopsy (Rabinovici et al., 2011). Other entities in the differential diagnosis of dementia that could potentially be informed by amyloid PET include late life depression or other psychiatric disorder with cognitive impairment, prion disease (Villemagne et al., 2009) and semantic dementia with tauopathy (Drzezga et al., 2008). The situation for parkinsonian dementing syndromes is somewhat more complex, because amyloid deposition is a common but not universal feature of DLB, and may or may not be seen in Parkinson's disease with dementia (Gomperts et al., 2008). Similarly, posterior cortical atrophy (Migliaccio et al., 2009), progressive aphasia (Rabinovici et al., 2008) and corticobasal syndrome (Rabinovici et al., 2011) present substantial clinical and histopathological heterogeneity and may not at present be distinguishable with amyloid PET.

SUMMARY AND LIMITATIONS OF AMYLOID IMAGING

Amyloid PET is an emerging technology and the FDA approved an amyloid radiotracer, Florbetapir F18, in April of 2012. At the time of this writing (mid-2012), amyloid PET has not been widely deployed in clinical practice. Whatever clinical value that could be expected is entirely dependent upon the availability of good quality images and accurate interpretation. Although clinical FDG PET scanning is generally available for nonbrain indications, experience with brain imaging is quite variable and depends on local circumstances.

Since essentially no one is free of risk for developing amyloid deposition, the clinical utility of amyloid PET could theoretically extend to nearly any circumstance in which the

underlying basis of suspected neurodegenerative disease could be A β . However, the high cost of PET and its uncertain impact on clinical management have limited enthusiasm for widespread adoption of (both FDG and) amyloid PET when expert dementia specialist evaluation is available. While utility at this time remains to be precisely defined, the availability of disease modifying AD therapy will almost certainly change the level of demand. At present, appropriate use criteria are still being discussed and refined, but would optimally integrate amyloid PET technology into the existing framework of dementia evaluation, so that amyloid status can be placed in the appropriate context of medical, neurological, neuropsychological, and neuroimaging data.

ADNI AND STANDARDIZATION OF NEUROIMAGING BIOMARKERS

The successful incorporation of neuroimaging biomarkers into multi-site clinical trials has relied upon unprecedented levels of collaboration across the major equipment manufacturers to identify approaches that would yield consistency sufficient to provide meaningful enrichment and outcome measures. Much of the groundwork for these efforts was provided through the Alzheimer's Disease Neuroimaging Initiative (ADNI). The ADNI included an intensive preparatory phase to develop and assess image preprocessing steps that would enhance longitudinal stability of the measures. Variability across imaging sites, manufacturers, and equipment upgrades remains a source of noise in multi-site imaging studies, but the preparatory phase of ADNI and its cross-institutional collaborative efforts were critical to establishing the potential for the incorporation of neuroimaging biomarkers in large-scale clinical trials, which is already nearly universal. As of April 2012, 298 papers were published or in press using the ADNI study open access data, and the image repository had dispensed more than one million image downloads (http://www.adni-info.org/scientists/Pdfs/09_Green_Data_and_Publications.pdf). Since the initial ADNI study, a number of spinoff and continuation studies

Figure 62.3 Map representation of worldwide studies examining biomarkers of AD. Multisite imaging and biofluid biomarker studies are planned or underway in Europe, China, Taiwan, South Korea, Japan, and Australia. These studies were influenced by the pivotal ADNI study in North America. (Source: World map template from <http://presentationmagazine.com>.)

have begun within and beyond the field of AD. As further testament to the success and influence of the study, a number of international efforts have begun that have been modeled on the methods of ADNI (Fig. 62.3).

ADDED VALUE OF BIOMARKERS IN COMBINATION

A significant advance attributable to ADNI and its readily available dataset is the more complete description of the regional structural and metabolic changes associated with AD, a finding that has been consistent across a number of analysis approaches. Results from ADNI have suggested that structural, metabolic, and amyloid biomarkers may be used in a complementary manner, given a putative temporal progression of biomarker positivity across the development of the disease (Jack et al., 2010). Such hypothesized progression of disease markers in typical, late onset, AD remains, as yet, unsupported through directed experimentation and therefore highly controversial, but several studies that have examined a combination of biomarkers for predicting progression of symptoms toward dementia have found them to provide additive information that may be related to differential sensitivity and dynamic changes that vary with disease stage. Specifically, it appears that amyloid deposition is detectable 10–20 years before the onset of symptoms, whereas tau positivity within the CSF and vMRI changes are relatively concurrent with cognitive changes detectable with specialized neuropsychological testing (see, e.g., Heister et al., 2011; Bateman et al., 2012). Thus, while amyloid positivity suggests that a patient is at higher risk for development of AD, atrophy or hypometabolism suggests that

the patient has entered the neurodegenerative stage of disease and is at risk for imminent clinical decline (Fig. 62.4).

The apparent complementary and differential disease-stage sensitivity of amyloid testing and vMRI or FDG PET provides additional leverage for clinical trial design, such that amyloid testing can be incorporated at screening to enrich the trial with subjects that have objective evidence of the targeted disease (or even the targeted protein), and baseline vMRI or FDG PET can provide complementary information about disease stage. Further, the imaging studies provide information that is relatively independent from and orthogonal to the cognitive complaint that led to subject selection, whereas cognitive measures provide information that overlaps with complaint and so could yield positive results even for etiologies that are not neurodegenerative. Consistent with this, studies using ADNI data have shown remarkable power advantages for enrichment based on baseline atrophy that could not have been achieved using any of the available cognitive measures from ADNI (McEvoy et al., 2010). As such, quantitative PET and MRI neuroimaging show promise for enriching clinical trials of prodromal AD with individuals likely to progress to AD and to decline in the period of study (Jack et al., 2008; Kovacevic et al., 2009; McEvoy et al., 2009).

In addition to potential usages in clinical trial enrichment, vMRI and amyloid biomarkers appear to provide complementary secondary outcome measures when acquired across time. Neuroimaging of brain structure through vMRI provides a measure that does not vary based on day-to-day fluctuations in the cognitive abilities of subjects that are caused by wakefulness, medication effects, motivation, and the like, and it has been shown to be less variable across time than cognitive

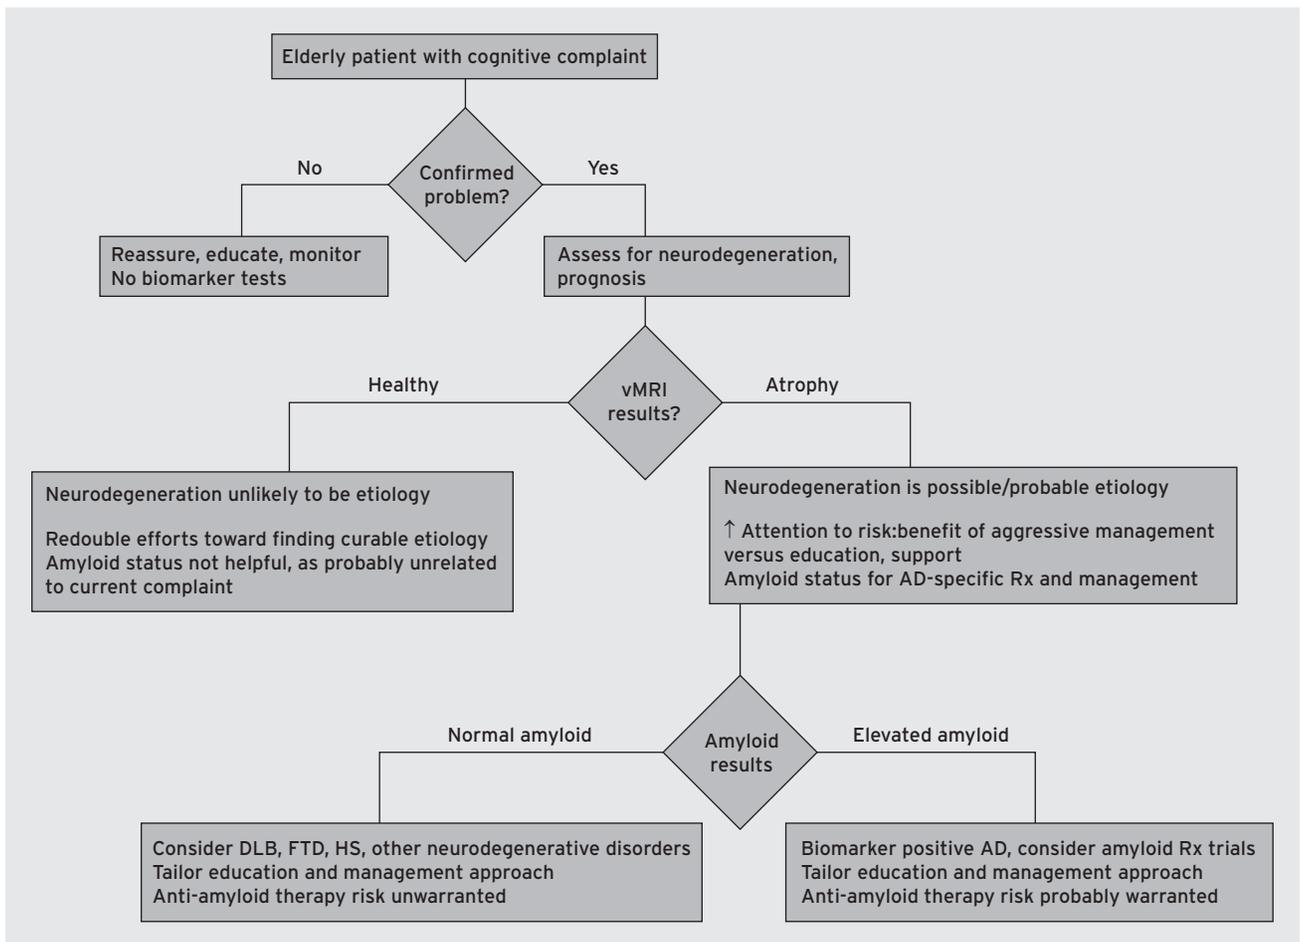

Figure 62.4 Example decision tree presenting one approach to incorporating vMRI and amyloid biomarkers in clinical practice. HS, Hippocampal sclerosis. (McEvoy, L.K., & Brewer, J.B. (2012). Biomarkers for the clinical evaluation of the cognitively impaired elderly: amyloid is not enough. *Imag Med*, 4(3), 14.)

measures (Weiner et al., 2012). Amyloid measures, though less sensitive to disease progression, may support putative effects of the therapy on disease pathology. The combination of regional amyloid measures with regional measures of brain atrophy may be especially powerful, because changes in amyloid burden can be colocalized with structural neuroimaging to examine interactions between amyloid and atrophy as well as a study drug's effects on each. Neuroimaging biomarkers might therefore support claims that a medication's effect on cognition is likely due to halted neurodegeneration or reduction of pathological burden rather than due to a brief symptomatic benefit.

CONCLUSIONS

Neuroimaging in the assessment of the elderly with cognitive impairment has changed from its previously limited role, in ruling out discrete lesions, to an integral role, in quantitatively assessing the cardinal components of neurodegeneration, neural dysfunction, and pathological burden observable in AD. Both MRI and PET benefit from wide flexibility in application, given the various anatomical, functional, and pathological features that might be assessed with each. The path toward clinical application was guided primarily by large scale, multisite

pharmaceutical trials, in which a more direct assessment of the effects of therapies was sought. Such efforts demonstrated the feasibility of obtaining these measures across sites in clinical practice, though a great deal of work remains to determine how best to integrate the information into clinical assessment, and how each can be used to inform predictive prognosis and guide management in individual patients (Brewer, 2009). Though publicly accessible databases of clinical trial enrollees have assisted in these efforts, the recent availability of highly standardized acquisition techniques and FDA-approved quantitative imaging approaches will allow such research to proceed in the unselected populations encountered in clinical practice.

DISCLOSURES

Dr. Brewer is supported by NINDS K02 NS067427, NIA U01 AG10483, NIA P50 AG005131, NIA R01 AG034062. He is an investigator for and receives research funds from Janssen Alzheimer Immunotherapy. He also has received research funds from General Electric Medical Foundation; holds stock options in Cortechs Labs., Inc; and has served on advisory boards for Elan, Avanir, Bristol-Myers-Squibb, and Lilly Biomarker Business Unit.

Dr. Sepulcre has no conflicts of interest to disclose.

Dr. Johnson has served as a site investigator for Avid, Pfizer, Janssen, Bristol-Myers-Squibb, and as a consultant to Bayer, Bristol-Myers-Squibb, Genzyme, and Siemens.

63 | FLUID BIOMARKERS FOR ALZHEIMER'S DISEASE

ANNE M. FAGAN

Alzheimer disease (AD), the most common cause of dementia in the elderly, is a progressive and fatal neurodegenerative disorder that currently affects ~10.6 million people in the United States and Europe, with projected estimates reaching epidemic proportions (15.4 million) by the year 2030 (http://www.alz.org/national/documents/Facts_Figures_2011.pdf). Alzheimer's disease leads to a loss of memory, cognitive function, and ultimately independence, causing a heavy personal toll on patients and their families and a tremendous financial burden on health care systems globally. Indeed, the cost for care of AD patients in 2011 in the United States alone was over \$183 billion, with projected annual costs increasing to \$1 trillion by the year 2050 unless effective disease-modifying treatments are developed (Brookmeyer et al., 2011).

At present, a definitive diagnosis of AD can only be obtained at autopsy, requiring postmortem identification of the presence of two hallmark brain lesions: extracellular deposits of the β -amyloid peptide (amyloid plaques) and intraneuronal accumulations of hyperphosphorylated tau protein (neurofibrillary tangles). A clinical diagnosis of AD during life is based on guidelines established in 1984 by the National Institute of Neurological Disorders and Stroke—Alzheimer's Disease and Related Disorders Association (NINCDS-ADRDA) (McKhann et al., 1984). Unfortunately, the accuracy of current clinical AD diagnostic methods to predict pathologic diagnoses, though promising in some specialized dementia centers and clinics, is generally quite low; a recent study involving research participants ($N > 900$) evaluated in more than 30 Alzheimer's Disease Centers in the United States reports sensitivities ranging from 70.9% to 87.3% and specificities from 44.3% to 70.8% (depending on the specific histopathological diagnostic criteria employed) (Beach et al., 2012). This variable and inadequate performance is particularly troubling given the high level of expertise of the clinicians in such specialized AD centers. Diagnostic accuracies in secondary or primary care settings are likely even lower. Therefore, there is an urgent need for objective tests that can increase diagnostic accuracy in the shorter term, to aid in the design and evaluation of treatment efficacy of clinical trials, and in the longer term, for individual patient care.

Another imperative is early disease diagnosis. To date clinical trials of AD therapeutics have been unsuccessful in reversing, halting, or even slowing cognitive decline (see Chapters 65 and 66 in this book). A widely held belief is that some of this failure is because of the exclusive enrollment of individuals who already exhibit mild or moderate dementia, stages of AD that are accompanied by robust neuronal cell death.

At even earlier stages of the disease (very mild dementia and mild cognitive impairment due to AD), neuron loss in certain vulnerable brain regions is already severe (Price et al., 2001). Thus, it is critical to diagnose individuals at very early disease stages—and enroll them in clinical trials—in order to identify and apply therapies that have the best chance of preserving *normal* cognitive function.

ALZHEIMER'S DISEASE IS A CHRONIC DISEASE

The past several years have brought about an appreciation of the chronic, evolving nature of AD pathogenesis in large part because of advances in the AD biomarker field. The clinical construct of mild cognitive impairment (MCI) (Petersen et al., 1999), defined by impairments in cognitive abilities (compared with age-matched normative values) but that are below the threshold considered to be “dementia,” has been hypothesized to represent a transition between healthy aging and AD dementia for those with AD pathology. Furthermore, clinicopathologic correlation studies support the notion of a long asymptomatic (preclinical) stage of the disease, with brain pathology estimated to begin years, even decades, prior to significant neuronal cell death and the appearance of *any* behavioral signs or symptoms, including MCI (Price et al., 2009). This appreciation has fueled a paradigm shift in therapeutic goals from disease “cure” (considered to be virtually impossible in the “end-stage” dementia stage associated with significant neuron loss), to halting, delaying, or even preventing cognitive decline due to AD pathology in the very early, even preclinical/presymptomatic, stages of the disease.

FLUID BIOMARKERS OF ALZHEIMER'S DISEASE

Given the current limitations of clinical diagnostic accuracy during the preclinical and early clinical stages of the disease, fluid (and imaging) biomarkers of AD pathologies are currently being sought. A biomarker is defined as a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacological responses to a therapeutic intervention (Biomarkers Definitions Working Group, 2001). As such, a biomarker can be used to guide clinical diagnosis (diagnostic), estimate disease risk or prognosis (prognostic), evaluate disease stage, and

monitor progression and/or response to therapy (theragnostic) (Blennow et al., 2010). Because cerebrospinal fluid (CSF) is in direct contact with the extracellular space of the brain, biochemical changes in the brain are reflected in the CSF. Therefore, CSF is considered an optimal source for AD biomarkers. Indeed, analysis of CSF has yielded the most promising biomarker candidates and has also provided important insights into the temporal ordering of neuropathological changes during the normal course of the disease. Although CSF collection via lumbar puncture is considered by some an invasive procedure, its risks are similar to those of standard venipuncture when performed by a trained clinician. Furthermore, when using atraumatic (Sprotte) spinal needles, the incidence of postlumbar puncture headache is low (<2%) in older individuals, including those with mild to moderate AD (Peskind et al., 2009).

CEREBROSPINAL FLUID MARKERS OF CORE ALZHEIMER'S DISEASE PATHOLOGIES

Ideally, a core biomarker should reflect the underlying pathology of a disease. One of the challenges in AD (and most neurodegenerative diseases) is that biomarker validation requires comparison of fluid collection during life with neuropathological findings at autopsy (the current gold standard for diagnosis), and the time lag between CSF collection and autopsy makes such comparisons difficult. Because the 42 amino acid form of the A β peptide (A β 42) and the tau protein are the primary components of amyloid plaques and neurofibrillary tangles, respectively, the levels of these proteins in CSF have been assessed as potential biomarkers of these core pathologic features. Normally A β is produced by neurons and subsequently cleared from brain interstitial fluid into the CSF and blood via passive and active transport processes. In AD, this normally soluble A β peptide aggregates to form insoluble, higher-order structures with β -pleated sheet confirmation, termed β -amyloid. The mechanism(s) by which this aggregation occurs in AD continues to be the focus of much research and likely involves alterations in the production and/or clearance of the peptide. In AD, levels of CSF A β 42 have been shown to negatively correlate with amyloid plaque load at autopsy (Strozyk et al., 2003; Tapiola et al., 2009) as well as more recently in the living brain as determined by amyloid imaging using positron emission tomography (PET) with amyloid-binding compounds (Klunk, 2011; Villemagne & Rowe, 2012). The most widely accepted explanation for the reduced CSF level of A β 42 in AD is that the aggregation of A β into plaques (and thus retention in the brain parenchyma) results in less A β being available to diffuse into the CSF.

Tau is a microtubule-associated protein expressed predominantly by neurons in the brain, where it functions to stabilize microtubules (among other less known functions). In AD, for unknown reasons, tau becomes hyperphosphorylated, thus impairing its ability to bind microtubules. As a result, tau forms structures called paired helical filaments, which aggregate to form intracellular neurofibrillary tangles. However, although the presence of tangles is required for the neuropathologic diagnosis of AD, they are also observed in other neurodegenerative conditions (i.e., tauopathies) such

as frontotemporal lobar degeneration (FTLD). Tangles also increase in normal aging, albeit to a much lesser extent. Levels of CSF tau increase in AD (Blennow et al., 2010; Olsson et al., 2011; Sunderland et al., 2003), supporting the notion of it being a marker of tangles. However, levels also increase markedly (but transiently) in acute disorders such as stroke and brain trauma, with the magnitude of the increase positively correlating with the size of the damage (Hesse et al., 2001; Neselius et al., 2012; Stern et al., 2011). Levels are also highly elevated in Creutzfeldt-Jakob disease (CJD), a neurodegenerative disease involving rapid neuronal degeneration (VanHarten et al., 2011). These observations suggest that CSF tau is a more general marker of neuronal cell death. In contrast, levels of hyperphosphorylated tau species (p-tau) increase in AD but not in CJD (VanHarten et al., 2011) or in response to traumatic injury, thus supporting the idea of p-tau being a more specific marker of tangles in AD. Consistent with this notion, elevated CSF p-tau levels positively correlate with tangle pathology at autopsy (Buerger et al., 2006).

DIAGNOSTIC PERFORMANCE IN ALZHEIMER'S DISEASE DEMENTIA

Because the current criteria for the clinical diagnosis of AD requires the presence of dementia (McKhann, et al., 1984), the majority of biomarker studies have evaluated the performance of analytes in differentiating individuals with dementia believed to be due to AD from individuals with no dementia. In such analyses, elevated CSF levels of tau and p-tau (~300%) and reduced levels of A β 42 (~50%) perform quite well, typically with sensitivities and specificities above 80% (Blennow et al., 2010). Combined analyses of these biomarkers (e.g., high levels of tau(s) in the presence of low A β 42) perform better than any single biomarker on its own (Galasko et al., 1998; Maddalena et al., 2003). Importantly, CSF levels of these markers are normal in several other disorders that are often accompanied by cognitive impairment such as depression and Parkinson's disease (Blennow, 2004). CSF p-tau, in particular, can aid in the differentiation of AD from other dementias, such as frontotemporal dementia (FTD) and Lewy body dementia (LBD) (Hampel et al., 2004). However, the overall diagnostic performance of these CSF biomarkers to discriminate AD dementia from dementia caused by other pathologies is not optimal, likely reflecting the relative abundance of mixed pathologies in people presenting with dementia (Halliday et al., 2011), as well as inaccuracies in differential clinical diagnosis, especially at early disease stages.

DIAGNOSTIC PERFORMANCE IN PRODROMAL ALZHEIMER'S DISEASE

Development of disease-modifying drugs for AD likely requires testing in patient populations at very early disease stages. This critical interest in early diagnosis coupled with the appreciation of the long time period (estimated to be 10–20 years), during which AD pathology develops prior to clinical or cognitive symptoms of dementia, has fueled efforts to identify biomarkers of AD pathology prior to the onset of dementia. As a group, cohorts of individuals clinically diagnosed with MCI (defined by impairments in cognitive abilities compared with

age-matched normative values but at levels that are below the threshold considered to be “dementia”) typically display mean AD biomarker profiles of CSF A β 42, tau and p-tau intermediate to those of cohorts with AD dementia and non-demented controls (Blennow et al., 2010; Weiner et al., 2012). However, there is significant overlap between individuals in the MCI and the other diagnostic groups, with approximately two-thirds displaying profiles consistent with AD pathology and one-third appearing in the normal range (Shaw et al., 2009). Such heterogeneity likely reflects differences in the underlying etiology of the cognitive impairments. Indeed, longitudinal studies in several international cohorts have shown that the combination of low CSF A β 42 and high CSF tau and p-tau is highly predictive of which MCI cases will progress to AD dementia (Buchhave et al., 2012; Mattsson et al., 2009; Shaw et al., 2009; Visser et al., 2009), as well as their rate of cognitive decline (Snider et al., 2009). Such studies have prompted a proposal for the use of these CSF biomarkers to define (probabilistically) the underlying etiology of MCI cases in research as well as clinical settings (Albert et al., 2011) (see the following).

DIAGNOSTIC/PROGNOSTIC PERFORMANCE IN ASYMPTOMATIC (PRECLINICAL) ALZHEIMER'S DISEASE

The ultimate goal in AD therapy, to *prevent* cognitive decline (prior to irrevocable neuronal cell loss), provides a unique challenge because, by definition, clinical measures will be unable to identify individuals in this presymptomatic phase. Therefore, the use of validated disease biomarkers will be required for such patient identification. Clinicopathologic studies have shown that roughly one-third of cognitively normal elderly individuals who come to autopsy meet the histopathologic criteria for AD (Price et al., 2009). Data from more recent biomarker studies in large cohorts of cognitively normal individuals confirm this finding; a similar proportion of cognitively normal elders exhibit low levels of CSF A β 42, and low levels correlate with the presence of cortical amyloid as detected by PET amyloid imaging (Fagan et al., 2009). A subset of cognitively normal elders also displays high levels of CSF tau and/or p-tau in the setting of reduced levels of A β 42. Importantly, the combination of these pathologic markers (e.g., as estimated by the ratio of CSF tau(s)/A β 42) has been shown to be highly predictive of future cognitive decline (to MCI as well as to AD dementia) within three to five years in these cognitively normal individuals (Fagan et al., 2007; Li et al., 2007). Recent data from members of families with known AD-causing mutations indicate that robust alterations in CSF A β 42 and tau(s) can be observed in asymptomatic mutation carriers ~15 to potentially 25 years prior to their predicted age of symptom onset (defined as the age at which their parent developed symptoms) (Bateman et al., 2012). Because mutation carriers will go on to develop AD dementia with a virtual 100% certainty, these data strongly support the feasibility of using CSF markers as predictors of future dementia. The precise timing of such changes in the presymptomatic stage of the more common “sporadic” form of the disease is currently a topic of much investigation and will be important to consider if an AD diagnosis is ever to be made in the absence of cognitive symptoms (Sperling et al., 2011).

THE NEED FOR NOVEL BIOMARKERS

Despite the association between the levels of these established CSF analytes and underlying AD pathology, measures of biomarker accuracy for clinical diagnosis vary widely among studies. Such variability underscores the need for the development of additional biomarkers that will, either on their own or in combination with more established core markers, increase diagnostic accuracy. Novel biomarkers are also needed that will identify additional processes involved in AD pathogenesis, such as markers of neuroinflammation and early neuronal stress and dysfunction prior to overt cell death. Given that other neurodegenerative conditions (e.g., FTL, LBD, vascular dementia [VaD], progressive supranuclear palsy, hippocampal sclerosis) can present with AD-like clinical symptoms, and individuals with AD frequently have comorbid pathologies, additional markers are needed that can aid in differential diagnosis and identify cases with mixed pathologies. Markers will also be required to define the pathophysiological stages of AD (in parallel with clinical stages; preclinical, MCI due to AD, AD dementia) and identify those individuals at increased risk of rapid cognitive decline.

The pathophysiology of AD is complex. In addition to the hallmark lesions of β -amyloid plaques and neurofibrillary tangles, AD pathology includes gliosis/neuroinflammation, oxidative damage, synaptic dysfunction/loss, and eventually neuronal cell death (Fig. 63.1; Table 63.1). Because the sophistication and power of proteomics technology has evolved tremendously over the last decade, proteins comprise the vast majority of novel candidate markers of such processes. Individually, many candidates show utility for differentiating cohorts of AD dementia cohorts and “controls,” and many of these also show potential to improve upon the diagnostic accuracy of A β 42, tau, and p-tau (Fagan and Perrin, 2012). A shorter list of candidates shows potential to track disease progression, and even some have been reported to predict rate of cognitive decline. Although a detailed discussion of all the individual candidates is beyond the scope of this chapter, general categorical mentioning is warranted.

Several promising CSF biomarkers are related to the processing of the amyloid precursor protein (APP) and the metabolism and amyloidogenesis of A β itself; these include soluble fragments of APP, APP cleaving and transport enzymes, truncated and oligomeric A β species, and several A β -binding proteins. As potential markers of tangles, levels of tau species that are phosphorylated at different amino acid residues (e.g., serine 231 vs. 181) are also being explored, especially for differential diagnosis. Potential CSF markers of synapse loss and/or neurodegeneration include several members of the granin family of dense core vesicle proteins, synaptic adhesion molecules and neuron-specific proteins. One neuron-specific marker that warrants discussion because of its great promise is visinin-like protein 1 (VILIP-1), which is a neuron-specific calcium sensor protein. Like tau, the level of VILIP-1 in the CSF is elevated in AD (Lee et al., 2008; Tarawneh et al., 2011) and, when combined with CSF A β 42, is a strong predictor of future cognitive decline in very mild AD dementia/MCI and cognitively normal controls (Tarawneh et al., 2011; Tarawneh et al., 2012), potentially performing even better than the tau/A β 42 ratio. Perhaps not unexpectedly, levels of CSF VILIP-1

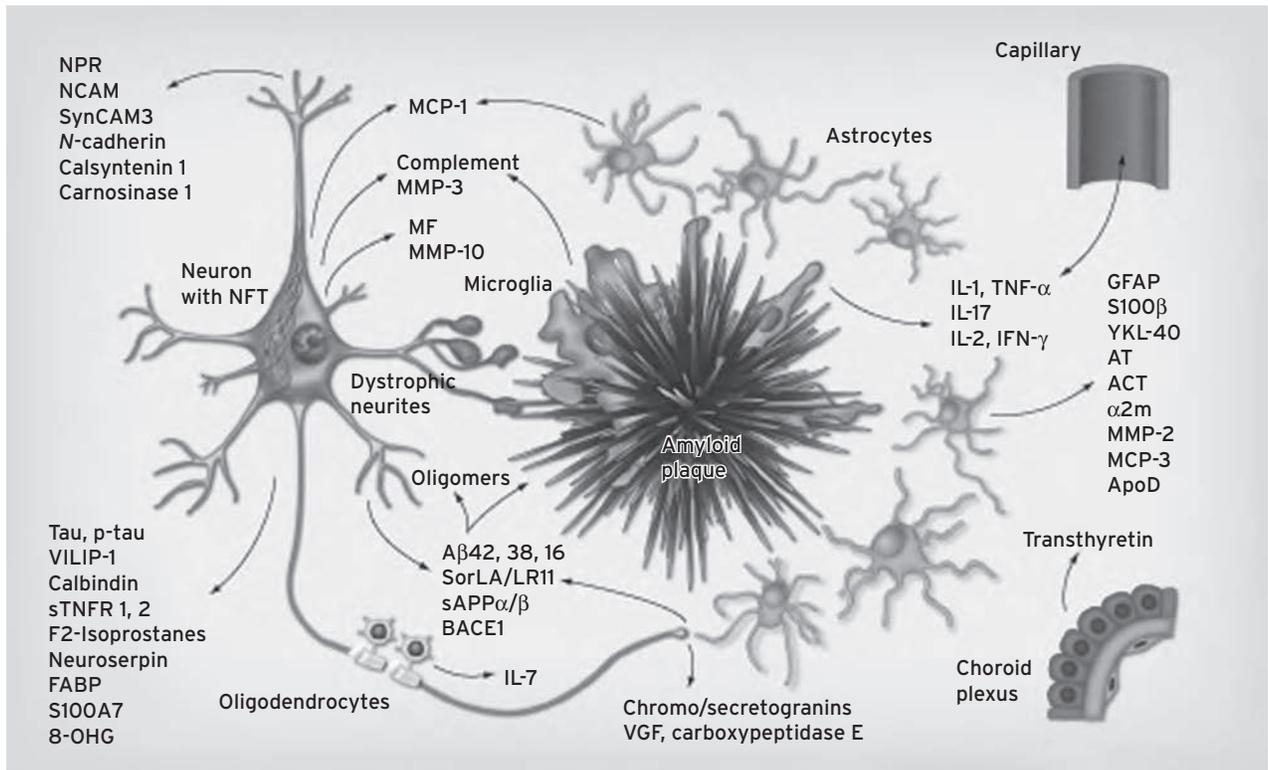

Figure 63.1 Schematic histological representation of origins of upcoming and established CSF biomarkers. Synaptic adhesion molecules, other neuronal proteins, and dense core vesicle proteins generally decline in AD, perhaps reflecting synapse loss (upper left, bottom center, respectively). Other neuronal proteins (bottom left), including tau and p-tau, and oxidation products increase in AD and may reflect neuronal injury. Also produced by neurons, A β 42 (center, left) preferentially oligomerizes and partitions into plaques, but other proteins associated with the processing of the amyloid precursor protein (APP), including shorter A β species, soluble fragments of APP, and secreted processing enzymes such as β -APP cleaving enzyme (BACE 1), do not. Different subsets of neuroinflammatory molecules are secreted by each of the parenchymal cells represented here; neurons selectively produce macrophage migration inhibiting factor (MIF) and matrix metalloproteinase-10 (MMP-10) (upper center), but share responsibility with microglial cells for MMP-3 and factors of complement. Microglial cells themselves produce most of the other cytokines and chemokines (upper right), though many of these can also cross the blood brain barrier from the periphery. Among the neuroinflammatory mediators of greater significance as potential biomarkers, oligodendroglial cells produce IL-7 (lower left), and astrocytes produce MMP-2 and YKL-40 (center right). Astrocytes are also responsible for shedding some intrinsic proteins (glial fibrillary acidic protein [GFAP] and S100 β) and for secreting many other miscellaneous proteins implicated in AD pathogenesis. Transthyretin (lower right), one of the most abundant proteins in the CSF, is produced principally by the choroid plexus. Not pictured are many other candidate biomarker molecules for which the cell(s) of origin are unknown (e.g., miRNAs), not specific (e.g., cystatin C), or too prolific (e.g., astrocyte products), prohibiting the inclusion of all their relevant secreted products. (Reprinted with permission from Fagan, A., and Perrin, R. (2012). Upcoming candidate cerebrospinal fluid biomarkers of Alzheimer's disease. *Biomarkers Med*, 6, 455–476.)

are positively correlated with tau, and both are increased in response to stroke and acute traumatic brain injury (Laterza et al., 2006). Whether VILIP-1 provides diagnostic or prognostic value beyond that of tau in AD remains to be determined.

A broad array of neuroinflammatory molecules with known or hypothesized neurotoxic and/or neuroprotective roles have also been identified as potential AD CSF biomarkers; these include complement proteins, proteases and their inhibitors, cytokines and their receptors, chemokines, and markers of astrogliosis. Although neuroinflammation and gliosis are not specific to AD, markers of such inflammatory processes may be useful as part of a biomarker panel. Several apolipoproteins in CSF have shown AD-associated changes, some of which may be involved in A β metabolism and/or fibrillogenesis. Again, although not specific for AD, markers of pathological oxidative processes such as modified lipid species (e.g., F2-isoprostanes) and nucleic acids (e.g., 8-OHG), may have a role in early stage diagnosis, prognosis, and biomarker outcomes in clinical trials. “Metabolome” screens and surveys

of micro RNAs in CSF are also being investigated but are still in the method development phase.

PLASMA BIOMARKERS

There is widespread interest in identifying blood-based biomarkers of AD since blood is more easily obtained than CSF in routine clinical settings. Unfortunately, efforts to discover reliable AD biomarkers in blood have yielded little success, but it is unclear whether this failure reflects the true biology of the disease or limitations of current analytical methods. The most obvious candidate, and hence the one most extensively examined, is plasma A β (see Table 63.1). Unfortunately, findings from the many published studies are contradictory (Mayeux and Schupf, 2011). Some groups report slightly higher plasma levels of either A β 42 or A β 40 in AD, although with broad overlap between AD and control groups, whereas most studies find no change. Some studies report that a high level of plasma A β 42, or a high A β 42/A β 40 ratio, is an indicator

* Direction is therapeutic agent-specific

of increased risk for future AD; however, other studies have reported the opposite. These discouraging results may be due to the fact that the majority of plasma Aβ is derived from peripheral tissues (especially platelets), and does not reflect brain Aβ turnover or metabolism. Observations of a lack of correlation between plasma Aβ species and brain amyloid load as determined by *in vivo* amyloid imaging (Fagan et al., 2009) are consistent with this notion. It is conceivable, however, that

the binding of Aβ to various proteins in plasma may result in epitope masking and other analytical interference, thus impairing the ability of current assays to accurately measure Aβ levels in blood-derived samples. Alternate analytical methodologies are being explored.

Other studies have utilized hypothesis-driven approaches (such as screening with predetermined protein arrays) or exploratory proteome-based methods in plasma and serum

from AD and control groups, as has been performed in CSF (see Table 63.1). Multivariate analyses of several defined panels have identified groups of proteins (notably growth factors and proteins involved in signaling or inflammation) that discriminate clinical groups (AD vs. controls) (Doecke et al., 2012; Hu et al., 2012; Nagele et al., 2011; O'Bryant et al., 2011; Ray et al., 2007) Unfortunately, some results have not been replicated, whereas others require additional validation in independent cohorts. Furthermore, the reported accuracies are inferior to those observed for the core AD CSF markers (A β 42, tau, p-tau). Another more recent approach uses libraries of known peptides or, in a novel assay, synthetic, unnatural "peptoids," to screen serum samples from AD and control individuals for potential disease-related autoantibodies (Reddy et al., 2011). The reported diagnostic accuracies are impressive, rivaling those of the core CSF markers, although the results need to be replicated

in larger and better characterized cohorts before definitive conclusions can be drawn. Such studies are in progress.

POTENTIAL USE OF FLUID BIOMARKERS OF ALZHEIMER'S DISEASE

The field of AD biomarker research has made tremendous progress over the past decade, not only leading to more accurate disease diagnosis and prognosis in research participants, but also providing a window into the trajectories of neuropathologic changes over the normal course of the disease, especially during the long asymptomatic (presymptomatic, preclinical) phase. Results from many cross-sectional studies support a model in which dynamic reductions in CSF A β 42 (indicative of the presence of amyloid plaques) occur early in the pathologic

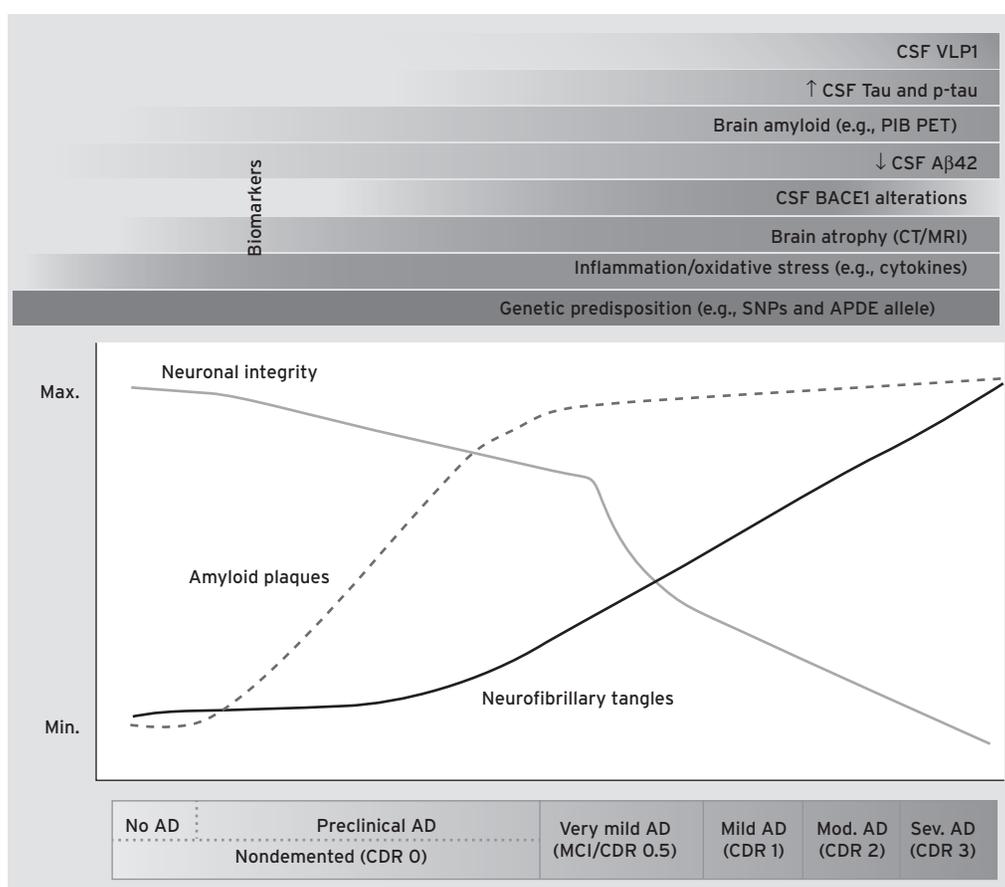

Figure 63.2 Hypothesized trajectory of AD pathologic changes as evidenced by CSF and imaging biomarkers. The clinical stages of AD, described as very mild dementia or mild cognitive impairment (MCI), mild, moderate, and severe, correspond to the Clinical Dementia Rating (CDR) scores of 0.5, 1, 2, and 3, respectively. These symptomatic stages are associated with abundant amyloid plaques (dashed line), the gradual accumulation of neurofibrillary tangles (dark gray line), and synaptic and neuronal loss in certain brain regions (light gray line). During the “preclinical” stage of AD (estimated to range from ~10–20 years), the A β 42 peptide aggregates to form amyloid plaques in asymptomatic individuals (CDR 0) and is hypothesized to damage neuronal processes and synapses. Dementia onset is associated with significant neuronal cell death in vulnerable brain regions. These pathologic changes can be measured by biochemical examination of cerebrospinal fluid (CSF), and/or a variety of radiological imaging modalities (e.g., computed tomography [CT], magnetic resonance imaging [MRI], and amyloid imaging [PIB PET]). The most promising CSF biomarkers to date have been A β 42 and tau species, which show diagnostic and prognostic utility. VILIP-1 as a potential marker of neuronal death and BACE 1 as an indicator of A β production warrant further study, as do panels of inflammatory markers and markers of oxidative stress. Genetic variations (e.g., single nucleotide polymorphisms [SNPs]) may also be considered biomarkers that allow the earliest possible estimation of risk. (Reprinted with permission from Fagan, A., and Holtzman, D. (2010). Cerebrospinal fluid biomarkers of Alzheimer's disease. *Biomarkers Med*, 4, 51–63.)

cascade (during the asymptomatic/preclinical phase) and do not change substantially during the subsequent symptomatic phase, whereas an elevation in CSF tau is a biomarker of downstream neurodegenerative pathologies that are dynamic later in the course of the disease, as people approach and move through the symptomatic phase (Jack et al., 2010; Perrin et al., 2009) (Fig. 63.2). Consistent with this model, cognitive decline is more closely related to biomarkers of neuronal injury than amyloid load. Investigation of longitudinal change in biomarkers within individuals over time, especially during middle-age, will be required to test this model and is currently underway.

Although measurements of CSF levels of Aβ42, tau, and p-tau in clinic patients can already be obtained by physicians, these measures are not part of the current clinical criteria for the diagnosis of AD dementia; however, this may soon change. The current clinical diagnostic criteria for AD were developed more than 25 years ago by the National Institute of Neurological and Communicative Disorders and Stroke and the Alzheimer’s Disease and Related Disorders (NINCDS-ADRDA) Work Group (McKhann et al., 1984). The criteria depend largely on the exclusion of causes other than AD for dementia. These criteria state that a diagnosis of AD cannot be made until the patient has dementia, which is defined as “cognitive symptoms severe enough to interfere with social or occupational activities.” The DSM-IV criteria, which are used for routine diagnosis, also require that a patient demonstrate dementia before a diagnosis of AD is possible (American Psychiatric Association, 2000). Given that dementia is the end-stage of the disease and disease-modifying therapies will likely have the most benefit if administered earlier in the disease process, new criteria for different stages of AD have recently been proposed by three National Institute on Aging and the Alzheimer Association Workgroups (Albert et al., 2011; McKhann et al., 2011; Sperling

et al., 2011). Similar revisions have been proposed by others (Dubois et al., 2010). These criteria have been developed, in principle, to permit a diagnosis of AD in earlier disease stages, and involve assessment of cognition as well as biomarkers, including MRI, PET, and CSF markers, in order to increase the confidence of AD being the underlying etiology of a clinical impairment. More detailed guidelines are currently being discussed to establish if and how the use of biomarkers can be implemented in clinical practice, not only in the presence of dementia (Fig. 63.3) but at earlier disease stages, such as MCI (Fig. 63.4), or even before the development of any dementia symptoms (Fig. 63.5).

In the shorter (and present) term, biomarkers are being used in AD secondary prevention trials of potential disease-modifying therapies. Levels of CSF Aβ42, tau, and/or p-tau are being used to: (1) enrich the number of patients who actually have underlying AD pathology (diagnostic), (2) stratify patients according to the presence and/or the amount of underlying pathology (prognostic), and (3) assess therapeutic target engagement and monitor the effects of treatment on downstream pathogenic events (theragnostic). Not only will this approach result in an overall reduction in required patient numbers, trial duration, and cost, but it is also expected to provide information particularly suitable for making go/no-go decisions whether to move candidate therapies forward into large and expensive Phase II and III trials.

CHALLENGES AND FUTURE DIRECTIONS

The AD biomarker field is faced with several challenges it must overcome in order to move promising analytes into clinical practice. From a methodological perspective, biomarker

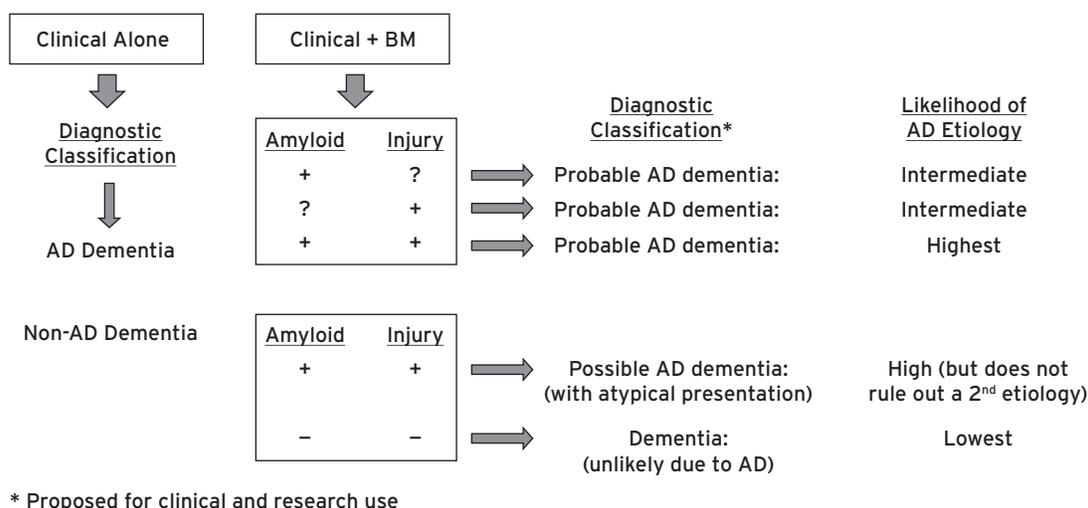

Figure 63.3 Proposed diagnostic classifications of AD dementia according to clinical criteria alone compared with clinical criteria plus AD pathology-related biomarkers. The addition of biomarker (BM) information to clinical evaluation permits an assessment of probability (likelihood) that dementia symptoms are caused by underlying AD pathobiological processes. Positive amyloid markers include low levels of CSF Aβ42 and/or positive amyloid PET. Positive neuronal injury markers include high levels of CSF tau, glucose hypometabolism via FDG-PET, and/or atrophy via structural MRI. Still evolving are standards for determining biomarker positivity, evaluations of potential rankings of the various fluid and imaging markers for identifying underlying disease processes, and decision making in cases of indeterminate or conflicting fluid and imaging markers within a biomarker category. These criteria are proposed for clinical and research use. (From McKhann, G., Knopman, D., Chertkow, H., Hyman, B., Jack, C., Kawas, C., et al. (2011). The diagnosis of dementia due to Alzheimer’s disease: Recommendations from the National Institute on Aging and the Alzheimer’s Association Workgroup. *Alzheimers Dement*, 7, 263–269.)

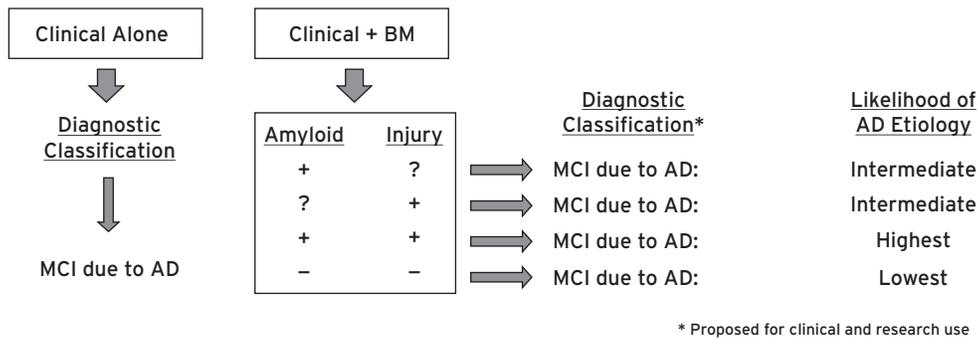

Figure 63.4 Proposed diagnostic classifications of Mild Cognitive Impairment (MCI) according to clinical criteria alone compared with clinical criteria plus AD pathology-related biomarkers. The addition of biomarker (BM) information to clinical evaluation permits an assessment of probability (likelihood) that MCI is caused by underlying AD pathobiological processes. Positive amyloid markers include low levels of CSF Aβ42 and/or positive amyloid PET. Positive neuronal injury markers include high levels of CSF tau, glucose hypometabolism via FDG-PET, and/or atrophy via structural MRI. Still evolving are standards for determining biomarker positivity, evaluations of potential rankings of the various fluid and imaging markers for identifying underlying disease processes, and decision making in cases of indeterminant or conflicting fluid and imaging markers within a biomarker category. These criteria are proposed for clinical and research use. (From Albert, M., DeKosky, S., Dickson, D., Dubois, B., Feldman, H., Fox, N., et al. (2011). The diagnosis of mild cognitive impairment due to Alzheimer's disease: Recommendations from the National Institute on Aging-Alzheimer's Association workgroups on diagnostic guidelines for Alzheimer's disease. *Alzheimer's Dement*, 7, 270–279.)

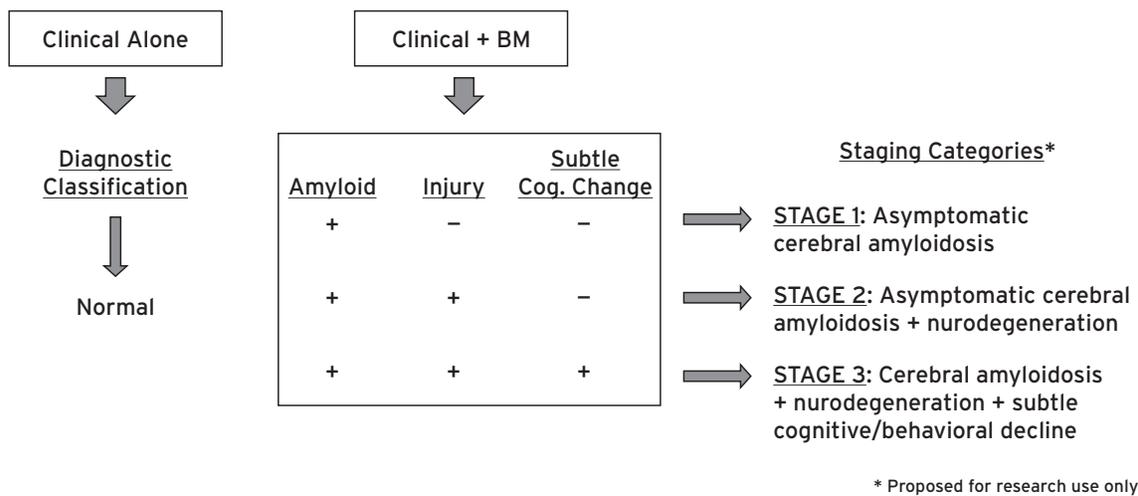

Figure 63.5 Proposed staging of preclinical AD according to clinical criteria alone compared with clinical criteria plus AD pathology-related biomarkers. Use of biomarker (BM) information in asymptomatic individuals permits an assessment of the presence of AD pathobiological processes. Positive amyloid markers include low levels of CSF Aβ42 and/or positive amyloid PET. Positive neuronal injury markers include high levels of CSF tau, glucose hypometabolism via FDG-PET, and/or atrophy via structural MRI. Subtle cognitive change awaits definition but may include declines in episodic memory and/or non-memory cognitive domains. Still evolving are standards for determining biomarker positivity, evaluations of potential rankings of the various fluid and imaging markers for identifying underlying disease processes, and decision making in cases of indeterminant or conflicting fluid and imaging markers within a biomarker category. It is important to note that these criteria are proposed for research use only. (From Sperling, R., Aisen, P., Beckett, L., Bennett, D., Craft, S., Fagan, A., et al. (2011). Toward defining the preclinical stages of Alzheimer's disease: Recommendations from the National Institute on Aging and the Alzheimer Association Workgroup. *Alzheimer's Dement*, 7, 280–292.)

candidates must be validated in large, well-characterized research cohorts, with care taken to evaluate the potential impact of important AD-related covariates such as age, gender, and APOE genotype (the strongest genetic risk factor for AD). For the most part, this has been accomplished for the core CSF markers Aβ42, tau, and p-tau. However, protocol and assay standardization for these analytes must still

be achieved in order to maximize biomarker sensitivity and reliability. For example, because potential diurnal variations in CSF Aβ levels have been reported (Bateman et al., 2007), sample collection and processing procedures must be standardized. In addition, significant between-assay and within-assay performance inconsistencies must be overcome (Mattsson et al., 2011), and worldwide standardization

efforts toward this goal are currently underway. Such assays need to eventually be transformed into platforms with high-throughput capabilities. Given the long preclinical stage of AD, biomarker validation should define sensitivity and specificity (and associated positive and negative predictive values) for underlying AD pathology, not merely clinical diagnosis that is often inaccurate. To date, very few studies have been able to correlate biomarkers in antemortem samples with results of histologic postmortem examination, and the time interval between the two evaluations can be large. Thus, cross-sectional studies employing only clinical measures must be large to compensate for the loose correlation between functional and pathological decline. Methods to image neurofibrillary tangles and inflammatory responses *in vivo* are currently being developed and will be very informative for providing pathologic validation for CSF markers (Fodero-Tavoletti et al., 2011). Evaluation of biomarker utility for differential diagnosis in cohorts with known underlying non-AD pathologies (FTLD, LBD, VaD, etc.) is also needed. Characterizing the change in biomarker profiles within individuals with disease progression, both in terms of underlying pathology as well as the severity of clinical symptoms, will be important for disease staging purposes, and large, longitudinal AD biomarker studies are currently underway in the United States and abroad. It is likely that changes in analyte levels within individuals over time may be more useful as biomarkers than baseline measures alone.

It is predicted that combinations of biomarkers will prove most useful for disease diagnosis (presence vs absence of AD pathology) and prognosis (predicting cognitive decline), within modalities or between modalities (e.g., fluids and imaging) (Perrin et al., 2009). Ongoing studies that collect multiple types of biomarker data will be critical for that assessment. The combination of CSF A β 42 and tau (total and/or phosphorylated tau species) will likely remain the essential biomarker panel to aid in AD diagnosis and prognosis because they represent core features of AD pathology. However, markers of more general neurodegenerative processes (e.g., neuroinflammation, synaptic loss/dysfunction) may eventually complement CSF A β 42 and tau(s) for AD diagnosis, prognosis, and staging. Novel markers of other neurodegenerative pathologies (e.g., Lewy bodies, TDP-43-inclusions, α -synuclein inclusions, etc.) are still needed to aid in differential diagnosis as well as for diagnosing mixed dementias. Specific markers for non-AD dementias have received somewhat less research attention owing to limited CSF collections, but several efforts focused on LBD and FTD are underway and will facilitate such biomarker discovery. It remains to be determined whether any viable plasma biomarkers will emerge in the near future, but many research groups are actively engaged in the search, given the clinical appeal of diagnostic blood tests.

CONCLUSIONS

The AD field is experiencing an exciting evolution, both in its appreciation of the dynamic nature of the disease and the

development of therapeutic strategies aimed at truly modifying the underlying disease pathogenic processes (as opposed to simply ameliorating dementia symptoms), and biomarkers have been at the forefront of these paradigm shifts. The core CSF analytes, A β 42, tau, and p-tau, have not only withstood the test of time in identifying individuals with AD dementia, but they have also been shown to strongly predict the development of future cognitive decline in individuals at very early, pre-dementia stages. Importantly, the AD biomarker signature of low CSF A β 42 and high tau/p-tau can be detected in individuals while they are still cognitively normal, thus providing a potential window for therapeutic interventions aimed at *preventing* cognitive decline, not just delaying or halting it once impairments are already clinically apparent. The field is also actively researching novel biomarker candidates (in CSF and plasma/serum) that will aid in discriminating AD from non-AD neurodegenerative diseases (differential diagnosis) and those that will identify additional processes involved in AD pathogenesis (e.g., markers of neuroinflammation and early neuronal stress and dysfunction prior to overt cell death). Multiplexed panels of biomarkers will likely be informative for pathophysiological disease staging (in parallel with clinical stages; preclinical, MCI due to AD, AD dementia) and identifying individuals at increased risk of rapid cognitive decline. A better understanding of the temporal trajectories of disease pathogenic processes will inform the design of clinical trials and the evaluation of efficacy of proposed disease-modifying therapies. Eventually the hope is to bring validated biomarkers to the clinic in order to increase diagnostic accuracy in symptomatic individuals and prognostic accuracy in individuals at early disease stages and perhaps even prior to any cognitive symptoms. Realization of this goal requires worldwide standardization of biomarker protocols, consensus among researchers and clinicians regarding the clinical utility of assessing biomarkers in patient care settings, and eventually the endorsement and adoption of such procedures and practices into global health care systems. Given the large and expanding aging population, we cannot afford to wait.

DISCLOSURES

Dr. Fagan is supported by grants from the National Institute of Aging of the National Institutes of Health (P01 AG03991, P01 AG026276, and U01 AG032438), the Hope Center for Neurological Disorders, the Alzheimer's Association, and the DIAN Pharma Consortium. She is a member of the Alzheimer's Disease CSF Biomarker Development Advisory Board for Roche and the U.S. Alzheimer's Disease Advisory Board for Lilly USA. No conflicts of interest exist.

MARY SANO AND JUDITH NEUGROSCHL

The awareness of cognitive loss and dementia has grown dramatically in the past 20 years. The most common etiology of dementia is Alzheimer's disease (AD), a neurodegenerative condition characterized by progressive cognitive and functional deterioration. Alzheimer's disease has an estimated prevalence of approximately 5.2 million in the United States (Alzheimers Association, 2012), with an estimated 36 million people worldwide currently suffering with dementias (Prince et al., 2011). The CDC has estimated that the US population older than age 65 will more than double from 2010 to 2050, with the population older than 85 more than tripling (Administration on Aging, 2010). Age is the greatest risk factor for Alzheimer's disease and other dementias, thus the number of individuals with dementia will continue to rapidly rise unless significant advances are made. In January 2011, the National Alzheimer's Project Act was signed into law in the United States, establishing a national project to facilitate and coordinate research efforts on Alzheimer treatment and prevention and to improve diagnosis and coordination of care, particularly in minority populations.

Although five medications representing two classes of drugs were approved by the US FDA for the treatment of Alzheimer's disease since 1994, there have been no approved agents since 2003. However, several randomized trials have provided additional information about the efficacy of these FDA-approved medications in subgroups of patients with AD. The development of these agents preceded the most current approaches to diagnosis including imaging confirmation of cerebral amyloid, which might yield a somewhat different patient population in trials. This specificity of diagnosis may or may not change the efficacy of the current agents. Currently there are approximately 330 trials registered in the US and recruiting subjects for the treatment of AD and there are over a thousand that have been registered and completed.

This chapter will review the pharmacology underlying the currently approved treatments, and the data supporting efficacy. Several approaches have also been well studied in rigorously conducted clinical trials, which have increased our knowledge about what primarily does not work. These include hormones, agents that modify cardiovascular and metabolic risk as well as a number of vitamins and nutritional approaches. We also review this evidence.

FDA-APPROVED TREATMENTS FOR ALZHEIMER'S DISEASE

CHOLINESTERASE INHIBITORS

Acetylcholine has long been known to effect memory. Reductions in the activities of acetylcholinesterase and choline acetyltransferase, enzymes involved in the synthesis and degradation of acetylcholine, were found in brain tissues from Alzheimer's disease patients (Davies and Maloney, 1976). According to the cholinergic hypothesis of Alzheimer's disease, the destruction of cholinergic neurons in the basal forebrain and the resulting deficit in central cholinergic transmission contribute substantially to the cognitive deficits and behavioral symptoms observed in patients suffering from AD (Bartus et al., 1982).

After its release into the synaptic cleft the acetylcholine is degraded rapidly by the hydrolytic activity of cholinesterases, the most prominent being acetyl-cholinesterase, although butyryl-cholinesterase can also hydrolyze acetylcholine in the human brain (Mesulam et al., 2002). Inhibition of cholinesterases leads to an increase of acetylcholine concentration in the synaptic cleft and is thought to enhance cholinergic transmission and ameliorate cholinergic deficit. In 1983 the first acetyl-cholinesterase inhibitor (AChEI) was approved (tacrine [Cognex]). It was not well tolerated, with four times per day dosing, reversible hepatocellular injury in up to 50% of patients (Watkins et al., 1994), and significant procholinergic side effects of nausea, vomiting, and diarrhea. The three other AChEIs donepezil, rivastigmine, and galantamine, were released between 1996 and 2001 and have very similar efficacy. They have slightly different mechanisms of action. For example, rivastigmine also inhibits butyrylcholinesterase, and galantamine is an allosteric modulator of the nicotinic receptor. In general, these medications tend to effect a 3–18 month improvement in cognitive functioning, followed by deterioration along a parallel path. Rivastigmine has received an additional indication for dementia caused by Parkinson's disease (Olin et al., 2010). Systematic reviews of all available randomized, double-blind, multicenter and placebo-controlled studies by the Cochrane Collaboration showed moderate benefits of cholinesterase inhibitors on cognitive, behavioral, and functional symptoms (e.g., Birks, 2006), and they are considered standard of care for patients with Alzheimer's disease by the American Academy of Neurology (Doody, 2005).

Originally, AChEIs were approved for the treatment of patients with mild-to-moderate disease. However, since 2007 the indications have been expanded to severe dementia. There have been numerous studies supporting the efficacy of donepezil (Cummings et al., 2010), rivastigmine (Farlow et al., 2011), galantamine (Burns et al., 2009), with significant cognitive effects for all medications in severe AD. Continuing treatment into moderate and severe AD also has been shown to improve cognition and function over placebo, in a one year trial of patients with moderate to severe AD who were randomized to either continue or stop donepezil and add either placebo or active memantine. Combined treatment did not suggest an additional benefit (Howard et al., 2012). A similar positive finding was seen in trials of galantamine withdrawal (Gaudig et al., 2011). Of note, a trial examining the use of donepezil for agitation in AD did not show a significant placebo medication difference, although interestingly about 20% in both groups had a greater than 30% reduction in agitation scores (Howard et al., 2007).

Some of the cholinesterase inhibitors have been tried in higher doses (Farlow et al., 2010; Grossberg et al., 2011), with donepezil receiving FDA approval for a 23-mg formulation of Aricept in moderate to severe AD. Although there were data showing mild benefit in cognition there was no statistically significant difference in global functioning, a requirement for FDA approval, and significantly more procholinergic side effects such as nausea and vomiting, suggesting that the risk benefit ratio does not support the use of this higher dose. Other studies have suggested that the side effects are most pronounced in the first few weeks of treatment (Tariot et al., 2012), but given the lack of improvement in global functioning there is debate as to the true benefit of this dose.

Another significant question is the utility and efficacy of AChEIs in mild cognitive impairment (MCI). To date, trials of cholinesterase inhibitors in MCI have not shown a significant effect on progression to AD (Petersen et al., 2005; Winblad et al., 2008), but some studies have suggested that they may delay the conversion (Petersen et al., 2005) or possibly have a differential effect on subgroups based on genetics or gender (Ferris et al., 2009).

Recently, a placebo-controlled trial of a Chinese herb, Huperzine A, which is a cholinesterase inhibitor, was conducted in 210 individuals with mild-to-moderate AD. Huperzine A did not meet the primary efficacy endpoints of cognition, functional, or global change (Raffi et al., 2011).

There are numerous areas for further study concerning the cholinesterase inhibitors that will be facilitated by greater understanding of biomarkers in this disease as well as the newly available amyloid imaging. One is whether early or even presymptomatic treatment affects the course of disease, amyloid deposition, and/or later functional changes. As the prodromal stages of AD are better defined, this will open up many avenues of inquiry concerning the AChEIs as well as various other treatment strategies.

MEMANTINE

Glutamate is the main excitatory neurotransmitter in the central nervous system and a physiological level of glutamate-receptor activity is essential for normal brain function. Glutamate excitotoxicity, mediated through excessive activation of *N*-methyl-D-aspartate (NMDA) receptors is believed to play a role in the neuronal cell death observed in Alzheimer's disease and other neurodegenerative diseases by causing increases in intracellular calcium which then triggers downstream events that cause cell death (Hynd et al., 2004). Thus, NMDA-receptor antagonists may have a therapeutic potential for neuronal protection from glutamate-mediated neurotoxicity.

Memantine is a low-to-moderate affinity, voltage-dependent, noncompetitive NMDA receptor antagonist with rapid gating kinetics (Danysz et al., 2000). Its fast on/off kinetics and low-to-moderate affinity are key to memantine's action because it ameliorates the effects of excessive glutamate while preserving the physiologic activation of NMDA-receptors required for learning and memory. Like other NMDA-receptor antagonists, memantine at high concentrations can inhibit mechanisms of synaptic plasticity that are believed to underlie learning and memory, but studies have shown that at lower, clinically relevant concentrations memantine actually promotes synaptic plasticity and preserves or enhances memory in animal models of Alzheimer's disease (Johnson and Kotermanski, 2006).

Memantine was approved in the United States for treatment of moderate to severe AD in 2003, and the FDA rejected a request to extend its approval to mild AD in 2005. Systematic reviews of all available randomized, double-blind, multicenter and placebo-controlled studies by the Cochrane Collaboration showed that memantine treatment resulted in significant benefits in cognitive, functional, and behavioral assessments in the treatment group compared with placebo in patients with moderate to severe Alzheimer's disease (McShane et al., 2006). It is usually well tolerated; adverse effects included confusion, insomnia, and headache that occurred in a small percentage of the study participants (Tariot et al., 2004).

Memantine does not affect the inhibition of acetylcholinesterase by cholinesterase inhibitors. It is well tolerated with cholinesterase inhibitors, (Choi et al., 2011; Tariot et al., 2004). In some studies, memantine was shown to enhance AChEI therapy (Atri et al., 2008; Tariot et al., 2004), whereas others have not seen an effect (Choi et al., 2011; Howard et al., 2012).

The question of whether memantine affects the rate of decline in mild AD is being addressed in a current trial (<http://clinicaltrials.gov> ID: NCT00235716). This study examines the effect of vitamin E 2,000 IU, versus vitamin E plus memantine, versus memantine, versus placebo in a group of approximately 600 individuals with mild-to-moderate AD over the course of up to four years to see if the rate of decline is modified. Data collection began in August 2007, and was expected to be completed in the fall of 2012.

OTHER TREATMENT STRATEGIES

Based on epidemiologic studies and basic science research, a number of FDA-approved drugs, as well as vitamins, supplements, medical foods, and herbal medications have been considered in the treatment of AD.

ANTIINFLAMMATORY DRUGS

A number of lines of evidence supported the hypothesis that neuronal damage caused by increased immune system activity is a mechanism of AD pathogenesis. Increased concentrations of cytokines, acute phase reactants, and complement protein have been found on autopsy in the brains of Alzheimer patients compared with aged matched controls (e.g., Bauer et al., 1992; Fillit et al., 1991). Senile plaques are often surrounded by activated astrocytes and microglia cells and can also induce activation of the complement cascade (McGeer and McGeer, 2001). Epidemiologic studies looking at the risk for AD have suggested that use of nonsteroidal antiinflammatory or corticosteroids lessened the risk of developing Alzheimer's disease (e.g., Hayden et al., 2007; McGeer and McGeer, 2007).

Cyclooxygenase (COX) enzymes mediate the conversion of arachidonic acid to prostaglandins, which are crucial components of the proinflammatory process. The main target of nonsteroidal antiinflammatory drugs (NSAIDs) is COX enzymes. The inducible COX isoform, COX2, is upregulated in the brains of patients with AD (Yasojima et al., 1999), suggesting that NSAIDs might be beneficial in AD by reducing neurotoxic inflammation. A subset of NSAIDs have been found to lower A β levels independently of COX enzyme activity, apparently by directly modulating γ -secretase activity, which enzymatically cleaves A β from its larger precursor protein (Weggen et al., 2001). Flurizan (tarenfluril) was shown to be effective in modulating γ -secretase activity and ultimately in selective A β 42 lowering in animal models. In a phase II study the agent had no effect on a group of cognitive outcomes in mild-to-moderate AD, but a post hoc analysis showed some benefit at the highest dose for those with the mildest disease (Wilcock et al., 2008). This finding led to an 18-month phase III trial, which was also negative (Green et al., 2009). This is particularly interesting in light of the fate of semagacestat (LY450139), a gamma secretase inhibitor, which was shown to worsen patient outcomes more than placebo in two phase III trials (NCT00762411 and NCT00594568) (Lilly, 2010).

There have been a number of clinical trials that have examined a variety of antiinflammatory agents ranging from NSAIDs to prednisone, which have unfortunately shown no benefit as a treatment for AD (discussed in Aisen, 2008). Primary and secondary prevention trials with NSAIDs have also been negative (e.g., Lyketsos et al., 2007; Thal et al., 2005). In addition, the dropouts from many of these trials have been high, owing to significant side effects of NSAID use such as renal insufficiency and gastrointestinal intolerance or, more seriously, gastrointestinal bleeding. A trial of 2,538 elderly patients without AD called the Alzheimer's Disease

Anti-inflammatory Prevention Trial, has led to a number of publications suggesting a possible deleterious cognitive effect with both naproxen and celecoxib (Lyketsos et al., 2007). Although the trial was halted early, observation was continued for two subsequent years, and models have been reported to explain the findings based on disease stage and rapidity of decline. All of these analyses are post hoc and many characterize subjects in idiosyncratic ways, leaving doubt to their value (Breitner et al., 2011; Leoutsakos et al., 2012).

ANTIOXIDANTS

Oxidative stress and free radicals have been implicated in cell damage and aging in general, and in neurodegenerative diseases in particular, including MCI and AD (Lovell and Markesbery, 2007). Vitamin C and E have been found to protect from oxidative DNA damage (Huang et al., 2000) and vitamin E protects nerve cells from amyloid- β peptide toxicity (Behl et al., 1992).

Several population-based prospective observational studies that have used questionnaires to monitor the intake of vitamins C and E on the risk of developing dementia revealed mixed results (Boothby and Doering, 2005). A placebo-controlled, clinical trial of vitamin E and selegiline in patients with moderately advanced Alzheimer's disease was conducted by the Alzheimer's Disease Cooperative Study (Sano et al., 1997). Subjects in the vitamin E group were treated with 2,000 IU of vitamin E. The results indicated that vitamin E may slow functional deterioration. A more recent study looking at markers of oxidation in the CSF of patients with AD treated with vitamins E and C, and alpha-lipoic acid (ALA); or coenzyme Q3; or placebo (Galasko et al., 2012) showed no effect on CSF A β or tau and although the vitamin E/C/ALA group had lower CSF oxidative markers, they also showed worse mini mental scores over the four months. Other clinical trials with vitamin E were conducted in patients with MCI (2002; Petersen et al., 2005) that failed to demonstrate a significant difference in the rate of progression to Alzheimer's disease between the vitamin E and placebo group.

Unfortunately there are safety concerns with the use of vitamin E. A clinical trial of long-term vitamin E supplementation studying the effects on cardiovascular events and cancer showed no effect on cancer or major cardiovascular events but an increase in the risk of heart failure (Lonn et al., 2005). A metaanalysis of randomized controlled trials examined the potential dose-response relationship between vitamin E supplementation and total mortality showed dose-dependent and significantly increased all-cause mortality with the use of vitamin E (Miller et al., 2005). Recent recommendations are therefore not to advocate the use of vitamin E in individuals at risk or affected by Alzheimer's disease (Ames and Ritchie, 2007).

Interest remains in clarifying the risk/protective effects of vitamin E and two important ongoing studies will be informative. There is a current trial mentioned previously (<http://clinicaltrials.gov> ID: NCT00235716) looking at the effect of either vitamin E 2,000 IU versus memantine vs. a combination or placebo, in approximately 600 individuals for up to

four years, to see if the rate of decline is affected. Another trial is an “add-on” (called PREADVISE [<http://clinicaltrials.gov> ID: NCT00040378]) to a trial evaluating the use of vitamin E and/or selenium, to prevent prostate cancer (the SELECT trial with 35,533 participants). This trial was halted in 2008 because there was a nonsignificant increased risk of prostate cancer in the vitamin E group, and a nonsignificant increased risk of type 2 diabetes in the selenium only group (Lippman et al., 2009). The PREADVISE study continues to follow more than 5,000 individuals who had been taking vitamin E 400 IU alone or in combination with 200 mcg of selenium, or placebo, and will evaluate their effect on developing risk.

B VITAMINS/LOWERING HOMOCYSTEINE

Elevated plasma homocysteine levels are a risk factor for cardiovascular disease and stroke (e.g., Bostom et al., 1999; Stampfer et al., 1992) and may be related to an increased risk of Alzheimer’s disease (Seshadri et al., 2002). Deficiencies of folic acid and vitamin B12 and B6 intake increase homocysteine plasma levels. Folic acid and vitamin B12 are needed for the conversion of homocysteine to methionine, and vitamin B6 is needed for the conversion of homocysteine to cysteine. High dietary intake of folic acid and vitamin B12 and B6 decreased homocysteine levels in adults (2005). Theories about how homocysteine might act as a risk factor for AD range from potentiating Abeta production (Zhang et al., 2009) or toxicity to vascular-related effects.

A recent longitudinal cohort study reported higher folate intake decreased the risk of incident Alzheimer’s disease independent of levels of vitamin B6 and B12 (Luchsinger et al., 2007). However, metaanalyses of clinical trials addressing the influence of folic acid, vitamin B6, and vitamin B12 intake failed to show any beneficial effect on cognitive function (e.g., Malouf and Grimley Evans, 2008). Furthermore, two clinical trials on folic acid and vitamins B6 and B12 failed to show any reduction of the risk of major cardiovascular events and stroke (Bonna et al., 2006; Lonn et al., 2006). To see if lowering homocysteine in patients with AD would change the course of the illness, an 18-month prospective trial in 400 mild-to-moderate AD patients was done. The intervention (folate and vitamins B6 and B12) was quite successful at lowering homocysteine, but it did not slow cognitive decline, with no difference between the active and placebo groups on the rate of change of a cognitive measure (ADAS-cog) (Aisen et al., 2008). This was confirmed in a recent two-year trial looking at both vascular dementia and AD (Kwok et al., 2011).

Prevention trials have also been generally negative. One study of supplementation over a three-year period in nondemented older individuals selected on the basis of relatively high homocysteine levels indicated a favorable influence on cognitive function (Durga et al., 2007), whereas a two-year study in older individuals not selected on the basis of homocysteine levels did not (McMahon et al., 2006). Another trial of two years of vitamin supplementation in hypertensive men confirmed that lowering homocysteine did not significantly

alter the risk of cognitive decline, either in the whole sample, or when individuals with baseline high homocysteine were analyzed separately. Of the 299 patients assessed at baseline, 73 were followed a mean of 7.7 years for long-term follow-up, and again no significant differences were seen, although a trend toward less cognitive impairment was seen in the treatment arm (Ford et al., 2010).

Overall there is no convincing evidence that supplementation of B vitamins significantly changes either risk of AD or subsequent decline in AD, although it remains possible that lowering homocysteine in individuals with high levels at baseline might decrease risk.

OMEGA-3 FATTY ACIDS

Several epidemiologic studies showed a protective effect of increased fish consumption and omega-3 fatty acid intake for the development of Alzheimer’s disease (Barberger-Gateau et al., 2002; Morris et al., 2003). Docosahexanoic acid (DHA) is an omega-3 polyunsaturated fatty acid found in some marine algae as well as fish. These fatty acids are a component of synaptic plasma membranes. Animal research suggests a number of roles in the brain including neuroprotection, affecting the rate of signal transduction, and regulating gene expression.

A Cochrane metaanalysis of all available biological, epidemiological, and observational data suggested a protective effect of omega-3 fatty acids (Lim et al., 2006), but the author concluded that until there was significant randomized prospective data, no conclusions could be drawn. Since then clinical trials have been published examining both AD treatment, as well as dementia prevention.

One placebo-controlled treatment trial demonstrated that in 204 patients treated over a year, no effect was seen in patients with mild-to-moderate stage disease, but in a subset with very mild AD (MMSE >27), omega-3 fatty acids slowed cognitive decline, as evaluated by MMSE (Freund-Levi et al., 2006). An 18-month trial followed 402 patients with mild-to-moderate AD who had low dietary intake of DHA at baseline who were given either DHA or placebo. The two outcome measures, a cognitive outcome (ADAS-Cog) and a global one (Clinical Dementia Rating Scale Sum of Boxes), as well as other behavioral outcome measures, did not differ between the placebo and active group, and in a subset of 102 patients who underwent volumetric MRI there was no difference in the rate of brain atrophy (Quinn et al., 2010).

Other trials have looked at DHA for primary and secondary prevention. A trial looking at high- and low-dose DHA and eicosapentaenoic acid (EPA) in 302 cognitively healthy older adults (MMSE >21), showed no cognitive benefit over the 26 weeks of the trial (van de Rest et al., 2008). A six-month trial of DHA versus placebo in 485 elderly patients with a memory complaint using a visuospatial episodic memory test as the primary outcome measure demonstrated significantly fewer errors in the treatment group, as compared with their baseline scores (Yurko-Mauro et al., 2010). However, a large trial of 1,748 individuals aged 45–80 at risk for cognitive decline because of a history of myocardial infarction, unstable angina,

or ischemic stroke, did not show any significant effects on cognitive function after four years of treatment with either B vitamins (folate, B6, and B12); omega-three fatty acids (EPA and DHA); B vitamins and omega-3 fatty acids; or placebo (Andreeva et al., 2011).

Overall, the majority of data suggests that omega-3 fatty acids do not significantly alter the course of AD. The possibility remains that it may have an effect in individuals with only memory complaints. Given the short duration (six months) of that one positive trial, it is impossible to say anything about secondary prevention, although clearly in cardiovascular at-risk groups there was no benefit over four years.

GINKGO

Extracts of the leaves of the maidenhair tree, ginkgo biloba, have long been used in China, but also in several European countries as a traditional medicine for various disorders of health. A one-year randomized placebo-controlled treatment trial of 309 AD patients demonstrated a modest improvement on some measures (Le Bars et al., 1997), although two later six-month trials of 214 (van Dongen et al., 2000) and 513 (Schneider et al., 2005) patients, showed no benefit. Two recent metaanalyses of ginkgo for the treatment of AD suggested that overall there was a modest treatment effect, but again the trials were very heterogeneous concerning duration and patients included in the trials, as well as outcomes (Janssen et al., 2010; Weinmann et al., 2010). A Cochrane review in 2009 called the research on ginkgo is at best “inconsistent and unconvincing” (Birks and Grimley Evans, 2009).

In terms of prevention, the best trial to date was a placebo-controlled trial of ginkgo. Evaluations were done at six-month intervals for incident dementia. In this trial, 3,069 elderly individuals, approximately 16% of whom met criteria for MCI at the start of the trial, were followed for a median of six years. The rates of all-cause dementia, AD, as well as conversion to dementia from MCI were not statistically different in the two groups. In addition, there was no improvement on any secondary outcome, such as overall morbidity (DeKosky et al., 2008), nor did it have any effect on cognitive decline in any cognitive domain (Snitz et al., 2009).

The overall results are at best inconsistent (Schneider, 2008) and the British Association for Psychopharmacology concluded that ginkgo cannot be recommended for the prevention or treatment of AD (O'Brien and Burns, 2011).

CURCUMIN

Because curcumin has antiinflammatory and antioxidant properties, it has engendered interest in the AD community. In animal models it was found to decrease brain amyloid plaques (e.g., Frautschy et al., 2001)). A population-based cohort study found better cognition in elderly Asian subjects with high curcumin consumption (Ng et al., 2006). A small clinical trial in Hong Kong did not show any significant cognitive results (Baum et al., 2008). A trial has been completed in the United States and results were negative, but the preparation of curcumin was poorly absorbed with little to no curcumin found

in the bloodstream of participants (Ringman et al., 2008). Additional trials with other formulations are planned, such as a trial (<http://clinicaltrials.gov> ID: NCT01383161) that began recruitment in March 2012, looking at the effect of curcumin in 50–90 year olds with a cognitive complaint but no dementia over the course of 18 months.

RESVERATROL

Several observational studies have demonstrated that moderate consumption of wine is associated with a lower incidence of Alzheimer's disease. Wine is enriched in antioxidant compounds, with potential neuroprotective activities. Resveratrol, a polyphenol that occurs in abundance in grapes and red wine, is used by the plant to defend itself against fungal and other attacks. In the early 1990s the presence of resveratrol was detected in red wine wherein it is suspected to afford antioxidant and neuroprotective properties (Miller and Rice-Evans, 1995) and therefore to contribute to the beneficial effects of red wine consumption on neurodegeneration (Savaskan et al., 2003). In animal studies, resveratrol has a variety of antiaging effects, including extending the lifespan in *C. elegans* (Wood et al., 2004). In mice, it seemed to improve a variety of aging outcomes (bone health, cholesterol, coordination), but did not increase longevity (Pearson et al., 2008).

Resveratrol promotes intracellular degradation of Abeta via a mechanism that involves the proteasome (Marambaud et al., 2005), and it protected rats from Abeta-induced neurotoxicity (Huang et al., 2011). Resveratrol does not influence the Abeta-producing enzymes and therefore does not inhibit Abeta generation. In a transgenic Alzheimer model of Abeta amyloidosis, resveratrol significantly reduced amyloid plaque formation (Karuppagounder et al., 2009). A small clinical trial of low dose resveratrol in patients with Alzheimer's disease has shown encouraging results (Blass and Gibson, 2006), and another low-dose trial was recently completed (<http://clinicaltrials.gov> ID: NCT00678431). A large multicenter clinical trial of high dose resveratrol (ID: NCT01504854) began recruiting in May 2012.

MEDICAL FOODS

Medical foods for Alzheimer's disease have been marketed over the past decade. A medical food is defined as a specially formulated and processed product (as opposed to a naturally occurring food) required for the dietary management of the patient under medical supervision, which cannot be achieved by normal diet. This category of products does not undergo premarket review or approval by the FDA. Also individual medical food products do not have to be registered with FDA. However, ingredients used in medical foods must be approved or exempted food additives, and ingredients are “Generally Recognized as Safe” (GRAS). Axona (previously known as Ketasyn) is an example of a Medical Food marketed for AD. The product proposes to provide an alternative energy source for the production of glucose in the brain through a proprietary formulation of caprylic triglycerides that increases

plasma concentrations of ketone bodies. A clinical trial in mild-to-moderate AD demonstrated improvement in a cognitive test, though not in other outcomes (Henderson et al., 2009).

Another medical food, Souvenaid, which is not currently available in the United States, has been used in clinical trials for AD. The development of this product is based on the notion that coadministration of rate-limiting precursors for membrane phosphatide synthesis, such as the nucleotide uridine, omega-3 polyunsaturated fatty acids, and choline, can restore synapses, increase hippocampal dendritic spines, and surrogate markers of new synapses. In a “proof of concept,” placebo-controlled study of 212 drug naive subjects with AD, Souvenaid improved scores on a delayed memory score but not on other cognitive and functional measures (Scheltens et al., 2010). In a preliminary report of the The Souvenir II, a 24-week international study of 259 individuals with AD, Souvenaid significantly improved the memory domain of a neuropsychological test battery. No significant intervention effect was observed on other cognitive or functional outcomes (Scheltens et al., 2011). The S-Connect study, a 24-week randomized, controlled, double-blind study conducted in the United States in 527 subjects with AD who were on standard drug therapy reported no differences in any cognitive or functional outcome (Shah et al., 2011). Since it is likely that most individuals with AD will receive treatment with conventional medication, there is no indication that supplementation with medical foods has an additive benefit on clinical outcomes. Additionally, there are no trials of treatment in those who have failed other medications.

It is noteworthy that neither the mechanisms of intervention nor the efficacy of medical foods are well established, and are not supported. Despite this, the use of nutritional and dietary supplements in the United States is extensive. It is estimated that 65% of adults are self-described supplement users, according to a 2009 survey conducted by Ipsos-Public Affairs for the Council for Responsible Nutrition (Hlasney, 2009). Thus, patients and families are likely to be exploring these treatment options.

GONADAL HORMONAL TREATMENT OF DEMENTIA

Interest in a beneficial role on cognition and prevention of dementia for gonadal hormone, specifically estrogen and testosterone, has a long history with little to recommend these agents. As treatments for dementia there is little positive data to support a role for estrogen. A comprehensive metaanalysis of trials assessing forms of estrogen in the treatment of AD identified seven studies with over 350 women (Hogervorst et al., 2009). The cumulative summary of these results indicates worsening on clinical global measures, verbal memory, and finger tapping. Since that review several other trials have been described. A randomized trial using transdermal estrogen for up to three months in a small study of postmenopausal women with AD ($N = 43$) described improvements in visual and semantic memory (Wharton et al., 2011). Also a 12-month trial with low-dose estradiol with norethisterone in women

with AD ($N = 65$) yielded non-significant treatment differences on cognitive outcomes, although a beneficial treatment effect on mood was noted in those who did not possess the ApoE $\epsilon 4$ allele (Valen-Sendstad et al., 2010). In a small study of women with mild-to-moderate ($N = 27$) cognitive impairment, otherwise unspecified, Yamada et al. (2010) found improved cognition and function with six months of treatment with dehydroepiandrosterone, which increased plasma testosterone (Yamada et al., 2010).

In a randomized, double-blind, placebo-controlled design, women with surgically induced menopause ($N = 50$; mean [SD] age, 54.0 [2.9] years) received estradiol valerate in combination with testosterone undecanoate or placebo. The women were assessed with a self-report questionnaire regarding memory and neuropsychological tests for verbal and spatial episodic memory and incidental learning at baseline, at the time of crossover, and after completion of treatment. Results indicate testosterone had a negative effect on immediate but not delayed recall. Overall no treatment benefit was noted (Moller et al., 2010). Taken together, there is little consistent evidence that there is a benefit to estrogen or testosterone treatment in women with AD.

Several studies have examined testosterone in males with AD, though the trials have been small and brief. In one small study ($N = 16$) using testosterone in the form of hydroalcoholic gel (75 mg) applied topically for 25 weeks, there were no differences in cognition or behavior but a benefit was seen in the patient’s quality of life as reported by a caregiver. (Lu et al., 2006). In another small ($N = 32$) study of men with AD or MCI treated with intramuscular injections of 100 mg T enanthate for six weeks, improvements compared to placebo were seen in spatial memory and constructional tests (Cherrier et al., 2005).

A third small study ($N = 10$) of hypogonadal males (total testosterone <240 ng/dl or 7 nmol/l) with AD examined the effect of treatment with intramuscular testosterone, 200 mg every two weeks for up to a year compared with placebo. Benefits on global cognitive measures were seen on the ADAS cog and the Mini-Mental State Exam. Prostate-specific antigen levels were also elevated (Tan and Pu, 2003).

Although the focus of this chapter is treatments for dementia and Alzheimer’s disease, there have been several studies to assess the value of estrogen and testosterone in non-demented males to protect against cognitive decline or to enhance cognitive function. Several reviews are recommended (Wharton et al., 2011; Yamada et al., 2010); most report little evidence of a benefit in cognition or dementia prevention.

MODIFICATION OF CARDIOVASCULAR RISK FACTORS AS A TREATMENT OF DEMENTIA

Traditionally, AD has been thought to be a primary neurodegenerative disorder and not of vascular origin. However, many discussions of AD incidence and prevalence have included references to the vascular contributions to the symptoms of dementia (e.g., Barnes and Yaffe, 2011; Schrijvers et al., 2012).

Cardiovascular risk factors are highly prevalent in the elderly population and rarely exist in isolation. Diabetes mellitus, hypertension, hyperlipidemia, and coronary artery disease often coexist, and this constellation of cardiovascular risk factors has been found to increase the risk for cognitive decline, vascular dementia, and AD (Luchsinger and Mayeux, 2004). The risk of AD has been found to increase with the number of vascular risk factors present in an individual (Luchsinger et al., 2005). However, many randomized clinical trials have been conducted to capture this benefit but to date few have succeeded in demonstrating that treatments for hypertension, hyperlipidemia, or diabetes can modify cognitive decline, incident dementia, or the trajectory of AD. These approaches are summarized as follows.

CHOLESTEROL LOWERING

A 2009 Cochrane review of two randomized trials of cholesterol lowering agents in adults with cardiovascular risks, with primary outcomes for reducing cardiovascular events, described the absence of benefit on cognition and dementia prevention (McGuinness, Craig et al., 2009). In the most recent trial with pravastatin (PROPSER), there was no effect on cognition or incident dementia despite robust assessment (Trompet et al., 2010), despite the fact that cognitive tests showed a significant decline over time, confirming sensitivity to cognitive deterioration with age. The review concludes that despite biological feasibility, there is good evidence from RCTs that statins given in late life to individuals at risk of vascular disease have no effect in preventing AD or dementia.

Another series of studies examined the effect of statins on improving the cognitive deterioration of individuals with AD who did not have cardiovascular risk factors. A study using atorvastatin, which does not have CNS penetration (Feldman et al., 2010) as well as a study with simvastatin, which does (Sano et al., 2011), had similarly negative results. Both showed no benefit on any cognitive, functional, or clinical outcome, despite evidence of significant lipid lowering, although both studies demonstrated acceptable safety. The efficacy of statins for preventing cardiovascular events prevents the ethical conduct of studies to assess the effects of these agents on cognition among individuals with AD who do have cardiovascular risks. Although these agents have efficacy for reducing events that are associated with cognitive impairment, there is no evidence of direct clinical or cognitive benefit in AD.

ANTIHYPERTENSIVES

Hypertension is a well-known risk factor for cardiovascular disease and stroke, and thus for vascular dementia. Vascular contribution to AD has been proposed and neuropathological studies suggest that these are independent and additive (Launer et al., 2008). However, the treatment of hypertension is not so clearly associated with a reduction in risk of dementia or a benefit in cognition. Treatment trials usually use a combination of agents from several classes to achieve maximum control of hypertension, including diuretics, ACE inhibitors, angiotensin receptor blockers, and calcium channel blockers.

In a comprehensive review of antihypertensive treatment trials, four were identified that assessed incident dementia as an outcome (McGuinness, Todd et al., 2009). This metaanalysis found no treatment-related differences in incident dementia, despite a trend in that direction in three of the four trials. Three of the four also assessed cognitive change as an outcome, with only one trial, Hypertension in the Very Elderly Trial (HYVET-COG), showing a trend in the positive direction (Peters et al., 2008). A recent report, modeling the effect over longer intervals indicated persistence of the small benefit with treatment (Peters et al., 2010).

In a recent metaanalysis of more than 60,000 cases, vascular dementia was considered separately from all other dementias and the results detected a benefit of antihypertensive treatment on vascular dementia but not on other dementias (Chang-Quan et al., 2011). It is important to note that in these large-scale trials the dementia diagnosis is a clinical one and seldom includes technologies that assess the underlying pathology of amyloid, tau, or synaptic loss and dysfunction. Thus these trials might have yielded different results in subsets of individuals with specific AD pathology.

While the direct benefit of medications to lower cardiovascular risk on cognitive outcomes does not support its use to prevent or treat AD, evidence-based medicine indicates these agents should be used to treat cardiovascular disease. Yet there is evidence that patients with AD and related disorders are undertreated with these agents (Rattinger et al., 2012).

TREATMENTS FOR DIABETES MELLITUS

The association between cognitive impairment and dementia and diabetes has been supported by many epidemiological studies. In type II diabetes, cognitive impairment mainly affects learning and memory, mental speed, and flexibility (Allen et al., 2004). The association between diabetes mellitus and AD is particularly strong among carriers of the apolipoprotein $\epsilon 4$ (ApoE4) allele (Peila et al., 2002). Treatments for diabetes, including insulin, have been studied in large and small randomized clinical trials with mixed results. Two categories of studies are of note: one includes the treatment of individuals with diabetes with antidiabetic agents and assesses the impact on cognition and dementia. Sato et al. described a six-month, randomized trial in patients with AD and type II diabetes mellitus treated with 15–30 mg pioglitazone daily ($N = 21$) or not ($N = 21$) (Sato et al., 2011). While cognitive improvement over baseline was reported in the treated group but not the placebo group, no drug placebo comparison was conducted. A secondary analysis, comparing diabetic and non-diabetic patients with The ACCORD-MIND study examined the cognitive effect of intensive versus standard glucose lowering of individuals with type II diabetes, aged 49–79. No benefit on memory, attention, or executive function was observed (Launer et al., 2011). The authors indicate that intensive antidiabetic therapy is not recommended to reduce the adverse effects of diabetes on the brain.

The other category of studies assesses individuals with AD to determine if typical antidiabetic drugs can improve symptoms or modify disease course. Two phase 3 studies evaluated

the safety and efficacy of the peroxisome proliferator-activated receptor gamma agonist, rosiglitazone, in nondiabetic patients with AD. More than 2,000 subjects were enrolled, with one cohort receiving concomitant AD medications and the other not. There was no effect on cognition or other clinical measures and no interaction with ApoE ϵ 4 (Harrington et al., 2011). Studies with Piaglitazone, though smaller and fewer, show comparable results (Geldmacher et al., 2011). Small single site studies have indicated that insulin, administered by infusion or intranasally, may have some cognitive benefits. One study found a benefit with infused insulin in individuals with mild cognitive impairment who were ApoE ϵ 4 carriers (Watson et al., 2009). Another larger study ($N = 100$) of individuals with MCI found better scores on memory with a low dose (20/mg) of intranasal insulin but poorer performance at a higher dose (Craft et al., 2012). This result will be explored in a larger trial in AD which was recently funded.

CONCLUSIONS

Although there are few currently FDA-approved treatments for AD, the data on the cholinesterase inhibitors consistently show robust although modest effect on cognitive improvement across disease severity. Some data suggest that higher doses provide greater effect, though this is limited by side effects. Memantine has shown less robust effects and primarily in moderate to severely impaired populations, but not in more mild individuals. A large current trial is again looking at effects in milder disease stages.

Despite the very significant need, no novel treatments have been approved over the past nine years. Although future research is likely aiming at prevention strategies, the challenge of treating symptomatic AD will continue to persist, given increased longevity. Novel approaches that target hallmark pathology may or may not have an effect at the fully symptomatic stage. New approaches may include addressing synaptic dysfunction and cell death, which should be relevant at a wide range of disease severity.

Future development of therapeutics for AD will undoubtedly include treatments for symptomatic individuals who are considered to have prodromal AD, and later trials will probably turn to those with no symptoms but who have imaging biomarkers that may prove to be associated with AD development later in life.

Although risk reduction of competing conditions has been proposed as an effective approach for the treatment and prevention of AD (Barnes and Yaffe, 2011), population-based studies suggest that these risks may already be well managed (Schrijvers et al., 2012), mitigating (Langa et al., 2008) the expectation of further benefit. Thus only new therapeutics hold a hope for true improvement.

DISCLOSURES

Dr. Sano reports that she has been a paid advisor/consultant to Eli Lilly, Esai, Medivation, Medpace, Nutricia, Sanofi-Aventis,

and Takeda. Dr. Sano reports she has been an unpaid advisor to Merck.

Dr. Neugroschl has no conflicts of interest to disclose.

65 | DISEASE-MODIFYING THERAPIES FOR ALZHEIMER'S DISEASE

JOSHUA D. GRILL AND JEFFREY CUMMINGS

Alzheimer's disease (AD) is an age-related progressive neurodegenerative disorder. It is the most common cause of dementia, underlying 60–70% of all cases of late-onset cognitive decline. In the United States alone, more than 5 million persons are afflicted with AD and the prevalence is increasing. Whereas modern medicine has seen significant decline in deaths resulting from human immunodeficiency virus/acquired immunodeficiency syndrome, stroke, heart disease, and prostate and breast cancer, AD-related death has sharply risen. Alzheimer's disease is the sixth leading cause of death in the United States. The association of AD with age is marked; disease risk doubles for every five years of life beginning after age 60. With the recent explosion of the baby boomer generation into retirement age and the expected increases of the world's elderly population, an epidemic of AD is upon us. More than 30 million patients have dementia worldwide and the global prevalence of AD will double every 20 years (Ferri et al., 2005). The progressive course of AD eventually results in complete dependence and a high burden of care. The cost of this care is substantial, estimated at \$180 billion annually in the United States, with worldwide expectations of unsustainable increases in cost. Thus, finding interventions that can reduce the burden associated with AD represents one of the most important scientific challenges in medical research.

The previous chapters in this section have described the substantial increases in understanding AD over the last several decades. The clinical phenomenology of AD is now well characterized and understood to include the slow and unrelenting progression of dementia, as well as a decade-long period of silent and then prodromal disease that eventually leads to clinical dementia. These predementia phases are characterized by accumulation of pathological substrates in the brain and initial neurodegeneration and may represent the ideal time of treatment.

Significant discoveries related to the genetic, molecular, and cellular underpinnings of AD have also been described in the preceding text. These discoveries have led to the identification of a wide array of therapeutic targets. Despite this, few drugs have achieved regulatory approval. Moreover, none of the approved drugs impact the underlying course of AD, instead providing mild improvement related to AD symptoms.

This chapter describes the state of the science of the pursuit of therapies that are capable of slowing the course of disease and,

if started early enough, can impact the impending epidemic of AD. Specifically, the chapter:

- Defines disease modification and discuss its demonstration in the setting of AD clinical trials
- Presents the current state of trial design and outcome choices for studies of new potential disease-modifying agents
- Identifies the challenges to disease-modifying trials and how they may differ depending upon the clinical population enrolled
- Reviews findings from AD trials and how they contribute to the current understanding of potential disease modification and trial conduct
- Describes the current understanding of AD pathology and classes of drug candidates for disease-modification
- Presents the identified targets and candidate agents for potential disease-modifying therapies for AD

DEFINING DISEASE MODIFICATION

Many current clinical trials for AD address the pathophysiology of the disorder using pharmacologic targets affecting A β , tau-protein related mechanisms, mitochondrial function, neuroprotection, apoptosis, or neuroregenerative strategies (Salloway et al., 2008). These “disease-modifying” interventions aim to prevent, delay the onset, or slow the progression of the disease process. Neuroregenerative strategies or interventions that rescue dysfunctional but not moribund neurons could theoretically produce an improvement in function. These mechanism-based strategies are generally contrasted with symptomatic interventions that aim to compensate for deteriorating neural systems function but do not slow or ameliorate the underlying disease process. Neurotransmitter-related interventions, for example, are viewed as compensatory and not disease-modifying interventions.

No specific consensus definition of disease modification has evolved. Katz (2008) suggested that a strong definition of disease-modification is “a therapy that affects the underlying pathology and structure of the disease.” Cummings (2006) suggested that a disease-modifying agent is a pharmacological treatment that intervenes in the neurobiological processes that lead

to cell death and produces a corresponding clinical response. This definition is essentially identical to that of the European Medicines Agency (EMA) (Committee for Medicinal Products for Human Use, 2008) that states that “for regulatory purposes a disease-modifying effect will be considered when the pharmacologic treatment delays the underlying pathological or pathophysiological disease processes and when this is accompanied by an improvement of clinical signs and symptoms of the dementing condition.” The EMA goes on to suggest a two-step approach in which the first step depends on delaying the course of the progression of the disease based on clinical signs and symptoms and leading to the limited claim of delay of disability. If these results are supported by a convincing package of biological and/or neuroimaging data (e.g., slowing, delay in the progression of brain atrophy) a full claim of disease modification can be considered.

The distinction between disease-modifying and symptomatic compounds cannot be drawn sharply. Some agents have dual action—such as *ladostigil* with cholinesterase inhibition plus monoamine oxidase inhibition (Weinreb et al., 2011)—and agents such as cholinesterase inhibitors that are viewed as largely symptomatic may have modest disease-modifying effects (Sabbagh et al., 2008).

Disease modification from a clinical trialist or regulatory point of view may differ from that of a practicing physician or patient and caregiver. Patients and caregivers would likely see a therapy that slows clinical progression but does not produce improvement of symptoms as less than successful.

The terminology of disease modification is typically not used in regulatory language appearing in the package insert for a medication. Interferon beta-1a, for example, has clinical and biomarker support as a disease-modifying intervention for multiple sclerosis. Its label reads, “to slow the accumulation of physical disability and decrease the frequency of exacerbations.” Similarly, *etanercept* has clinical and biomarker evidence of disease modification for rheumatoid arthritis. Its label notes its utility for “inhibiting the progression of structural damage and improving physical function” (Cummings, 2009). Regulatory terminology for AD interventions with clinical and biomarker evidence of disease modification will likely have similar trial-specific labeling regarding reduction in loss of cognition and function with supporting evidence from a specified biomarker.

The FDA tends to avoid mechanism-related terminology. The language for the indication for the use of a cholinesterase inhibitor is “for the treatment of mild-to-moderate Alzheimer’s disease” and does not stipulate that this is symptomatic or disease-modifying therapy (Katz, 2008).

The development of therapies targeting the pathophysiology and biology of AD has led many companies to adopt trial outcomes that will support labeling related to disease modification. Two strategies have been discussed in this context. The randomized withdrawal design and the randomized start design can theoretically demonstrate delay of progression in the absence of a biomarker. However, the statistical and ethical issues involved in these designs (Bodick et al., 1997; Rascol et al., 2011) have led to rare use of this approach. These are discussed in more detail in the following.

For practical purposes of constructing clinical trials and demonstrating disease-modifying properties of an intervention,

a combination of a clinical trial demonstrating a drug–placebo difference in clinical outcomes and accompanied by a related drug–placebo difference in key biomarker outcomes is typically used. The terminology for the indication will likely reflect the clinical trial outcomes, such as reduction in loss of cognition and activities of daily living and corresponding improvement in a biomarker indicative of the biology of the disease such as atrophy on magnetic resonance imaging (MRI), amyloid burden on amyloid imaging, brain-metabolism on fluorodeoxyglucose positron emission tomography (FDG PET), or spinal fluid measures such as cerebrospinal fluid (CSF) A β 42, tau, or phospho-tau. There remains substantial uncertainty about exactly how a regulatory agency such as the FDA will view data from biomarkers included in clinical trials of disease-modifying compounds (Katz, 2004). Paradoxical effects have confounded clinical trial interpretation; the observation that patients in the AN 1792 trial (active vaccination comprised of A β 42) with a more robust antibody response had greater atrophy was unanticipated (Fox et al., 2005). Similarly in a trial of *divalproex* designed to show disease modification with a kinase inhibitor, there was greater MRI atrophy in the treatment than the placebo group (Fleisher et al., 2011). These observations complicate the planning for optimal use of biomarkers in trials.

DEMONSTRATING DISEASE MODIFICATION IN CLINICAL TRIALS

CLINICAL TRIAL DESIGNS

Two clinical trial designs have been suggested as adequate to indicate disease modification: These are the staggered start design and the randomized withdrawal design (Bodick et al., 1997). In the staggered start design, individuals are randomized to drug or placebo at study onset (Fig. 65.1A). After a defined interval, individuals in the placebo arm are switched to active treatment. If the switched group “catches up” with the original treatment group, then no disease modification has been demonstrated and a symptomatic benefit is concluded. On the other hand, if the delayed treatment group fails to “catch up” with the original treatment group, this suggests that the disease has been modified in the group first randomized to therapy (Fig. 65.1B). There are several uncertainties with this design. It is unclear how long of a therapeutic exposure might be required to establish therapeutic benefit, and likewise it is unclear how long of an observation period would be required to determine if the delayed start group has “caught up” with the original therapy group.

A novel interpretation of the delayed start design is the observation that in any recruitment period some patients begin early after the trial is initiated and some may begin as long as twelve months later (e.g., in a twelve-month recruitment period). Patients recruited later in the trial can be compared with patients recruited earlier in the trial. This allows a statistical “staggered start” analysis (Fig. 65.1C) (Hendrix S., personal communication).

The randomized withdrawal design is based on the fact that a group withdrawn from therapy will decline to the level of function expected of a placebo group if no disease modification

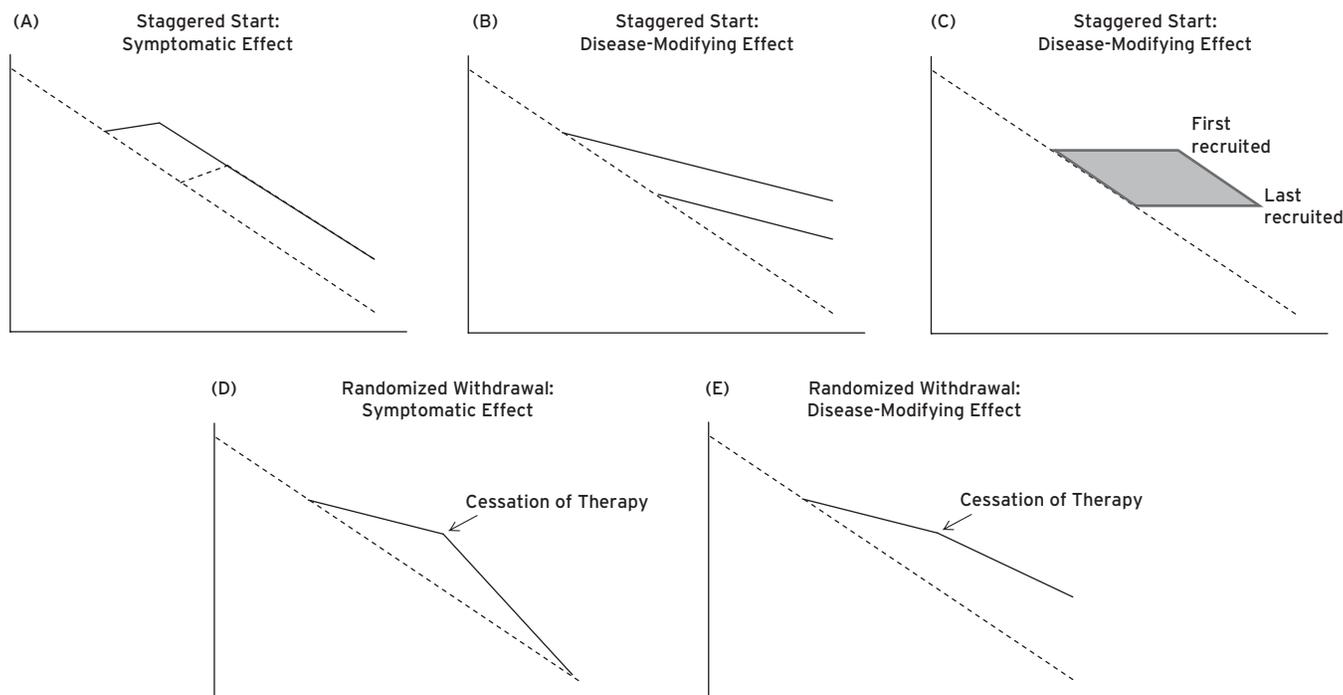

Figure 65.1 (A) Staggered start design with symptomatic effect shown. (B) Staggered start design with disease-modifying effect shown. (C) Natural history staggered start with observations collected over the course of the recruitment period. (D) Randomized withdrawal design with symptomatic effect shown. (E) Randomized withdrawal design with disease-modifying effect shown.

has occurred (Fig. 65.1D), whereas a withdrawal group that continues to remain above the expected level has experienced disease modification (Fig. 65.1E). The randomized withdrawal design is subject to the same uncertainties as the randomized start design. The duration of treatment and the duration of observation off treatment are both uncertain.

These designs have rarely been implemented in neurodegenerative disorders due to their complexities and uncertainties. When used in a Parkinson's disease trial, the results did not lead to a clear-cut conclusion, interpretation (Rascol et al., 2011), and/or new labeling.

Delay of disability is consistent with disease modification but can be achieved with symptomatic therapy (Mohs et al., 2001). Delay of milestones is not conclusive evidence of disease modification.

Use of biomarkers in conjunction with clinical outcomes is an alternative for establishing that an agent has changed the underlying biology of the disorder. Most biomarkers are inferential in that they represent imaging findings, electrophysiological observations, or peripheral indicators of a central process. The central process itself is undocumented. Although MRI correlates with nerve cell loss, nerve cell loss does not account for all the variance of MRI atrophy (Burton et al., 2012). This suggests that other as yet unidentified factors account for some aspects of MRI atrophy. Atrophy is also common across neurodegenerative disorders, is not specific to AD, does not identify a mechanism of action of an intervention, and does not indicate a specific change in pathology. Similarly, FDG PET is a measure of metabolism, a non-specific indicator of synaptic activity. A beneficial effect of an intervention on FDG PET compared with placebo would indicate improved

neuronal and synaptic function in the treatment group, but would not establish the mechanism for such improvement. Symptomatic agents may improve FDG PET activity in AD (Keller et al., 2011; Mega et al., 2005). Amyloid PET provides specific information on deposited fibrillar amyloid in the cortex, and its removal can be demonstrated by amyloid imaging in clinical trials (Rinne et al., 2010; Ostrowitzki et al., 2012). However, fibrillar amyloid may be a nontoxic species of A β and removal of fibrillar amyloid does not necessarily predict cognitive benefit (Holmes et al., 2008). Fibrillar A β is a proxy for the amyloidogenic process and possibly the presence of neurotoxic oligomers. It is not necessarily a direct measure of a neurotoxic species or the effect on neuronal and synaptic function. Serum and CSF measures such as A β 40 and A β 42 or CSF tau and phospho-tau are measures of cellular products and processes that have migrated from the interstitial space of the brain across the blood-brain or brain-CSF barrier and into the serum or CSF. Measures of these elements provide indirect reflections of the processes leading to cell death and dysfunction (Clark et al., 2003) but are not direct brain measures. Biomarkers are indirect and inferential measures of the basic processes leading to cell death and dementia.

To be supportive of a disease-modifying effect, the response of a biomarker (drug-placebo difference) should be correlated with the clinical outcomes. Biomarkers chosen as key outcomes should correlate with the primary clinical outcomes. For example, hippocampal atrophy may be a good choice to support a diagnosis of AD, but whole brain atrophy or ventricular enlargement may correlate better with trial outcomes such as Alzheimer's Disease Assessment Scale-Cognitive Subscale (ADAS-Cog) and Clinical Dementia Rating (CDR)

(Ridha et al., 2008). The correlation of a biomarker with a clinical outcome is necessary but not sufficient evidence to establish that the biomarker and clinical outcomes reflect a common mechanism. Most drugs have multiple effects, some known and some unknown. Biomarker and clinical effects could be mediated by different pathways or could even have opposite effects. Establishing the relationship between a biomarker and a clinical outcome will take experience across multiple clinical trials and multiple therapeutic mechanisms (Katz, 2004).

To incorporate a biomarker in a clinical trial and be included in the package insert labeling of a therapeutic agent, the biomarker must go through a qualification process with review by the FDA. Decisions about how the biomarker is best included in the trial and how biomarker data will be managed in data analysis plan (Cummings, 2011b; Wagner et al., 2007) must be prespecified.

The use of biomarkers as an outcome for treatment in prevention trials including patients who are without symptoms is under consideration (Aisen et al., 2011; Vellas et al., 2011). A surrogate marker would have predictive value for a drug–placebo difference on a clinical outcome. No biomarker has risen to surrogate status. Although biomarkers have been shown to correlate with clinical measures, none have been shown to predict clinical outcomes. An incremental evolutionary approach is most likely to succeed in developing surrogate measures over time. Showing that a biomarker change predicts a clinical outcome in a mildly affected patient population would be a step towards incorporating the biomarker in a trial of asymptomatic individuals. The biomarker might eventually replace the clinical outcome and serve as a surrogate. This is a multiyear, multitrial process.

Clinical trial outcomes used in conjunction with biomarkers in trials of disease-modifying agents might include a drug–placebo difference at trial conclusion, delay in milestones, increasing drug–placebo difference or time, and change in slope of decline (discussed in more detail in the following).

POPULATIONS CONSIDERED FOR DISEASE-MODIFYING TRIALS

AD is traditionally described as a disease with a progressive clinical course over 8–12 years, ultimately resulting in complete dependence and then death. Fulfillment of the National Institute on Neurological and Communicative Disorders and Stroke–Alzheimer’s Disease and Related Dementias Association (NINCDS-ADRDA) criteria for probable AD has been used as an inclusion criterion in most trials. The NINCDS-ADRDA criteria are purely clinical and incorporate the concept of dementia. A patient must demonstrate memory impairment and impairment to another domain of cognition, and these cognitive impairments must affect the patient’s ability to perform activities of daily living and not be better accounted for by another possible cause. The cognitive impairment must be progressive and present for at least six months.

The course of AD, however, spans 20 years and includes a period of biological onset that precedes dementia. Recent improvements to AD criteria incorporate biomarkers, increase

diagnostic accuracy, and facilitate earlier diagnosis—including before criteria for dementia are met. Differing nomenclatures and clinical and biological criteria for the phases of AD have been proposed. Disease-modifying trials can use these criteria as an initial means for defining the population to be studied and can enroll any sample of patients with AD, be they asymptomatic, mildly symptomatic, or demented. The group of patients to be included is decided based on trial goals.

TRIALS ENROLLING ASYMPTOMATIC PATIENTS AT GREATEST GENETIC RISK

Alzheimer’s disease can be predicted with certainty from conception in a fraction of cases. Autosomal dominant AD results from gene mutations to the *amyloid precursor protein (APP)*, *presenilin-1*, and *presenilin-2* genes. Within families that carry these mutations, there is a 50% heritability, 100% penetrance, and substantial consistency in the age of symptom onset. This creates an opportunity for trial designs that initiate therapy at an approximate time frame preceding clinical onset to examine drug potential to delay that onset. Two major international programs are currently underway with the objective of better characterizing this familial form of AD and conducting prevention trials (Bateman et al., 2011; Reiman et al., 2010). The Dominantly Inherited Alzheimer’s Network includes seven US sites, one UK site, and three Australian sites. The AD Prevention Initiative (API) is a collaboration between US and Colombian investigators that follows the largest known kindred of familial AD, a cohort of *presenilin-1* mutation carriers in Antioquia, Colombia. Asymptomatic offspring will be enrolled (non-randomly assigning non-carriers to placebo). Crenezumab, a monoclonal antibody targeting A β , is the candidate agent to be studied in this cohort.

A second component of the API proposes trials in those at greatest genetic risk for the sporadic form of AD: carriers of the $\epsilon 4$ allele of the *apolipoprotein E (APOE)* gene. *Apolipoprotein E* was the first identified and remains the strongest known genetic risk factor for sporadic AD. Three alleles have been identified: $\epsilon 2$, $\epsilon 3$, and $\epsilon 4$. The $\epsilon 3$ allele is most common among the general population. Hetero- and homozygotic carriers of $\epsilon 4$ are at significantly increased risk for sporadic AD. Current studies estimate up to a 12-fold increased risk associated with $\epsilon 4$ homozygosity (see <http://www.alzgene.org/>). Furthermore some $\epsilon 4$ carriers, by middle age, demonstrate AD-like abnormalities on functional MRI, FDG PET, and amyloid PET. Therefore, enrollment of $\epsilon 4$ carriers is an enrichment strategy.

Takeda and Zinfandel pharmaceuticals are conducting a prevention trial in which patients are selected on the basis of risk associated with *APOE* and *TOMM40* carrier status for specific age strata. Those at highest risk are assigned to pioglitazone or placebo and those at low risk are assigned to placebo.

For each genetic risk strategy, it is unknown what proportion of asymptomatic patients will meet biomarker criteria for trial entry (see the following) and at what time points. The overlap between genetics and biology is substantial, but imperfect. Combined biomarker and genetic inclusion criteria are feasible.

TRIALS ENROLLING ASYMPTOMATIC PATIENTS AT GREATEST BIOLOGICAL RISK

Disease-modifying trials can identify and enroll cognitively normal older persons who demonstrate AD biomarkers. At autopsy, approximately 20–40% of cognitively normal elderly (age 65 or older) meet criteria for neuropathological diagnosis of AD. Amyloid PET imaging reveals a similar proportion of *amyloid positive* older living individuals who, at the time of scanning, have no cognitive impairment. A growing literature supports the inclusion of such patients in disease-modifying trials, because they are at substantially increased risk to develop cognitive impairment and symptomatic AD. For example, in one study of 159 nondemented participants with follow-up periods ranging from one to five years, amyloid PET positivity at baseline was associated with a hazard ratio of 4.85 [95% CI: 1.2–19.0] for progression to AD dementia (Morris et al., 2009).

The first trial enrolling biomarker positive cognitively normal older participants is being planned. The *anti-amyloid* in asymptomatic AD (A4) trial will enroll amyloid PET positive volunteers age 70 or older and randomize to placebo or amyloid immunotherapy. These patients have been described as asymptomatic at risk (Dubois et al., 2010) or preclinical AD (Sperling et al., 2011). The length of the asymptomatic phase of AD is unknown, and one challenge for the A4 trial is to determine an optimal study length. Too short of a trial would not permit examination of prevention or delay of onset of cognitive impairment as an outcome. Alternatively, amyloid biomarker positive patients experience greater and more rapid change in other biomarkers, such as brain volume and metabolic rate, but such outcome measures are unlikely to satisfy FDA requirements for approval (see previous). Validation of biomarkers in demented populations may lead to a regulatory pathway for demonstration of disease modification in asymptomatic patients (Aisen et al., 2011). Another potential pitfall of preclinical AD trials is that they will require very large numbers of subjects and are likely to encounter high rates of screen failures for biomarker criteria for entry (Grill, Di et al., 2012a).

TRIALS ENROLLING SYMPTOMATIC PATIENTS

Most disease-modifying trials are conducted in impaired patients. DuBois and colleagues describe the earliest symptomatic phase of disease as “prodromal AD.” Prodromal AD patients demonstrate episodic memory impairment (adjusted for education) and AD biomarkers. Recent trials have applied these criteria for entry. Prodromal AD trials have used A β biomarkers (low CSF A β 42, high ratio of CSF tau/CSF A β 42, or amyloid PET).

The development of criteria for prodromal AD was in part the result of challenges previously met by trials enrolling patients with mild cognitive impairment (MCI). MCI is based only on clinical criteria for impairment of memory or other cognitive domains (generally 1 to 1.5 standard deviations below age- and education-adjusted norms). MCI trials that examined the rate of conversion to AD dementia as a primary outcome measure frequently met lower than expected rates of conversion, necessitating trial extension in some cases. No trial succeeded in demonstrating a therapeutic effect in MCI patients. MCI is a heterogeneous

disorder with several underlying pathologies and diverse clinical outcomes. Many observational studies have shown that MCI patients demonstrating AD biomarkers are at greatest risk for progression to AD dementia and proposed research criteria have incorporated biomarker support to the diagnosis of MCI caused by AD (Albert et al., 2011). The use of prodromal AD criteria obviates the need for the MCI construct.

The majority of AD trials have enrolled patient populations meeting criteria for dementia and mild-to-moderate AD. As discussed, the most commonly applied diagnostic criteria are those developed by the NINCDS-ADRDA. Criteria for mild-to-moderate severity are frequently defined using the Mini-Mental State Examination (MMSE), typically set at MMSE 14–26. Most AD patients will meet these criteria at the time of dementia diagnosis or shortly thereafter and for approximately the next three to five years. By the time of AD dementia diagnosis, most but not all AD patients will be readily identifiable on multiple AD biomarkers. Recent work suggests that some biomarkers such as amyloid PET may reach a plateau (peak level of abnormality) by the time of AD dementia diagnosis (Jack et al., 2010). Such findings suggest that this phase of AD biology may already be too advanced for targeted treatments to be successful. Alternatively, biomarkers such as hippocampal volume, cortical thickness, and FDG PET metabolism appear to decline linearly through the dementia phase of AD. Therapeutic strategies able to arrest this decline may therefore still be able to modify the natural history of disease, rescuing brain tissue or function. Since no trial for disease-modifying agents has succeeded in any AD populations, it is premature to conclude which population are most treatment responsive.

AD trials have been conducted in more impaired patients, including moderately demented (e.g., global CDR = 2) or severely demented patients (e.g., defined as minimum MMSE of 5–7 and maximum MMSE defined as 14–17). The capacity of severely demented patients to sign informed consent or complete cognitive outcome assessments is diminished. For many families, these trials represent a last attempt to find alternative therapy, often out of desperation. Successful disease modification that fails to provide clinical improvement in severely demented patients, however, presents a serious ethical dilemma; the likely outcome is prolongation of a significantly compromised state.

CHALLENGES RELATED TO TRIAL SAMPLES

Trial inclusion and exclusion criteria are designed to ensure a homogeneous sample and facilitate interpretation of trial results. Trials that enroll heterogeneous samples face significant challenges. Mild-to-moderate AD dementia trial populations are often wide-ranging in age, requiring various stratifications as part of randomization strategies (e.g., age, genotype, site, MMSE). These trials may also have enrolled heterogeneous populations in terms of disease biology. Most AD dementia trials have applied clinical criteria without biomarker requirements related to disease diagnosis. It is likely that a portion of trial participants do not suffer from AD, but instead some other underlying pathology, potentially affecting trial internal validity. The application of biomarker criteria,

even in dementia trials, may facilitate improved sample homogeneity. Even the application of biological criteria, however, is not a guarantee of sample homogeneity. For example, amyloid PET may label some Lewy body dementia patients (and may fail to label some AD patients). Furthermore, a large portion (20–40%) of AD patients suffer vascular comorbidity and a smaller portion (<5%) may suffer comorbid neurodegenerative disease. Only through combined clinical and biological criteria (including MRI exclusion of those with vascular pathology likely to contribute to cognitive impairment) can enrollment of an appropriate and homogeneous sample be achieved. Evolving biomarkers may allow further narrowing of populations to better match biological subtype and mechanism of action of the test compound.

CLINICAL OUTCOMES IN DISEASE-MODIFYING TRIALS

Dependent upon the trial design and the population enrolled, a large number of clinical outcome scenarios may be used to examine if a drug or other treatment is capable of altering the natural history of AD. As yet, there is no clear preferred outcome choice for disease-modifying AD trials. Broadly categorized, these trials either directly examine efficacy or test the ability of a drug to delay a milestone. For each choice, primary comparison is versus placebo. An active comparison is sometimes included as a means of assessing trial quality. A trial with donepezil that did not demonstrate a donepezil-placebo difference would be regarded skeptically.

DRUG-PLACEBO DIFFERENCE AT TRIAL END

The most straightforward outcome metric for assessing drug efficacy is to compare the group randomized to drug to the group randomized to placebo at trial end. This parallel design assumes successful randomization (otherwise the groups might not be equivalent at baseline, complicating analyses and interpretation). In most trials to date, mean group changes from baseline were compared, rather than cross-sectional comparisons at trial completion. The parallel group design has been used in most mild-to-moderate or moderate-to-severe AD dementia trials, including those that resulted in the regulatory approval of the cholinesterase inhibitors and memantine.

DELAY IN ONSET OF MILD COGNITIVE IMPAIRMENT

When enrolling asymptomatic patients, a delay-to-milestone approach can be used, incorporating the mean time to a diagnosis of MCI as the outcome or using a survival-type design. Both primary prevention trials (enrolling community based samples with no clinical or biological sign of disease) and secondary prevention trials (enrolling “asymptomatic at risk” or “preclinical AD”) could use the MCI construct as an outcome. If the mean time to MCI diagnosis is delayed or a significantly lower proportion of subjects randomly assigned to the active medication fulfills MCI criteria at a predetermined time point, the claim of

delay of disability would be supported. As with all predementia disease-modifying trials, there is currently little guidance on the choice of trial length. A resulting potential challenge is that insufficient numbers of subjects may develop cognitive impairment to provide adequate statistical power to examine a drug effect. Adaptive designs with variable lengths determined by prespecified outcomes are one solution to this problem. To support a claim of disease modification, the delay in MCI should be supported by delay in progression of biomarkers.

DELAY IN ONSET OF DEMENTIA

Trials enrolling MCI populations can examine a treatment’s ability to delay dementia onset. Several trials have employed this design, including trials of rofecoxib, rivastigmine, and donepezil and vitamin E (Jelic et al., 2006). These trials employed fulfillment of NINCDS-ADRDA criteria for possible or probable AD or fulfillment of NINCDS-ADRDA and DSM-IV-TR criteria for AD as primary outcomes. In most cases, assessment of progression to dementia was performed every three months. In the trial of donepezil and vitamin E, there was a suggestion after one year that fewer participants assigned to donepezil had progressed to dementia than in the placebo group (secondary outcome). By three years (the time point of the primary outcome assessment), however, there was no difference in the proportion of participants who had progressed to dementia between the groups. A primary outcome at one-year (or a one-year trial) might have concluded drug efficacy or inappropriately concluded a disease-modifying effect. No other MCI trial has observed even a trend toward disease modification. In the trials of rofecoxib and rivastigmine, fewer than expected participants progressed to dementia (in both the treatment and the placebo groups). The rofecoxib trial was halted prior to completion because of this low conversion rate and high drop out. The rivastigmine trial was subsequently extended to permit examination of the primary outcome. Symptomatic benefit will delay onset of dementia and by themselves the delay to dementia designs do not establish disease modification. These challenges encountered in the cholinesterase inhibitor dementia progression trials demonstrate the importance of trial planning and adequate data support for trial design decisions.

DELAY IN OTHER MILESTONES

Besides delay to diagnostic outcomes (onset of dementia or onset of MCI), AD trials have examined other milestones and the ability of a drug to delay the onset of those milestones. Two very large trials in MCI examined progression to a global CDR score greater than or equal to 1 (mild dementia, see the following) as a primary outcome. The rofecoxib MCI trial discussed earlier incorporated this endpoint as a secondary outcome. Other trials enrolling dementia populations, such as that examining vitamin E and selegiline, have incorporated a time to global CDR score 3 (severe dementia), loss of activities of daily living (ADLs), institutionalization, or death. An ADCS study of valproic acid enrolled moderate AD patients with no history of agitation or psychosis and investigated the drug’s ability to reduce (relative to placebo) the time to emergence of such symptoms.

Mohs and colleagues demonstrated in a one-year trial of moderate AD patients that donepezil delayed the time to functional decline, relative to placebo, as measured by the functional assessment and change scale. This trial, especially in combination with the results of the donepezil MCI trial, display the possibility for symptomatic benefit to imitate disease modification. Longer studies, at least 18-months, and combined clinical and biological support are necessary to support a claim of disease modification in AD.

SLOPE CHANGE

The progressive nature of AD presents an opportunity to examine drug effect on disease course. In contrast to endpoint comparisons, slope analyses examine drug effect throughout the course of study, in effect using the entire course of the trial as an outcome. Drug ability to slow the *rate* of cognitive decline over time serves as the primary outcome. The phase III trial of tarenflurbil included a prespecified slope analysis as a secondary outcome, with the aim of supporting a claim of disease modification, though the drug failed to demonstrate efficacy. Statistical slope analyses are complicated and challenging, due in large part to the nonlinear progression of disease and the influence of outliers (see the following). Placebo response and potential symptomatic effects, especially at trial initiation, can further complicate these analyses. Nevertheless, slope analyses may be sufficient for a disease-modifying label for the European Medicines Agency; the US Food and Drug Administration (FDA) has not, as yet, agreed that successful demonstration of altered disease slope of decline is sufficient for this claim.

CLINICAL OUTCOME MEASURES FOR DISEASE-MODIFYING TRIALS

The registration trials of the available symptomatic AD treatments provided a roadmap to drug approval that has subsequently been embraced by regulatory agencies, investigators, and sponsors. This has been particularly relevant in the choice of clinical outcome measures. To receive marketing approval from the FDA, a new AD drug must demonstrate efficacy on copriary outcomes, including one cognitive measure and one functional or global measure. The *standard* approach to trial designs and outcome choices may soon require amending, however. It remains unclear if this approach is optimal in disease-modifying trials that aim at new targets, test medications with unique mechanisms of action, that depend more on biomarkers, and that ultimately incorporate more challenging (and beneficial) objectives, including early symptomatic and presymptomatic intervention.

COGNITIVE OUTCOME MEASURES

Successful registration trials in mild-to-moderate populations have utilized the ADAS-cog. The ADAS-cog is a 70-point instrument that examines memory, orientation, comprehension of language and commands, naming, word finding, and ideational and constructional praxis. The ADAS-cog lacks linearity when used as a longitudinal or cross-sectional measure

of disease severity. In early or late dementia, the annual change in the ADAS-cog is minimal, relative to that observed in mild-to-moderate dementia. This issue is particularly critical in trials that move earlier in disease with the goal of intervention at a stage of minimal neuropathological burden. An 80-point version of the ADAS-cog that includes a delayed recall task (ADAS12) is available and multiple lines of evidence suggest increased sensitivity for the ADAS12 in MCI and prodromal AD populations, relative to the standard ADAS-cog. A 13-item version of the ADAS-cog includes executive measures.

Few trials in mild-to-moderate AD have implemented other cognitive outcomes. The neuropsychological test battery (NTB) was developed as alternative to the ADAS-cog, attempting to account for some of its weaknesses (the standard version of the ADAS-cog largely fails to examine attention, working memory, and executive function). Preliminary analyses of psychometric properties and longitudinal change in early AD suggested that the NTB may be more sensitive than the ADAS-cog to cognitive change in early AD. Administrative demands of the NTB are high. In moderate-to-severe dementia, only the severe impairment battery has been used in trials to successfully demonstrate cognitive efficacy.

GLOBAL AND FUNCTIONAL OUTCOMES

The most common choice of second copriary outcome measure for AD trials has been the ADCS-activities of daily living (ADCS-ADL) scale. Similar scales include the Disability Assessment for Dementia and Functional Assessment Questionnaire. The overriding principle behind each of these informant-based scales is impairment to basic and instrumental ADLs and a sensitivity to detect further impairment, slowing of that decline, or improvement with treatment.

Alternatively, some AD dementia trials have incorporated the CDR as a global outcome. This scale includes assessment of memory and function and may offer greater sensitivity in milder populations, including MCI and prodromal AD. The CDR can be examined as an outcome measure in two capacities. A global staging score can be calculated using a scoring algorithm that weights memory (relative to the other components: orientation, judgment and problem solving, community affairs, home and hobbies, and self-care). Alternatively, the six components or “boxes” can be treated equally and summed (sum of the boxes score, CDR-sob).

Another commonly used global scale is the Clinician Interview Based Impression of Change plus caregiver input (CIBIC+). This tool compares the outcomes at prespecified intervals to baseline global severity. The interview assesses cognition, function, and behavior. The CIBIC+ has generally been used in shorter trials (3 and 6 months) and the CDR-sob in longer-duration trials (12 and 18 months).

OUTCOME CHOICES IN FUTURE DISEASE-MODIFYING TRIALS

With the evolution of AD research and the realization of the need for trials earlier in the disease, use of single outcome measures to demonstrate drug efficacy has been proposed (Aisen

et al., 2011). The CDR-sob may represent a logical choice as a single outcome. The CDR includes memory, cognition, and function; it lacks behavioral measures included in other global assessments. In very mild AD, the CDR is internally valid, sensitive to change over time, and requires fewer trial participants than do cognitive outcome measures. In trials of the earliest AD patients, however, which will enroll asymptomatic at risk or preclinical populations, the CDR-sob may not achieve the necessary sensitivity. Ongoing discussions and research aim to identify and develop unique metrics to quantify the earliest cognitive impairments in AD. For example, the planned API prevention trial in autosomal dominant mutation carriers, the proposed ADCS A4 trial in asymptomatic preclinical participants, and the pioglitazone trial are likely to use newly developed composite measures of cognition.

SECONDARY OUTCOMES IN DISEASE-MODIFYING TRIALS

Alzheimer's disease trials include a large variety of secondary outcome measures. The neuropsychiatric inventory is the most commonly included metric of behavioral symptoms. Behavioral symptoms occur in 75% of AD patients and few safe treatment options adequately manage these symptoms. Importantly, even in the prodromal stages of AD, behavioral symptoms are common and behavior tends both to worsen in severity and change in type over the course of AD. Both earlier and later stage trials therefore generally include the neuropsychiatric inventory.

Global and functional measures such as the CDR, MMSE, and ADCS-ADL, if not used as coprimary outcomes in a given trial, are often included as secondary outcomes. Scales that will support the registration and use of a drug if it is approved also are commonly incorporated into disease-modifying trials. These include scales of quality of life (QoL). In particular, the QoL-AD has been developed for use in AD studies and is now commonly incorporated. Three variants of the QoL-AD exist: the patient's assessment of patient QoL, the caregiver assessment of patient QoL, and the caregiver assessment of caregiver QoL. A variety of other scales measure the burden of care: these include the Dependence Scale.

Increasingly, sponsors may need to anticipate data required by payers to inform decisions regarding adopting drugs, placing them on formularies, and reimbursing their costs. The Resource Utilization in Dementia scale examines caregiver time spent supervising and assisting the patient with ADLs. This and other pharmacoeconomic tools are needed to provide insight into the clinical meaningfulness of treatment effects.

COMPUTERIZED OUTCOMES

Computerized cognitive assessment batteries may bring additional sensitivity and convenience to outcomes assessment in disease-modifying trials. Sufficient data now exist to support use of computerized measures in elderly populations, including the development of age normative data. These batteries are associated with reduced variance and may afford smaller sample sizes, especially in early phase trials. Although computerized

testing affords standardized administration and response/reaction time measurements, the correlations between computerized tests and activities of daily living are less established (Wild et al., 2008). A major strength (and rationale for development) of computerized batteries is to increase sensitivity to very mild changes in cognition. In theory, batteries could use adaptive testing and item response theory to examine cognitive ability more efficiently, though none of the currently available systems uses such technology. Computerized cognitive testing systems include the NeuroTrax Mindstreams system, the Cambridge Neuropsychological Test Automated Battery, and the CogState.

PATIENT-REPORTED OUTCOMES

The FDA has recently provided guidance recommending the use of patient-reported outcomes (PRO) as supportive for the demonstration of drug efficacy. As is implied by their names, PROs require no interpretation from a clinician. The PRO in cognitive impairment (PROCOG) has been developed for possible use in disease-modifying trials. The PROCOG has been validated in MCI and AD and was designed to assess cognition, as well as behavior, function, and quality of life.

BIOMARKERS FOR CLINICAL TRIALS

Neuroimaging and fluid biomarkers are discussed in Chapters 62 and 63, respectively. The characteristics of biomarkers will not be reviewed here. Biomarkers can have multiple roles in clinical trials (Table 65.1). State or trait markers might be used for clinical trial enrollment. *APOE* $\epsilon 4$ is a trait marker of increased risk for AD. Patients with MCI who are $\epsilon 4$ carriers are more likely to progress to AD than those who are not $\epsilon 4$ carriers. *APOE* $\epsilon 4$ carrier status could be used to enrich a population of MCI patients likely to progress to AD (Elias-Sonnenschein et al., 2011). State biomarkers can be used for enrollment also. Asymptomatic individuals who have positive amyloid imaging for example, might be considered at risk for progression to symptomatic AD (Dubois et al., 2010; Sperling et al., 2011). Similarly, low CSF A $\beta 42$ or low A $\beta 42$ and high tau or phospho-tau could also be used as biological measures that would enrich an asymptomatic or MCI population likely to progress to AD dementia (Heister et al., 2011). Biomarkers could also be used to further enrich a population in ways that would match the proposed mechanism of action of an intervention. For example, patients with high serum isoprostane levels might be appropriate candidates for antioxidant interventions, or patients with high cytokine levels might be appropriate candidates for anti-inflammatory interventions (Cummings, 2011a).

Biomarkers can be used to demonstrate target engagement and proof of mechanism. Stable isotope labeled kinetics (SILK) (Bateman et al., 2006) can be used to show inhibition of amyloid production by secretase inhibitors (Bateman et al., 2009). SILK is valuable for demonstrating target engagement of agents that affect A β reduction or clearance. The long-term relationship and clinical outcomes related to these relatively brief physiologic measures has not yet been established.

TABLE 65.1. Potential roles of biomarkers in clinical trials (examples of biomarker applications)

Patient selection
Amyloid imaging
Hippocampal atrophy
CSF with low A β 42 or elevated tau/phospho-tau
APOE ϵ 4 allele
Target engagement
Stable isotope labeled kinetics (SILK)
Serum A β 40 or A β 42
Amyloid imaging
Efficacy
Whole brain atrophy or ventricular enlargement
FDG PET
CSF tau/phospho-tau
Amyloid imaging
Cytokines
Isoprostanes
Side-effect monitoring
MRI for effusions and microhemorrhages
Liver function tests and other safety measures

An important use of biomarkers is to support disease modification with proposed disease-modifying intervention. Reduced atrophy on MRI, reduced hypometabolism on FDG PET, and reduced CSF tau or phospho-tau compared with placebo groups in a placebo-controlled clinical trial would be evidence of disease modification. Isoprostane and cytokine measures might also reflect disease-modifying activity of therapeutic candidates. Neuronal injury biomarkers promise to be better measures of disease modification than amyloid biomarkers because amyloid measures such as CSF A β and amyloid imaging have had limited relationships to cognitive decline and dementia (Engler et al., 2006).

Biomarkers have an important role in detecting adverse events associated with antidementia therapies. Encephalitis associated with AN1792 was evident on MRI scans (Orgogozo et al., 2003) and MRI is used to follow amyloid related imaging abnormalities (ARIA), hemorrhagic type (ARIA-H) and ARIA effusion (ARIA-E), associated with immunotherapy and possibly with other amyloid related interventions (Salloway et al., 2009; Sperling et al., 2012).

A biomarker tightly linked to the mechanism of action of a drug might be approved in combination with the agent as a “theranostic” combination. For example, if an AD population with a specific genotype was identified as responding

to a specific intervention, the test for the genotype might be approved together with use of the intervention conditional on the presence of the associated biological abnormality.

CHALLENGES TO DISEASE-MODIFYING TRIALS

Disease-modifying trials for AD face many unique barriers to success. Throughout, this chapter has addressed the many challenges to disease-modifying trial design. This section outlines some of the specific challenges to successful disease-modifying trial conduct.

RECRUITMENT

Essentially all clinical trials struggle to meet their recruitment goals. For most trials, the actual exceeds the planned time to complete study enrollment. In other cases, slow enrollment of sufficient numbers of suitable trial candidates can require study amendment (to add sites or altered inclusion/exclusion criteria), render a trial underpowered, or stop a trial entirely. Some barriers to trial enrollment are ubiquitous. These include low trial awareness, low rates of primary care (and even specialty) referrals to trials, and patient skepticism of research.

Alzheimer’s disease trial enrollment has many specific barriers (Grill and Karlawish, 2010). AD is a disease of the elderly and older patients are less likely to qualify for trials. The average American over the age of 60 takes 6–12 prescription medications and, especially in early phase trials, such medications may be prohibited by protocols. Elderly patients also suffer a variety of comorbidities that may prevent trial participation. These include cancers, diabetes (especially if uncontrolled), hypertension (especially if uncontrolled), and other problems that impact cognition, mobility, or independence. In fact, based on data from the State of California’s Alzheimer’s Disease Diagnostic and Treatment Centers, Schneider and colleagues estimated that less than 10% of AD patients are eligible for AD trials (Schneider et al., 1997). Using data from the National Alzheimer’s Coordinating Center, Grill and colleagues found that approximately 25% of participants in that large natural history study met generalized disease-modifying trial criteria for eligibility (Grill, Monsell et al., 2012c). Of eligible patients, only a portion will be aware of and interested in trials.

Less is known about the barriers to participation in disease-modifying trials in earlier (predementia) disease. In MCI/prodromal trials, a major barrier to enrollment is that few patients have received a diagnosis. Community screens inevitably identify a large number of patients with cognitive impairment, but after identification, there are no guarantees that these patients will be eligible or interested in trial participation. For example, those identified as MCI in community screens would need to undergo testing for AD biomarkers because entry criteria for prodromal AD trials and patient attitudes toward these biomarker testing procedures may be a barrier to participation (Grill et al., 2012b). Little is known about the barriers to disease-modifying trials in asymptomatic at-risk/preclinical populations.

RETENTION

Retention of enrolled participants is as important as their initial recruitment. Ethical guidelines outline the voluntary nature of research participation and ensure participant rights to withdraw consent and cease participation at any time. Therefore, participant retention begins with the recruitment process; investigators should enroll only participants likely to complete the trial. Like slow enrollment, high dropout can render a trial underpowered to examine the primary scientific question. Alternatively, skewed dropout can lead to scientific error. For example, were a symptomatic drug to lead to increased dropout throughout the trial (and the trial analyzed using the last observation carried forward analysis), the results could be misinterpreted as representing a disease-modifying effect.

Alzheimer's disease dementia trials reported in the literature have demonstrated an approximately 75% retention rate (Grill and Karlawish, 2010). Mild cognitive impairment trials have had a lower mean rate of retention, with dropout ranging from 40% to 50%, rendering these trials far more challenging to interpret (Jelic et al., 2006). MCI trials of cholinesterase inhibitors have been hypothesized to suffer high dropout as a result of drug side effects, since dropout is higher in the group randomized to drug. Trial retention in early (preclinical) disease will be critical, as these trials are likely to require long durations. Though existing primary AD prevention trials have had good retention rates, most have employed benign interventions and infrequent visits (e.g., annual) and may not provide optimal guidance for preclinical AD studies. Preclinical trials studies are likely to employ riskier interventions that require more frequent assessment of safety.

Retrospective analyses have examined factors that predict trial dropout. In the ADCS MCI trial of donepezil and vitamin E, Edland and colleagues found that minority participants were more likely to drop out than non-Hispanic white participants and non-married participants were more likely to drop out than married participants (Edland et al., 2010). In a recent examination of six ADCS dementia trials, Grill, Raman et al. (2012d) observed dropout rates of 25% for patients with spouse partners, 32% for those with adult child partners, and 34% for those with other study partners. Edland and colleagues also observed a significantly higher rate of drop out at commercial trial sites, relative to academic sites. We recently observed a similar (though not statistically significant) difference between academic and non-academic sites in the rate of trial completers in a phase II mild-to-moderate dementia trial.

REPRESENTATIVE SAMPLES

Another major challenge in AD disease-modifying trials is increasing the representativeness of trial samples. Alzheimer's disease trials enroll predominantly highly educated non-Hispanic White participants who are joined in their participation by spouse caregivers. Faison and colleagues examined minority participation in a sample of trials conducted over a ten-year period and observed less than 10% participation in ADCS trials and less than 3% participation in

industry-sponsored trials. It is critical to increase the diversity of AD trial samples, especially because African Americans and Hispanics may be at increased risk for AD. Lower education has also been suggested as a risk factor for AD, though trial samples generally are of high education levels. Similarly, 67% of participants enrolled in a sample of ADCS trials did so with a spouse study partner (Grill, Raman et al., 2012d), despite the observation that in the U.S. most AD patients receive care from non-spouse family members.

GLOBALIZATION

Given the frequent struggles of AD trials to meet enrollment goals, there is an increasing need to conduct trials outside of the United States, where abundant samples of (especially treatment naïve) AD patients may exist. The majority of AD trials now include international (non-US) sites (Cummings et al., 2011). The conduct of clinical trials in a wide variety of global regions is associated with a variety of challenges. Life expectancy and access to health care vary substantially across global regions. Such variance is likely to manifest in differences in survival especially in the setting of longer trials, may affect the probability of adverse events, and may impact the representativeness of trial results. Mean levels of education also are considerably different among global regions that conduct AD trials. In addition to potential implications related to education-associated differences in AD progression, educational differences have substantial impact on the psychometric properties of cognitive outcome measures. Other challenges to interpreting global AD trials include potential differences in genetics among populations under study, including drug metabolism and AD risk genes; differences in attitudes toward AD diagnosis or biomarker procedures; and cultural differences in caregiving (and subsequent implications to trial outcome measures that rely on an informant). Finally, the availability of qualified investigators and nation-specific differences in trial regulations may hinder successful disease-modifying trials conducted globally.

TRIAL ETHICS

A number of ethical issues are raised in AD trials. Whether a patient suffering cognitive impairment is capable of providing truly informed consent and how to assess which patients are and which are not capable remains a challenging issue. Having capacity is not an all-or-none phenomenon. At one time, a patient may have capacity to make one decision (what they would like to eat for dinner) but lack the capacity to make another decision (whether to enroll in a high-risk trial). A variety of capacity scales exist and trials and the institutions in which they are conducted often standardize the metrics for assessing the patients' understanding of the trial.

For trials that may directly benefit the patients or advance the science of the field, proxies may provide surrogate consent for AD patients that lack it. The use of surrogate consent has substantial research support. Many studies have examined the attitudes toward surrogate consent of patients regarding their future selves, caregivers and families regarding patients, expert

investigators, and the general public. The wide consensus is in favor of the use of surrogate consent for the majority of AD trial scenarios and most current trials will enroll patients if there is a spouse, family member, or another person identified in an advanced directive that can provide informed consent on behalf of the patient. This varies only slightly from trial-to-trial; for example, the ongoing ADCS-conducted trial of nerve growth factor (NGF) gene transfer delivery to the basal forebrain will enroll only patients with capacity to provide informed consent. Greater variability exists on a state-by-state basis regarding who can provide informed consent in the patient's stead and trialists are referred to their local regulatory bodies to determine a decision tree for this issue. Informed consent practices vary among nations and must be carefully monitored in global trials.

With the successful development of the cholinesterase inhibitors, a brief debate over the ethics of placebo controlled AD trials occurred (Kawas et al., 1999). This debate subsided, in large part because of the recognition that the available medications were only symptomatic. Thus, withholding these medications for the sake of a trial is not seen to have long-term ramifications on patient health. Moreover, trials examining agents anticipated to possibly have disease-modifying properties will generally enroll patients on symptomatic AD drugs, provided that they are maintained on stable doses. It is unclear how this landscape may change in the scenario of approval of the first disease-modifying AD drugs. Further, as trials have become more global in their conduct, AD drug development may bring the ethical challenge of developing a drug where it may not be made readily available, if proven effective.

Despite the management of ethical matters in dementia trials, the initiation of prodromal and preclinical AD trials brings new challenges. As discussed, the testing of agents in predementia populations will be critical to disease understanding, testing the amyloid hypothesis, and effectively treating and defraying the cost of AD. Ethical challenges must not derail predementia AD trials. However, a variety of ethical issues remain understudied in the setting of predementia trials. For example, these trials will enroll MCI or asymptomatic patients at highest risk for AD. The language that should be used to describe the criteria for entry (preclinical AD, at risk for AD, and the like) is uncertain; few prospective studies of long-term outcomes related to biomarker positivity are available to guide study conduct, including informed consent; and how enrolled participants (or those deemed ineligible) will interpret risk information is unknown. The strongest guidance for delivering risk information has been provided by the Risk Evaluation and Education for AD study, which randomized cognitively normal participants with a family history of AD to learn their *APOE* genotype or not. In this study, learning *APOE* genotype did not cause depression or anxiety, but those who were informed they were $\epsilon 4$ carriers were more likely than those who learned they were non-carriers to begin taking vitamins and supplements. Grill, Raman et al. (2012b) have recently shown in a qualitative study that persons in a hypothetical situation of learning they are at increased risk for AD will approach the decision of whether to participate in AD prevention trials differently—more frequently citing a desire to lower their personal AD risk

and less frequently citing logistical barriers to participation. The ethical issues surrounding predementia trials are in need of future research to more adequately address each of these issues.

LESSONS LEARNED FROM TRIALS

There have been no successful phase III trials for any disease-modifying compound of any neurodegenerative disorder. All trials conducted to date have failed to show a compelling, consistent, and repeatable drug–placebo difference. In some cases, trial conduct is impugned and the efficacy of the drug in the clinical trial was inadequately tested. In others, appropriately conducted clinical trials failed to show a drug–placebo difference or there was an emergence of unacceptable side effects (Cummings, 2010). It is important to distinguish between failed trials and failed drugs because failed trials cannot provide evidence for or against a specific pathway or specific intervention. Hallmark features of failed trials include a failure of decline in the placebo group, failure to demonstrate a drug–placebo difference with the active comparator (typically donepezil), and excessive variability in measures (Table 65.2).

A well-conducted trial that fails to show a drug–placebo difference is valuable in demonstrating that the agent is not effective in this particular population, at this specific dose, used for this specific period of time. Trials answer very limited questions. Trials are focused experiments that can answer only limited questions and do not provide evidence of a possible effect in a different population, dose, or exposure duration.

A well-conducted trial that demonstrates excessive and unacceptable side effects also provides valuable information on whether to advance a molecule. The increased cognitive and functional decline and increased emergence of skin cancer associated with semagacestat—the gamma-secretase inhibitor—exemplifies a well-conducted trial in which adverse events were demonstrated suggesting that the agent should

TABLE 65.2. Approach to trials that fail to show a drug–placebo difference

Failed trials
No placebo decline or placebo improvement
No drug–placebo difference in an active comparator arm (e.g., donepezil)
High measurement variability or site-to-site inconsistency
Failed drugs
Lack of efficacy
<ul style="list-style-type: none"> • Did not cross the blood–brain barrier • Dose too low • Lack of effect on target
Unacceptable side effects

not be advanced, at least in patients with mild-to-moderate AD exposed at this dose (Cummings, 2010). More experience with gamma secretase inhibitors is needed before concluding whether these side effects are inevitably associated with gamma secretase inhibition or unique to semagacestat.

It is important to understand a compound as well as possible before advancing it to phase III pivotal trials. Phase III trials are large, long, and expensive. Agents not likely to succeed in phase III should not be advanced. Phase II trials large enough to show a drug–placebo difference are as large as phase III trials. Drug development programs often combine phases II and III (Cummings, 2008) in a II/III design, anticipating using the data for registration purposes. Alternatives to this approach include greater use of adaptive trial designs in phase II to adjust for duration, doses, and side effects, and greater use of biomarkers in phase II to insure patient selection, target engagement, and disease modification. Biomarkers may show disease modification in shorter times or with smaller populations than required for demonstration of clinical evidence of disease modification (Jack et al., 2003). Positive biomarker effects will de-risk a phase III program but do not guarantee its success since the predictive validity of biomarkers is currently unknown.

DISEASE-MODIFYING TREATMENTS OVERVIEW AND CLASSIFICATION

Many types of treatments are in development as disease-modifying therapies for AD and have advanced to the point of clinical testing (Table 65.3) (Grill and Cummings, 2010). They have various targets, potential mechanisms of action, and modes of administration. As is the case for any therapy targeting the CNS, candidate treatments must be able to penetrate the blood–brain barrier if on-target activity is to be achieved. Therefore, many drug candidates for AD are small molecules and are being developed as oral medications. The unique biology of AD, however, presents additional challenges, and many promising agents in clinical trials utilize alternate modes of administration. These include small peptides, such as davanetide (AL-108), a potentially neuroprotective agent that is administered intranasally. Similarly, a recent study of intranasal insulin administration suggested possible symptomatic efficacy in early AD (Craft et al., 2012). An active vaccination, AN-1792, was tested in phase I and phase II trials and served as a catalyst to development of a variety of immunotherapies, including some that are currently in development as intramuscular injections. Several candidate passive immunotherapies are in development and administered through intravenous infusion or subcutaneous injection. Finally, some treatments such as gene transfer and cell-based therapies are administered directly to the brain.

The broad range of modes of administration of these AD candidate therapies are paralleled by a variety of targets and mechanisms of action. Many small molecules aim to alter protein processing of one of the abnormally folded and accumulated proteins in the brains of AD patients. These include the two abnormally processed proteins responsible for the hallmark

TABLE 65.3. Classes and examples of emerging therapies for the treatment of Alzheimer’s disease

CLASS	MECHANISM	EFFECT OR AGENT	
Anti-amyloid therapies	Decrease APP expression	Posiphen	
	Increase A β metabolism	Neprilysin/IDE stimulators	
	BACE inhibition	MK-8931; LY-2811376	
	Gamma secretase inhibition	BMS708163	
	Gamma secretase modulation	EVP-0962	
	Alpha-secretase enhancement	M1 agonists	
	Aggregation inhibitors	AZD-103/ELND-005; PBT2	
	Monoclonal antibodies	Bapineuzumab; solanezumab; gantenerumab; crenezumab	
	Polyclonal antibodies	IVIg	
	Active vaccination	CAD-106; ACC-001	
Anti-tau therapies	BBB transport inhibitors (to brain)	RAGE inhibitors	
	BBB transport facilitators (to blood)	LRP enhancement	
	ApoE expression increase	Bexarotene	
	Aggregation inhibitors	Methylene blue	
	Kinase inhibitors	GSK-3 β inhibitors	
	Phosphatases	Protein phosphatase 2A (PP2A) enhancers	
	Microtubule stabilization	AL-108	
	Neuroprotective agents	Anti-inflammatory agents	NSAIDs
		Antioxidants	Resveratrol; curcumin; vitamin E
		PPAR gamma agonists	Pioglitazone; rosiglitazone
Trophic factors		NGF and BDNF-like molecules	
Regenerative approaches	Stem cell therapies	Cell replacement; generation of support cells	

APP, amyloid precursor protein; BBB, blood–brain barrier; BDNF, brain derived neurotrophic factor; LRP, lipoprotein receptor-related protein; NGF, nerve growth factor; NSAIDs, nonsteroidal antiinflammatory drugs

pathologies first identified by Alzheimer himself, the amyloid beta ($A\beta$) protein that accumulates in neuritic plaques within the cortical parenchyma, and tau, the microtubule-associated protein intrinsic to every neuron that becomes hyperphosphorylated and condensed in neurofibrillary tangles. Most small molecules target specific molecular components of the cascade of events that lead to the formation of these brain pathologies (candidates are described further in the following).

Alternatively, treatments may target the cellular processes associated with disease, be they downstream or independent of plaques and tangles. Such targets include the known inflammation associated with AD; cellular metabolism and production of reactive oxygen species that may accompany AD and normal aging; mitochondrial functioning or malfunctioning as part of neurodegenerative disease; apoptosis and apoptosis-associated genes and cell cycling molecules; and genes or proteins that may result in neuroprotection. Despite a plethora of possible molecular targets, these therapies can largely be distilled to a single goal: preventing neuron and synapse loss in the AD brain. Once such synapse loss has occurred, which is likely to have begun by the time of prodromal AD or before, regenerative strategies may be necessary if a return to baseline function is to be achieved. Replenishing tissue through stem cell treatment, cell transplants, or treatment with neurotrophic factors that increase endogenous neurogenesis may offer such promise, though successful neuroregeneration remains a distant goal.

Most agents have more than one mechanism of action. Off-target action may be responsible for side effects of some agents. Off-target effects may also lead to repurposing agents for non-AD indications.

DISEASE-MODIFYING TREATMENTS— CLASSES AND AGENTS

$A\beta$ PRODUCTION

Neuritic plaques are pathognomonic to AD, and the $A\beta$ protein that accumulates in the plaques is a primary target for disease-modifying AD drug development. Central to the amyloid hypothesis is the abnormal proteolytic processing of the amyloid precursor protein (APP). Initial cleavage of APP occurs by either α - or β -site enzymes. In either case, the produced C-terminal fragment is subsequently modified by gamma secretase within the transmembrane region. If the α -secretase product is cleaved by gamma secretase, the resulting protein fragment (p3) is believed to be non-toxic. In contrast, the product of sequential beta-site cleavage enzyme (BACE) and gamma secretase cleavages are a variety of $A\beta$ peptide species ranging in size from ~37–43 amino acids in length. $A\beta_{40}$ is the most abundant species and $A\beta_{42}$ is less abundant but very important from the disease standpoint. $A\beta_{42}$ is especially prone to aggregation and concentrated in the core of neuritic plaques. Recent evidence suggests that high molecular weight species of $A\beta$ aggregated together (e.g., consisting of 2 to 20 $A\beta$ molecules), collectively referred to as oligomers, may represent the most synapto- or neurotoxic forms of $A\beta$.

Several candidate drugs targeting $A\beta$ are now in clinical development. Many of these drugs directly target APP or

molecules involved in its proteolytic processing. Posiphen is a positive enantiomer of phenserine, the acetylcholinesterase inhibitor. Though it has no cholinergic activity, Posiphen reduces expression of APP and subsequently lowers $A\beta$ in culture and animal models. Clinical studies of Posiphen are ongoing.

Small molecules that inhibit or modulate the enzymes critical to the amyloidogenic pathway may reduce levels of $A\beta$ and therefore slow disease course. Because it represents the most upstream cleavage step, BACE (also known as β -secretase and memapsin-2) may represent an ideal target to halt production of all pathologic posttranslational APP products. The activity of BACE on APP, however, requires multisite binding and successful inhibition may require large molecules (>500Da) that cross the blood-brain barrier with difficulty. Small lipophilic agents able to access the CNS have been developed and clinical trial results are pending. Alternatively, basic science studies have linked BACE-neutralizing antibodies to transferrin receptor antibodies as a novel mechanism of transporting larger molecules including antibodies into the CNS (Yu et al., 2011).

Gamma secretase inhibitors have been more approachable for small molecule drug development; candidates have reached clinical testing. Gamma secretase is a four-part complex, consisting of the membrane proteins presenilin-1 or -2, nicastrin, Aph-1, and Pen-2. Presenilin serves as the catalytic subunit and is critical to APP proteolysis, but also to function of other transmembrane proteins including the Notch signaling receptor. As a result, presenilin knockouts are lethal and potent nonselective gamma secretase (and Notch) inhibitors lack tolerability sufficient for clinical use. Semagacestat, the non-selective gamma secretase inhibitor in development by Eli Lilly Pharmaceuticals had phase III studies halted because of unacceptable levels of skin cancer and other adverse events, including worsening cognition. Other gamma secretase-targeting drugs remain under clinical study. For these drugs to be successful, activity must sufficiently lower $A\beta$ to have clinical impact (though to what extent is unknown) without causing significant off-target side effects. Alternatively, recent basic studies have identified other targets related to gamma secretase that include a protein critical to this secretase activity (He et al., 2010).

An alternate mechanism by which $A\beta$ production may be lowered without directly preventing APP cleavage by gamma secretase is the modulation of gamma secretase activity, such that the postcleavage product is an alternate-length peptide fragment. The obvious benefit of drugs with such mechanisms of action is that they may have therapeutic effect without altering Notch activity. Several compounds with gamma secretase modulating activity have been identified, including some non-steroidal anti-inflammatory drugs (NSAIDs). R-flurbiprofen is a non-NSAID gamma secretase modulator that was demonstrated as being no different from placebo on any outcome measure in a large phase III mild-to-moderate clinical trial. Penetration of the CNS by the agent may have been insufficient. Several other gamma secretase-modulating compounds have been identified and may soon enter clinical development.

Another mechanism to reduce $A\beta$ levels in the CNS would be to enhance alternate processing of APP through

the non-amyloidogenic pathway by enhancing the activity of α -secretase. Few compounds have been identified that successfully activate α -secretase. Laboratory studies have suggested such activating effects for muscarinic ACh receptor agonists. M_1 and M_3 receptor agonism may regulate APP processing. In one small uncontrolled trial of 19 AD patients, mean decline in CSF A β was observed after treatment with an M_1 agonist (Nitsch et al., 2000).

AMYLOID BETA DEGRADATION

Endogenous A β degradation occurs through activity of neprilysin (also known as neutral endopeptidase), insulin-degrading enzyme (IDE), endothelin-converting enzyme, angiotensin-converting enzyme, metalloproteinase 9, and as many as 15 other recently identified proteinases. Neprilysin and IDE are thought to be the primary regulators of A β degradation and are reduced in AD. Studies in transgenic mouse models suggest that degrading enzyme activity is dose-dependently related to AD pathology and may be a suitable target for new treatments, but that targeting multiple degrading enzymes may be needed to ensure that treatment effect is not washed out by compensatory pathways. For example, APP transgenic mice that overexpress the neprilysin transgene demonstrate increased A β degradation but not behavioral improvement (Meilandt et al., 2009). Mice engineered to overexpress neprilysin and IDE, alternatively, have reduced A β levels, reduced astrogliosis, microgliosis, and dystrophic neurites, and improved spatial memory.

Targeting molecular regulators of A β degrading enzyme levels *in vivo* may be more readily accomplished. Saito and colleagues identified somatostatin receptors as a potential regulator of neprilysin activity (Saito et al., 2005), and Cabrol and colleagues recently completed a high-throughput screen in which they identified multiple small molecule activators of IDE (Cabrol et al., 2009).

ANTIAGGREGATION AND IMMUNOTHERAPIES

In the CNS, A β is prone to aggregation. Dimers, trimers, and other high-molecular-weight combinations of A β may provide a compelling treatment target, since transgenic animals with reduced plaque burden but high oligomer levels do not demonstrate behavioral improvement (Cheng et al., 2007). Small molecules may specifically inhibit oligomerization (Necula et al., 2007), fibrillization, or both, and it remains unclear which (if any) is optimal for slowing the course of AD.

The only antiaggregation agent tested in a large phase III trial—tramiprosate—failed to demonstrate efficacy, but a variety of other agents that aim specifically to prevent the oligomerization of A β are in development. Cyclohexanehexol (also known as AZD-103 and ELND-005) prevents oligomerization *in vitro*, improved behavioral performance in a mouse model of AD, and was tolerated in a human phase I trial. A metal protein attenuating compound, PBT2, is believed to prevent A β oligomerization by chelating copper and zinc, which have been proposed as critical to this process. The compound demonstrated initial efficacy in AD, lowering CSF levels of

A β and mitigating cognitive deterioration, relative to placebo (Lannfelt et al., 2008).

A β plaques may be deleterious to synaptic function and can be removed from the brain. Several types of immunotherapies have demonstrated an ability to reduce fibrillar amyloid burden, as measured by amyloid PET, and AD immunotherapies represent the most active area of disease-modifying trials.

Active vaccination with a synthetic full-length A β peptide (AN1792) in 300 mild AD patients initially suggested a clinical benefit in participants who received therapy and generated antibodies against A β but was halted because of a 6% incidence of T-cell mediated meningoencephalitis. Although analysis of the primary outcomes at the time of trial interruption demonstrated no drug–placebo difference, long-term follow up of survivors suggested a benefit in activities of daily living among antibody responders. Long-term follow-up to autopsy of the first subjects to die demonstrated that there was no impact on the rate of progression to severe dementia, but that responders demonstrated substantial and sometimes complete removal of plaque burden. Pathological examination has also suggested an impact on hyperphosphorylated tau and dystrophic neurites in the hippocampus of antibody responders (Serrano-Pozo et al., 2010). These findings have challenged the validity of A β plaques as a target in AD. A β vaccinations modified to remove T-cell activity, consisting primarily of peptide fragments, are in clinical development.

The initial active vaccination studies sparked initiation of robust passive immunotherapy development programs. Treatment with antibody therapy should avoid the T-cell mediated response that was believed to underlie meningoencephalitis in the AN1792 studies. Furthermore, since only a portion of patients administered the vaccine responded by generating antibodies, passive immunotherapy is hypothesized to increase the proportion of patients who respond to therapy. Several not mutually exclusive hypotheses for the mechanism of action of anti-A β antibodies have been proposed and studied in animal models. In such studies, passive immunization has been demonstrated to result in enhanced breakdown of A β through activation of microglia and some antibodies appear to serve as a “peripheral sink” binding A β in the blood and creating a flow of A β out of the brain.

Multiple antibodies in development for AD have demonstrated ability to reduce fibrillar A β burden, as measured by amyloid PET (Ostrowitzki et al., 2012), and one has been shown to alter tau levels in the CSF (Blennow et al., 2012). Ongoing studies will determine if these biological drug effects are associated with reduced cognitive decline. In the first phase III studies, the monoclonal antibody bapineuzumab was reported to not meet its primary outcome measures in mild-to-moderate AD. It will be important to know whether the antibody was efficacious in reducing amyloid plaques in this trial. Although no safety issues related to meningoencephalitis have been observed with passive immunotherapies to date, antibody treatments do result in symptomatic and asymptomatic amyloid-related imaging abnormalities (ARIA), which have been categorized as consisting of vasogenic edema and effusion changes (ARIA-E) or the deposition of hemosiderin indicating microhemorrhages (ARIA-H) (Sperling et al., 2012). Ongoing trials will determine

the rates of occurrence of ARIA and its subtypes, as well as how often ARIA results in symptoms. It is likely that these rates will differ among candidate therapies and some antibodies are being developed specifically with the goal of improving the profile. Preliminary data suggest that ARIA may be most likely in areas of substantial A β removal.

While most antibodies in development for AD are monoclonal and specifically target a particular fragment of the A β peptide, polyclonal antibodies may also remove A β and provide clinical efficacy. Plaques in the brains of untreated AD patients are decorated with IgG antibodies, which elicit a microglial response, and an inverse relationship exists between IgG level and plaque burden in AD patients. Therapeutic use of naturally produced autoantibodies in the form of intravenous immunoglobulin (IVIg) as treatment for AD is a current area of clinical investigation. Treatment with IVIg increased plasma and decreased CSF levels of A β in a study of eight AD patients (Relkin et al., 2008). There is a large multisite clinical trial of IVIg in the United States and a second trial is planned.

One hypothetical mechanism by which immunotherapies reduce A β is through transport across the blood–brain barrier (BBB). Apolipoproteins do not cross the BBB, but play a role in A β transport and may regulate passage of A β between the CNS and the periphery. Beside age, *APOE* genetic status is the most well established risk factor for AD. The extent to which the different isoforms of ApoE bind A β is debated (Fan et al., 2009). ApoE ϵ 4 likely decreases passage of A β from brain to blood. Mouse models that overproduce and deposit A β , when combined with transgenic animals that lack ApoE, have reduced A β deposition (Bales et al., 1997). Synthesized compounds that prevent ApoE binding to A β reduce plaque deposition and memory impairment in animal models of AD (Sadowski, Pankiewicz et al. 2006). Alternatively, in another mouse model, the FDA-approved cutaneous T-cell lymphoma drug, bexarotene, demonstrated rapid plaque clearance and behavioral improvement. Bexarotene targets ApoE and liver X receptors and is being considered for clinical development for AD (Cramer et al., 2012).

One proposed mechanism by which ApoE regulates brain A β is by facilitating passage across the BBB via the low-density lipoprotein receptor-related protein (LRP). Antibodies against the LRP reduce A β efflux from the brain, and peripheral administration of soluble LRP as a mechanism to pull A β out of the brain has been proposed as a potential therapy. Alternatively, because A β travels bidirectionally, it may be useful to prevent its entry to the CNS from peripheral sources. The receptor for advanced glycation end-products (RAGE) is a multiligand receptor that binds A β with high affinity. Preventing ligands from binding RAGE lowers brain levels of A β . RAGE-inhibiting compounds are in development, though the first major phase II trial of a RAGE inhibitor failed to demonstrate efficacy and may have resulted in cognitive worsening, relative to placebo.

TAU

The second pathognomonic hallmark of AD is the neurofibrillary tangle (NFT). NFTs can be used to stage AD severity, based on a stereotypical progression that begins in the entorhinal

cortex and parahippocampal gyrus and progresses to include neocortical regions. Pathological studies have found the correlation between NFT pathology and disease progression to be stronger than that for neuritic plaque burden.

Neurofibrillary tangles are intracellular, composed of condensed hyperphosphorylated paired helical filaments of the microtubule-associated protein tau (MAPtau or tau). Although phosphorylation of tau is critical to its normal function, hyperphosphorylated tau (phospho-tau) aggregates into paired helical filaments rather than binding to microtubules. The resulting instability disrupts axonal transport and may result in neuronal injury and cell death, though neurons may live a decade or longer with neurofibrillary tangles (Braak and Del Tredici, 2011).

Abnormally high levels of phosphorylated or total tau in the CSF are indicators of neurodegenerative disease or injury. Clinical examinations suggest that abnormalities in A β do not predict cognitive decline unless p-tau levels are also abnormal (Desikan et al., 2012). In basic science models, tau is essential to AD and reducing tau can alleviate A β -dependent cognitive impairment (Roberson et al., 2007). Given that tau is a constitutive part of the cytoplasm of neurons, removal of cytoplasmic tau is not a realistic target. Staging of tau pathology in postmortem AD brains and a mouse model in which abnormal tau expression is limited to the entorhinal cortex but still develops pathology throughout the limbic structures (Liu et al., 2012) suggest that tau is transynaptically transported, perhaps underlying the anatomic spread of AD pathology. Investigational therapies aim to stabilize tau or to prevent its hyperphosphorylation, aggregation, or spread between cells.

Several classes of agents, including anthraquinones, polyphenols, aminothienopyridazines, and phenothiazines, may prevent tau aggregation. Wischik and colleagues have begun clinical development of the phenothiazine methylene blue as a treatment for AD (Wischik and Staff, 2009). The initial clinical trial of this agent failed to meet its prespecified endpoints but long-term observations and biomarker studies suggested possible benefit. Clinical development in AD continues. Methylene blue may reduce tau levels through autophagy (Congdon et al., 2012) and preventing tau fibril formation.

Reducing hyperphosphorylation might slow AD. Small molecule inhibitors of glycogen synthase kinase 3 beta (GSK-3 β) and the cyclin-dependent kinase-5 (cdk5), both of which phosphorylate tau at multiple sites, are logical candidates to prevent NFT development (Schneider and Mandelkow, 2008). Lithium and valproate inhibit GSK-3 β , but large controlled studies have failed to confirm initial promising results from small open label studies (Hempel et al., 2009; Tariot et al., 2009). Caffeine also inhibits GSK-3 β (Arendash et al., 2009).

Drugs that dephosphorylate tau may offer an alternative approach. Protein phosphatase 2A (PP2A) is decreased in AD and inhibition can cause tau hyperphosphorylation, tangle-like pathology, and behavioral impairment in animal models (Kins et al., 2001). Multiple PP2As exist and candidates capable of increasing PP2A activity, potentially through targeting upstream regulators, are logical (Iqbal et al., 2002), though no such candidates have reached clinical testing. NAP is an 8 amino acid

peptide and the active component of the glial-derived activity dependent neuroprotective protein (ADNP). NAP stabilizes microtubules and can reduce tau phosphorylation (Divinski et al., 2004). NAP reduced AD pathology in mouse models and has reached clinical investigation in an intranasal form (Gozes et al., 2005).

NEUROPROTECTION

Neuroprotection is defined here as including therapeutic strategies that aim to increase neuronal and synaptic survival in the face of AD pathology. Many neuroprotective strategies are independent of the actual mechanisms of cell and synapse loss. Epidemiological findings suggest AD-preventing properties for the NSAIDs and the cholesterol-lowering drugs (Sano et al., 2008). If these agents indeed prevent AD, the mechanisms by which they do so are unknown. As discussed, NSAIDs may alter proteolytic processing of APP, but AD pathology also includes a significant inflammatory component. Similarly, cholesterol may be involved in A β processing and statin therapy may impact AD pathology. Despite this and the epidemiologic results, prospective randomized trials in mild-to-moderate AD have failed to confirm disease-slowing properties for the NSAIDs diclofenac, misoprostol, rofecoxib, or naproxen; or for the HMG-CoA reductase inhibitors atorvastatin and simvastatin. Additionally, rofecoxib was no better than placebo at delaying conversion to dementia in MCI, and primary prevention trials of naproxen and celecoxib were halted for safety reasons (Sano et al., 2008).

Other therapies target the mechanisms by which cells die. Given that age is the strongest risk factor for AD, cellular aging is one logical correlate for study and the production of reactive oxygen species (ROS) in particular may be critical both in normal aging and AD. ROS may penetrate cellular mitochondria, and A β -dependent and independent mitochondrial dysfunction has been implicated in AD. The mitochondrial membrane stabilizer, latrepirdine (Dimebon, dimebolin) showed early promise in a small phase II trial, but two larger phase III studies failed to confirm latrepirdine's efficacy (Cummings, 2010). Other antioxidant compounds remove ROS and demonstrated preclinical efficacy in AD models, but trial results are generally mixed. One study suggested a delay in the time to severe AD (as measured with the CDR) in patients treated with vitamin E, but other trials have suggested no benefit (Sano et al., 2008). Sirtuins are another family of compounds believed to have antioxidant and potential A β -lowering properties. A large phase II trial of resveratrol, the sirtuin found in red wine and the skin of red grapes, is currently underway.

Both neuronal survival and apoptotic cell death are critical to proper CNS development and this process is largely dependent upon neurotrophic factor regulation. Because of their potent survival effects in development, neurotrophic factors are logical treatment candidates in neurodegenerative disease. Trophic factor therapies face a variety of challenges, most specifically size that limits penetration of the CNS and intolerability related to potent off-target effects (Eriksdotter Jonhagen et al., 1998). To address both of these challenges, neurosurgical delivery of gene transfer technology can be

applied. An ongoing clinical development program uses neurosurgery to deliver adeno-associated virus (AAV)-delivered nerve growth factor DNA to the trk-A receptor-expressing cholinergic neurons of nucleus basalis of Meynert. These cells provide cholinergic supply to the neocortex and hippocampus and are known to degenerate early in the disease. Their enhanced survival may increase cholinergic tone and slow disease progression. Similarly, in a primate model, gene transfer to the entorhinal cortex with brain-derived neurotrophic factor (BDNF) DNA enhances memory performance (Nagahara et al., 2009).

Cell-based therapies for AD present unique challenges. The synapse and cell loss in AD is widespread, making replacement unlikely. Recent animal studies suggest that replacement may not be necessary, however, to achieve therapeutic efficacy. In triple transgenic mice, stem cell therapy resulted in increased hippocampal synaptic density, possibly as a result of increased BDNF signaling (Blurton-Jones et al., 2009).

CONCLUSIONS

Alzheimer's disease is one of the most important areas of medical research. Without improvements in treatment options and earlier intervention AD will bankrupt world health care systems. No treatment can slow the course of AD, but a wide range of targets for potential disease-modifying therapies have been identified and many candidate drugs are in development. Clinical trials will be essential to finding disease-modifying drugs, but face a variety of challenges. As trials move earlier in disease, the reliance on standards set in dementia trials may hinder success. Improved outcome measures, surrogate biomarkers, and better means of enrolling samples are critically needed. Despite these challenges, optimism exists for the numerous compounds that have entered or will soon begin clinical study. The field is on the cusp of disease-modifying therapies, which may act as catalysts for continued improvement in therapeutics, implementation of trials to delay cognitive impairment, and amelioration of the human and financial toll associated with AD.

DISCLOSURES

Dr. Grill has received grant/research support from the National Institute on Aging (AG016570), the Alzheimer's Association (NIRG-12-242511), the John Douglas French Foundation, the Sidell-Kagan Foundation, and as a site investigator for clinical trials sponsored by Elan, Genentech Janssen Alzheimer Immunotherapy, Bristol-Myers Squibb, Medivation, Pfizer, and the Alzheimer's Disease Cooperative Study (ADCS). He has served as a paid consultant to Avanir Pharmaceuticals and Phloronol Inc.

Dr. Cummings owns the copyright of the Neuropsychiatric Inventory. He has provided consultation to Abbott, Acadia, ADAMAS, Anavex, Astellas, Avanir, Avid, Baxter, Bayer, Bristol-Myers Squibb, Eisai, Elan, EnVivo, Forest, GE, Genentech,

GlaxoSmithKline, Janssen, Lilly, Lundbeck, MedAvante, Medivation, Medtronic, Merck, Neurokos, Neurotrax, Novartis, Otsuka, Pfizer, Prana, QR Pharma, Sonexa, Takeda, and UBC. He owns stock in ADAMAS, Prana, Sonexa, MedAvante, Neurotrax, and Neurokos. He has been a speaker for Eisai, Forest, Janssen, Novartis, Pfizer, Lundbeck. Dr. Cummings has provided expert witness consultation regarding olanzapine and ropinirole.

STELLA KARANTZOULIS AND JAMES E. GALVIN

Lewy body dementia (LBD) is an umbrella term for two related diagnoses, Parkinson disease dementia (PDD), and dementia with Lewy bodies (DLB). Lewy body dementia is now recognized as the second most common cause of dementia after Alzheimer's disease (AD). The Lewy Body Dementia Association estimates that there are between 1 and 2 million Americans with LBD. Lewy body dementia symptoms can closely resemble the more widely recognized dementia syndrome of AD but can be distinguished with identification of the visuospatial, executive, and attentional components of dementia (rather than the marked episodic memory impairment that characterizes AD), together with evidence of parkinsonism, visual hallucinations, and rapid eye movement sleep behavioral disorder (RBD). Cognitive fluctuations, although quite specific for LBD, can be difficult to elicit even at specialized centers given the lack of standardized questionnaires validated in large populations. Additional suggestive features incorporated in the consensus criteria for LBD that may facilitate diagnosis include depression, hallucinations in other modalities, syncope and frequent falls, transient and unexplained loss of consciousness, severe autonomic dysfunction, alterations in personality and behavior, relative preservation of medial temporal lobe structures on structural neuroimaging, reduced occipital activity on functional neuroimaging, and low uptake myocardial scintigraphy. Management of LBD currently rests on both pharmacological (cholinesterase inhibitors, *N*-methyl-*D*-aspartate antagonists, antiparkinsonism agents; atypical antipsychotics used with caution) and non-pharmacological (therapeutic environment, psychological and social support, physical activity, behavioral management strategies, caregivers' education and support) therapy options for its many cognitive, neuropsychiatric, motor, autonomic, and sleep disturbances.

WHAT IS LEWY BODY DEMENTIA?

Over the past two decades, research has suggested that Lewy bodies (LBs) found in up to 40% of autopsied brains (Galvin et al., 2006) play a significant role in the spectrum of diseases that have come to be known as the Lewy body dementias (LBD). Lewy body dementias include Parkinson disease dementia and dementia with Lewy bodies. This chapter uses the term Lewy body dementia to describe the syndrome of LB disorders, and the terms Parkinson disease dementia and dementia with Lewy bodies when citing specific experimental and clinical data.

Parkinson disease (PD), one of the most common movement disorders of the elderly, affects one in 100 individuals greater than 60 years of age and 4% to 5% of older adults greater than 85 years of age (roughly 1.5 million Americans). Parkinson disease is characterized by the cardinal motor features of rigidity, bradykinesia, and tremor at rest. Historically, cognitive problems were not considered to be important features of PD. In his famous text, James Parkinson (1755–1824) stated, “by the absence of any injury to the senses and to the intellect that the morbid state does not extend to the encephalon.” It is now well recognized that cognitive impairment and dementia in the setting of PD are common and are two of the most debilitating symptoms associated with the disease. There is strong evidence that dementia not only has significant clinical consequences for PD patients in terms of increased disability, risk for psychosis, reduced quality of life, and increased mortality, but also results in a greater stress and burden of caring for patients with PDD and higher disease-related costs resulting from increasing chances of nursing home admission (Emre, 2003).

According to clinical diagnostic criteria (Table 66.1), PDD is a dementia syndrome that develops in the context of established PD (Emre et al., 2007). Like AD, PDD has an insidious onset with slow progression, and is defined as having impairment in more than one cognitive domain, representing a decline from prior levels. The deficits must be severe enough to affect daily social or occupational functioning or personal care and the deficits must be independent of the impairment resulting from motor or autonomic symptoms (Emre et al., 2007).

A wide variety of cognitive impairments have been reported in PDD, even early in the course of the disease. To date, the relationship between onset of initial deficits and subsequent decline to dementia has not been clearly established. Preliminary evidence suggests that an intermediate stage (PD-MCI) with predominant visuospatial and executive impairments may exist for one to three years (Johnson and Galvin, 2011). The neuropathology of PDD is controversial and it remains unknown whether or not dementia in PD occurs alone or only in the presence of other dementing disorders such as DLB and AD.

Dementia with Lewy bodies is now considered to be the second most common cause of dementia in elderly people. An international consortium on DLB resulted in revised criteria for the clinical and pathological diagnosis of DLB incorporating new information about the core clinical features and improved methods for their assessment (I. G. McKeith et al., 2005) (Table 66.2). Dementia with Lewy bodies, like all dementias, is characterized by a progressive reduction in cognitive

TABLE 66.1. Clinical diagnostic criteria for Parkinson disease dementia

<p>Core features (required for both probable or possible PDD)</p>	<p>Diagnosis of PD according to UK Brain Bank (Queen Square) criteria Dementia with insidious onset and slow progression in the context of of PD diagnosis, defined by:</p> <ul style="list-style-type: none"> • Impairment of more than one domain of cognition • Impairment represents a decline from premorbid functioning • Impairment in day-to-day functioning not caused by motor or autonomic dysfunction
<p>Associated features (typical cognitive profile in at least two of the four domains + at least one behavioral symptom = probable PDD; atypical cognitive profile in one or more domains = possible PDD, and behavioral disturbance may or may not be present)</p>	<p><i>Cognition</i> Impaired attention, may fluctuate within/across days Impaired executive functions (e.g., planning, conceptualization, initiation, rule finding, set maintenance or shifting, mental speed) Impaired visuospatial functions (e.g., visual-spatial orientation, perception, or construction) Impaired memory (typically with benefit from cuing, better recognition than recall) Preserved language (some difficulties with word-finding and complex sentence comprehension may be present)</p> <p><i>Behavior</i> Apathy Changes in mood and personality (including depression and anxiety) Delusions, typically of paranoid type Hallucinations, mainly visual, complex, and well formed Excessive daytime sleepiness/somnolence</p>
<p>Features making the diagnosis of PDD uncertain (none of these features can be present when diagnosing probable PDD; one or two features can be present when diagnosing possible PDD)</p>	<p>Another abnormality capable of impairing cognition, but judged not to be the cause of the dementia (e.g., vascular disease on neuroimaging) Time interval between onset of motor and cognitive symptoms is unknown</p>
<p>Supportive features (commonly present but lacking diagnostic specificity)</p>	<p>Cognitive and behavioral abnormality occurs solely in the context of other conditions, such as confusional state owing to systemic disease or intoxication, or major depressive disorder Features consistent with probable vascular dementia per NINDS-AIREN criteria</p>

J., Costa, D., Del Ser, T., Dubois, B., Galasko, D., Gauthier, S., Goetz, C. G., Gomez-Tortosa, E., Halliday, G., Hansen, L. A., Hardy, J., Iwatsubo, T., Kalaria, R. N., Kaufer, D., Kenny, R. A., Korczyn, A., Kosaka, K., Lee, V. M., Lees, A., Litvan, I., Londos, E., Lopez, O. L., Minoshima, S., Mizuno, Y., Molina, J. A., Mukaetova-Ladinska, E. B., Pasquier, F., Perry, R. H., Schulz, J. B., Trojanowski, J. Q., & Yamada, M. (2005). Diagnosis and management of dementia with Lewy bodies: third report of the DLB Consortium. *Neurology*, 65, 1863–1872.

functioning. The cognitive profile is one of mixed subcortical and cortical cognitive impairments that are often indistinguishable from PDD. Although the rate of dementia progression was once considered to be more rapid in DLB relative to AD, this has not been a consistent finding in the literature.

There is no one sign or symptom that definitively distinguishes PDD from DLB. Current clinical criteria for DLB distinguish PDD only by the temporal requirement that the dementia manifests more than 12 months after the onset of motor signs; if dementia precedes or is concurrent with parkinsonism, then DLB is diagnosed. In one study of 100 participants (10 nondemented controls, 40 patients with PD, 15 with DLB, and 35 with AD) enrolled in a longitudinal study of memory and aging, Galvin et al. (2006) found that postural instability is more common in PDD than DLB, whereas sexual disinhibition, alexia, and naming problems were more common in DLB relative to PDD. Galvin et al. also found that the presence of these features, whether at first evaluation or at any point in the course of PD, was highly predictive of PDD and the development of LBs at autopsy.

The core features of DLB include fluctuating cognition, recurrent well-formed visual hallucinations, and spontaneous parkinsonism. Extrapyramidal signs, including bradykinesia, facial masking, and rigidity are the most frequent signs of parkinsonism and can vary in severity. Resting tremor is not common. Parkinsonism is usually bilateral. There tends to be more axial rigidity and facial masking in DLB than in idiopathic PD.

Additional clinical features suggestive of DLB were also identified in the revised criteria. These include rapid eye movement sleep behavior disorder (RBD), severe neuroleptic sensitivity, and low dopamine transporter uptake in the basal ganglia demonstrated by single photon emission computed tomography (SPECT) or positron emission tomography (PET) imaging. Often present but not specific features of DLB include repeated falls and syncope, transient and unexplained loss of consciousness, autonomic dysfunction, hallucinations in other modalities, systematized delusions, depression, relative preservation of medial temporal lobe structures on structural neuroimaging, reduced occipital activity on functional neuroimaging, prominent slow wave activity on electroencephalogram (EEG), and low uptake iodine-123 metaiodobenzylguanidine (MIBG) myocardial scintigraphy.

According to the revised DLB consortium criteria, two core features (or one core feature and one suggestive feature) are sufficient for a diagnosis of probable DLB; one core feature or one or more suggestive feature is suggestive for a diagnosis of possible DLB (I. G. McKeith et al., 2005). As with AD, definitive diagnosis of DLB rests on brain autopsy following death. Although these features may support the clinical diagnosis of DLB, they lack diagnostic specificity and can be seen in other neurodegenerative disorders. These criteria permit 83% sensitivity and 95% specificity for the presence of neocortical LBs (I. G. McKeith, 2000b). These criteria are also more predictive of cases with pure or diffuse LB pathology than those with concomitant AD pathology, and fail to reliably differentiate between pure DLB (which is rare) and the more common mixed forms of DLB and AD. There are currently no definitive

radiological or biological markers available to support a diagnosis of DLB.

EPIDEMIOLOGY OF LEWY BODY DEMENTIA

The precise number of people with LBD remains unclear. The point prevalence of dementia in PD is close to 30% and the incidence rate is increased at four to six times relative to controls. The cumulative percentage is very high, with at least 75% of PD patients who survive more than 10 years likely to develop dementia (Aarsland and Kurz, 2010). The mean time from disease onset of PD to dementia is approximately 10 years. However, there are considerable variations, and some patients develop dementia early in the disease course. Old age, more severe motor symptoms (in particular, gait and postural disturbances), mild cognitive impairment at baseline, and visual hallucinations are reliably identified as risk factors for early dementia.

Prevalence estimates of DLB range from 0% to 5% in the general population and from 0% to 30.5% of all dementia cases (Zaccai et al., 2005). Very few studies have looked at the incidence rates in DLB. Miech et al. (2002) found the incidence of DLB to be about 0.1% in the general population, and 3% for all new dementia cases.

NEUROPSYCHOLOGICAL FEATURES OF LEWY BODY DEMENTIA

Neuropsychological evaluation has provided clinicians and researchers with profiles of cognitive strengths and weaknesses that help to define LBD, as well as distinguish LBD from AD. It is important to keep in mind that neuropsychological tests often tap a number of different domains and the reasons that patients may perform poorly on any given test for any number of reasons. Unfortunately, the underlying cognitive processes of widely used neuropsychological measures have yet to be elucidated more precisely. Generally speaking, cognitive symptoms in LBD include a combination of cortical and subcortical impairment; this is contrasted with a classic cortical profile of impairment predominant in AD. See Table 66.3 for a summary of the neuropsychological deficits differentiating LBD from AD.

ATTENTION AND EXECUTIVE FUNCTION

Lewy body dementia is typified by impairments in attention and executive functions. Marked attentional disturbance in DLB may serve as the basis of fluctuating cognition that is characteristic of DLB (Walker et al., 2000). A range of experimental, screening, and clinical neuropsychological measures have been used to compare attention in LBD relative to AD. Few studies have shown group differences on digit span tasks (Hansen et al., 1990). Rather, more consistent group differences emerge on more complex attentional tasks, such as those requiring mental control, visual search and set shifting, and visual selective attention. On cancellation tasks, regardless of

whether letters or shapes are used, Patients with LBD perform more poorly than AD patients. Additionally, the demonstration of greater attentional impairment and variability in reaction times in DLB relative to AD may be the function of the executive and visuospatial demands of the tasks (Bradshaw et al., 2004). Attentional deficits are important determinants of the inability to perform instrumental and physical activities of daily living, even after controlling for age, sex, motor function, and other cognitive profiles (Bronnick et al., 2006).

Early frontal/executive dysfunction may be predictive of incident PDD (Woods and Troster, 2003) and is considered a core feature of PDD (Emre et al., 2007). Executive functions comprise a number of cognitive skills (planning, abstraction, conceptualization, mental flexibility, insight, judgment, self-monitoring, and regulation) and are central to adaptive, goal-directed behavior. The executive dysfunction seen in patients with LBD includes impaired judgment, organization, and planning (Kehagia et al., 2010). These patients are also more susceptible to distraction and have difficulty engaging in a task and shifting from one task to another. They tend to perform more poorly on Stroop, card sorting, and phonemic verbal fluency tasks than comparably demented patients with AD (Calderon et al., 2001). In general, executive impairments tend to be worse in LBD than AD (Collerton et al., 2003; Simard et al., 2000).

The neurochemical basis of executive dysfunction is likely to be multifactorial in nature and associated with dopaminergic,

cholinergic, and noradrenergic deficits; although further study is required, increasing evidence from imaging and autopsy studies highlights the importance of cortical cholinergic loss (Emre, 2003).

VISUOSPATIAL/CONSTRUCTION

Visuospatial deficits are common in LBD and represent a very early and sensitive marker of PDD, especially when LB pathology and AD are mixed (Johnson and Galvin, 2011). Visuospatial changes are varied and can manifest across measures of facial recognition, spatial memory spatial planning, object-form perception, visual attention, visual orientation, and constructional praxis. Several studies have shown greater impairments in LBD than AD on visuospatial and constructional tasks (Collerton et al., 2003; Noe et al., 2004; Simard et al., 2003). Even brief-screening tests, such as pentagon copying from the Mini Mental State Examination (MMSE; Folstein et al., 2001) have been reported to be greater in LBD than AD (Ala et al., 2002; Cormack et al., 2004).

On complex figure copy tests, performance of patients with DLB is known to be affected partially by disrupted visual spatial perception and partially because of reduced frontally mediated skills such as organization, planning, and working memory. Furthermore, impairments on constructional tasks likely reflect more than just the motor demands of the tasks and the motor impairments of LBD, as these patients also show greater impairments than patients with AD on visual perceptual tasks without significant motor demands (Calderon et al., 2001) and even after controlling for the motor slowing characteristic in PDD (Johnson and Galvin, 2011). Subjects with DLB performed more poorly than patients with AD not only in size and form discrimination and visual counting, but also in recognizing overlapping figures. Studies have linked visual perceptual deficits in DLB to visual hallucinations (Mori et al., 2000); that is, those patients with visual hallucinations performed significantly worse on the overlapping figures test and performed worse in size and form discrimination than those subjects with DLB without visual hallucinations. Mosimann et al. (2004) also found that among patients with DLB and PDD, those with visual hallucinations performed significantly worse than those without hallucinations on tasks of angle, object-form, and space-motion discrimination. Because visual hallucinations are among the strongest predictors of DLB and PDD (Galvin 2006; Tiraboschi et al., 2006), the neuropsychological assessment of visual perceptual and constructional functions is important in suspected DLB and PDD and their differentiation from AD.

MEMORY

Generally speaking, patients with LBD perform better on episodic memory tasks than patients with AD. Memory may be spared early on in LBD and manifest as the disease progresses. Memory deficits are the presenting problem in 67% of patients with PDD, which is fewer than the number of patients with DLB (94%) and AD (100%) (Noe et al., 2004). The nature of the memory deficit in LBD differs from that noted in AD as it tends to be one of retrieval rather than encoding and/or

consolidation and storage, with significant improvement noted with cuing in LBD relative to AD (Burn, 2006). The more severe amnesic deficits in AD relative to LBD likely reflects the greater burden of neurofibrillary tangles in the entorhinal cortex and surrounding medial temporal lobe regions in AD.

Some studies have suggested better recall on verbal memory tests (including the California Verbal Learning Test; Simard et al., 2000; Logical Memory subtest of the Wechsler Memory Scale-Revised; Calderon et al., 2001; memory subtest on the Dementia Rating Scale; Aarsland et al., 2003) among patients with DLB than those with AD, but this has not been consistently reported, possibly because of the difficulty in isolating pure forms of DLB from LBD cases caused by concurrent AD pathology. Dementia with Lewy bodies tends to co-occur with AD in 80% of cases, with only 20% having pure DLB. Patients with pure Lewy body pathology have better verbal memory skills than those with pure AD or mixed DLB/AD (Johnson et al., 2005). Patients with pure AD and mixed DLB/AD show equivalent degrees of impairment on verbal memory testing. In contrast, combined AD and Lewy body pathology appears to have an additive effect on visual memory skills.

Remote memory may also be affected by PDD (Huber et al., 1986; Leplow et al., 1997). Contrary to patients with AD who typically show a temporal gradient in their memories (with greater impairment noted for recent than remote information), the memory loss in PDD tends to be equally severe across past decades. Recognition of famous faces (a measure of remote memory) may be comparably impaired in DLB and AD (Gilbert et al., 2004).

LANGUAGE

Patients with DLB generally show milder naming deficits than patients with AD on measures of confrontation naming and there are group differences in terms of error profiles (Williams et al., 2007). The naming deficits may become progressively more severe with disease progression in DLB. Patients with AD are more likely to make more semantic errors on confrontation naming testing than patients with DLB, whereas those with DLB make significantly more visuospatial errors than patients with AD. The disproportionate visuospatial dysfunction described in DLB may contribute to reduced ability to perceive objects accurately, leading secondarily to errors in naming. Measures of generative fluency have also proved to be useful in differentiating AD from DLB. Patients with DLB are equally impaired in category and letter fluency, whereas patients with AD perform significantly better with letters than categories (Lambon et al., 2001). This may be related to underlying mechanisms: whereas patients with AD have degraded semantic networks or retrieval difficulties affecting semantic networks, attentional and executive impairments likely contribute to the difficulties with word search and retrieval in DLB subjects.

The language impairments in PDD also tend to be mild, with aphasia being a rare occurrence. Verbal fluency impairments are reliably observed in PDD and the deficits tend to be greater in PDD than AD (Cahn-Weiner et al., 2002). Mild deficits on measures of semantic fluency have also been reported (Monsch et al., 1992). Additional features of language

impairment in PDD include decreased content of spontaneous speech, impaired naming, shorter phrase length, and dysarthria (Cummings et al., 1988).

BEHAVIORAL AND NEUROPSYCHIATRIC FEATURES

Neuropsychiatric features such as hallucinations and delusions are common in LBD, elicited primarily via informant ratings and less on formal diagnostic criteria. Perhaps most widely used of the informant ratings in LBD is the Neuropsychiatric Inventory (NPI; Cummings et al., 1988). Approximately 61% of PD patients exhibit neuropsychiatric disturbances. The most common features are depression (38%), hallucinations (27%), delusions (6%), anxiety (40%), sleep disturbances (60–90%), and sexual misdemeanor (5% to 10%). Galvin et al. (2006) found that visual hallucinations were the strongest single predictor of developing dementia in patients with PD and increased the risk of developing dementia 20-fold.

The phenomenology of visual hallucinations is similar in PDD and DLB. Visual hallucinations tend to be well formed, detailed, most commonly involving anonymous people (often described by the patient and dysmorphic or small), although they may also involve family members, animals, body parts, and machines. Hallucinations can occur in other modalities, including auditory, tactile, and olfactory. Auditory hallucinations are less common and generally not present in the absence of visual hallucinations. Hallucinations may be frightening and it is difficult to convince the patient that they are not real. This may pose safety problems, as the patient will feel that he or she will be attacked or have his or her home invaded.

Patients with DLB are more likely to show psychiatric symptoms and have more functional impairment at the time of initial evaluation than patients with AD. Visual hallucinations are typically present early in the course of the disease and do not diminish in later periods. In an analysis of autopsy-confirmed cases, hallucinations and delusions were more frequent with LB pathology (75%) than AD (21%) at the time of the initial clinical evaluation (Weiner et al., 2003). This was also true for those cases with mixed DLB and AD (53%) pathology relative to AD alone. The occurrence of visual hallucinations in the first four years after dementia onset has a positive and negative predictive value for DLB of 81% and 79%, respectively (Ferman et al., 2006).

There is a strong association between visual hallucinations and cholinergic depletion in the temporal cortex and the basal forebrain (Harding et al., 2002). Visual hallucinations may predict a good response to cholinesterase inhibitors (I. McKeith et al., 2004). The hallucinations of DLB do not seem to correlate with the dose of levodopa (L-dopa) or the occurrence of motor fluctuations seen with dopaminergic therapy (Sanchez-Ramos et al., 1996); however, hallucinations may be elicited or worsened with dopaminergic medications. Other suggested mechanisms for visual hallucinations include dysregulation of rapid eye movement (REM) sleep with the intrusion of dreams into wakefulness (Boeve et al., 2004).

Delusions also occur in 56% of patients with DLB at first presentation and 65% at some point in their illness. Delusions tend to be more common in DLB than in PDD or AD. Paranoid, Capgras (believing individuals are replaced by identical imposters), and “phantom boarder” (unseen individuals residing in one’s home) are among the most common delusions. Misidentification syndromes appear to be particularly prevalent in DLB, occurring in up to 40% of patients, compared with 10% in AD (Ballard et al., 1999). It is not yet clear whether misidentification delusions are also characteristic of PDD.

Depression is common in both PDD and DLB and there is equivocal evidence as to whether base rates of depressed mood and major depression differ between these disorders and AD (Ferman et al., 2006). A history of depression has been reported in 58% of persons with PDD, 50% of patients with DLB, and in 14% of AD cases coming to autopsy (Klatka et al., 1996). Risk factors for depression include early onset PD, presence of hallucinations or delusions, and an akinetic rigid presentation (vs a tremor predominant variant). The incidence of depression appears to be unrelated to the presence or absence of dementia or the severity of motor impairment (I. G. McKeith, 2000a). Anxiety and apathy co-occur, with depression in 40% and 15% of patients with PD, respectively. Apathy is also common in DLB, particularly with more severe dementia.

PERSONALITY CHANGES

Personality changes in DLB tend to occur with auditory and visual hallucinations and include diminished emotional responsiveness, resignation of hobbies, increased apathy, and purposeless hyperactivity (Galvin et al., 2007). Using principal components analysis, Galvin and his colleagues were able to identify three general personality traits in DLB. The first were irritable traits (accounting for almost 33% of the variance) and included increased rigidity, egocentricity, loss of concern, coarsening of affect, and impaired emotional control. The second were a passive group of traits (this explained just more than 12% of the variance) and included diminished emotional responsiveness, relinquished hobbies, growing apathy, and purposeless activity. The third reflected disinhibition (this explained an additional 10.4% of the variance) and included inappropriate hilarity and sexual misdemeanor. Using this three-factor structure, patients with DLB were more likely to manifest personality traits associated with passive personality traits than patients with AD. Using receiver operating characteristic curves, these authors also showed that the passive personality traits discriminated between AD and DLB, whereas both the irritable set of traits and those reflecting disinhibition were uncommon in both groups.

COGNITIVE FLUCTUATIONS

Fluctuations in cognition are one of the hallmarks of DLB, seen in 15% to 80% of patients with DLB (Ballard et al., 2002).

Cognitive fluctuations are also common in PDD and may be as frequent as in DLB (Ballard et al., 2002). These often involve waxing and waning of cognition, attention, concentration, functional abilities, or arousal in the absence of any clear precipitant. They are often described as episodes of behavioral confusion, inattention, hypersomnolence, and incoherent speech alternating with episodes of lucidity and capable task performance. Patients may be described as staring into space or being dazed and the episodes can last minutes to days, varying from alertness to stupor. An extreme form of fluctuations may occur when patients are found mute and unresponsive for a few minutes.

Given the large variability in the description and quantifications of fluctuations in patients with LBD, a number of scales have been developed, including the Clinical Assessment of Fluctuation and the One Day Fluctuation Assessment Scale, and the Mayo Fluctuations Questionnaires (Ferman et al., 2006). The Mayo scale describes four features of fluctuations that can reliably distinguish DLB from AD or normal aging. Three or four features of this composite occurred in 63% of patients who had DLB compared with 12% of those who had AD and 0.5% of normally functioning elderly people. The presence of three or four of these features yielded a positive predictive value of 83% for the clinical diagnosis of DLB against an alternate diagnosis of AD.

AUTONOMIC DYSFUNCTION

Autonomic dysfunction is a common clinical sign in LBD. Autonomic features tend to occur later in the disease course of DLB, although there have been some cases with early and prominent involvement. Symptomatic orthostasis is probably the most serious manifestation of autonomic dysfunction, observed in approximately 15% of patients with DLB. Other features include decreased sweating, excessive salivation (sialorrhea), seborrhea, heat intolerance, urinary dysfunction, constipation or diarrhea, and erectile dysfunction or impotence. In fact, constipation may precede any cognitive or motor symptoms by more than a decade. Patients with DLB also have a higher frequency of carotid hypersensitivity than elderly patients or those with AD. There is also evidence of cardiac denervation by MIBG scintigraphic scanning, a finding not seen in AD.

Autonomic dysfunction tends to occur in the late stages of PD and is related to disease severity and duration. Approximately one-third of patients have clinical features of autonomic dysfunction, although estimation of the prevalence of autonomic dysfunction is compounded by factors such as the use of antiparkinsonian medications. Most common in PD are decreased gastrointestinal ability and bladder dysfunction. Also common is constipation and there is a risk of more serious complications including intestinal pseudoobstruction and toxic megacolon. Other common features include bladder dysfunction with urgency, frequency and incontinence, and sexual dysfunction (decreased libido and erectile dysfunction). Symptomatic orthostasis is more common in association with cognitive impairment in PDD.

SLEEP DISORDERS

Many patients with LBD have parasomnias. Most common is REM sleep behavioral disorder (RBD), which tends to begin concurrently or after the onset of parkinsonism or dementia (Boeve et al., 2007). Rapid eye movement sleep behavioral disorder is marked by lack of normal muscle atonia that prevents movements (other than eye movements) during REM sleep in the presence of excessive activity while dreaming; this can result in vocalizations and sometimes wildly violent behavior. Rapid eye movement sleep behavioral disorder may be idiopathic or may be associated with LBD and other synucleinopathies. Patients may be unaware of the disorder and the history is therefore often dependent on the patient's bed partner. Rapid eye movement sleep behavioral disorder is more commonly found in men in their fifties and may precede the clinical signs associated with LBD by many years. Parkinson disease patients with RBD show impairments of some logical abilities as compared with subjects without RBD (Sinforiani et al., 2006). There are, however, no longitudinal studies confirming RBD as a risk factor for PDD. On the other hand, excessive daytime sleepiness has been reported to be a risk factor for PDD (Olson et al., 2000).

NEUROLEPTIC SENSITIVITY

Patients with DLB are notorious for their neuroleptic sensitivity. Reactions are observed in 30% to 50% of patients with DLB and are characterized by sudden onset of impaired sensitivity, acute confusion, psychotic episodes, and exacerbation of parkinsonism symptoms such as rigidity and immobility (I. McKeith et al., 1992). In some cases, these reactions can lead to death within several days. One survey (Aarsland et al., 2005) revealed a 58% frequency of neuroleptic sensitivity to olanzapine, with lower rates with clozapine (11%) and thioridazine (6%). These data support the notion of unacceptable safety profiles for some neuroleptics in LBD. Patients with DLB also tend to be activated by sedatives and awakened by sleep medications (Rogan and Lippa, 2002). Severe neuroleptic sensitivity has been reported in up to 40% of patients with PDD exposed to neuroleptic drugs (Aarsland et al., 2005).

NEUROPATHOLOGY

The main identifying pathological features of LBD are cortical and subcortical LBs and Lewy neurites (LNs). Lewy bodies are spherical intracytoplasmic protein deposits around the nucleus and throughout the dendrite of subcortical and cortical neurons. They consist of filamentous protein granules composed of α -synuclein and ubiquitin, and are surrounded by a halo of neurofilaments. Cortical LB sites include the cingulate gyrus, entorhinal cortex, insular cortex, frontal cortex, and amygdala (Fig. 66.1).

The different forms of LBD can have variations as to the extent and spread of α -synuclein pathology and variable

amount of AD pathology (see Fig. 66.1). For both PDD and DLB, staging/classification systems based on semiquantitative assessment of the distribution and progression pattern of α -synuclein pathology are used that are considered to be linked to clinical symptoms.

In PD, a six-stage system is suggested to indicate a predictable sequence of lesions with ascending progression from medullary and olfactory nuclei to the cortex (Braak et al., 2003) (see Table 66.3). Braak stages 1 and 2, with LB pathology involving medulla oblongata and pontine tegmentum, are considered asymptomatic or presymptomatic and may explain the early nonmotor symptoms (autonomic and olfactory). Braak stages 3 and 4, involving extension of LB pathology to midbrain and basal prosencephalon and mesocortex, has been correlated to clinical symptomatic stages. The terminal Braak stages 5 and 6, characterized by widespread neocortical LB degeneration, are correlated with significant cognitive decline associated with severe parkinsonism (Hurtig et al., 2000).

Dementia with Lewy bodies, according to consensus pathological guidelines, by semiquantitative scoring of α -synuclein pathology (LB density and distribution) in specific brain regions, is distinguished into three phenotypes: brainstem, limbic, and diffuse cortical. Concomitant AD-type pathology is also considered. Generally speaking, the more neocortical LBs and the lower the Braak stage, the more likely the patient will meet the criteria for DLB, whereas higher Braak stages and non-neocortical LBs are associated with a lower likelihood of obtaining DLB diagnosis. In one review of 88 autopsy-confirmed cases, identification of clinical DLB was inversely proportional to Braak staging of neurofibrillary pathology. It should be noted that clinician sensitivity was still poor regardless of classification scheme (Weisman and McKeith, 2007). Neuronal loss in the substantia nigra is greater in PDD than in DLB, whereas beta-amyloid patterns are more consistent in DLB. α -synuclein pathology is also greater in the striatum in DLB than PDD (Duda et al., 2002).

In PDD, Galvin et al. (2006) identified three neuropathological profiles when comparing autopsy reports of 103 cases followed longitudinally. Roughly one-third of PDD was found to be caused by neocortical LBs without evidence of AD pathology. Another one-third had abundant senile plaques and neurofibrillary tangles meeting criteria for both PD and AD. The final group had only brainstem pathology comprising LBs. These data are in line with the staging paradigm proposed by Braak and colleagues, suggesting that PD pathology begins in the lower brainstem and spreads in a caudal-rostral fashion (Braak et al., 2003). Importantly, recent studies have revealed exceptions to the general order of progression suggested by Braak and colleagues (e.g., Jellinger, 2008; Parkkinen et al., 2008).

GENETICS

In the past decade, tremendous advances have been made in understanding the genetic factors influencing the pathogenesis of LBD. Compelling evidence for a genetic basis for both PD and DLB followed the discovery of mutations in the α -synuclein gene (PARK1/4) in patients with autosomal dominant familial PD, and subsequently, mutations were identified

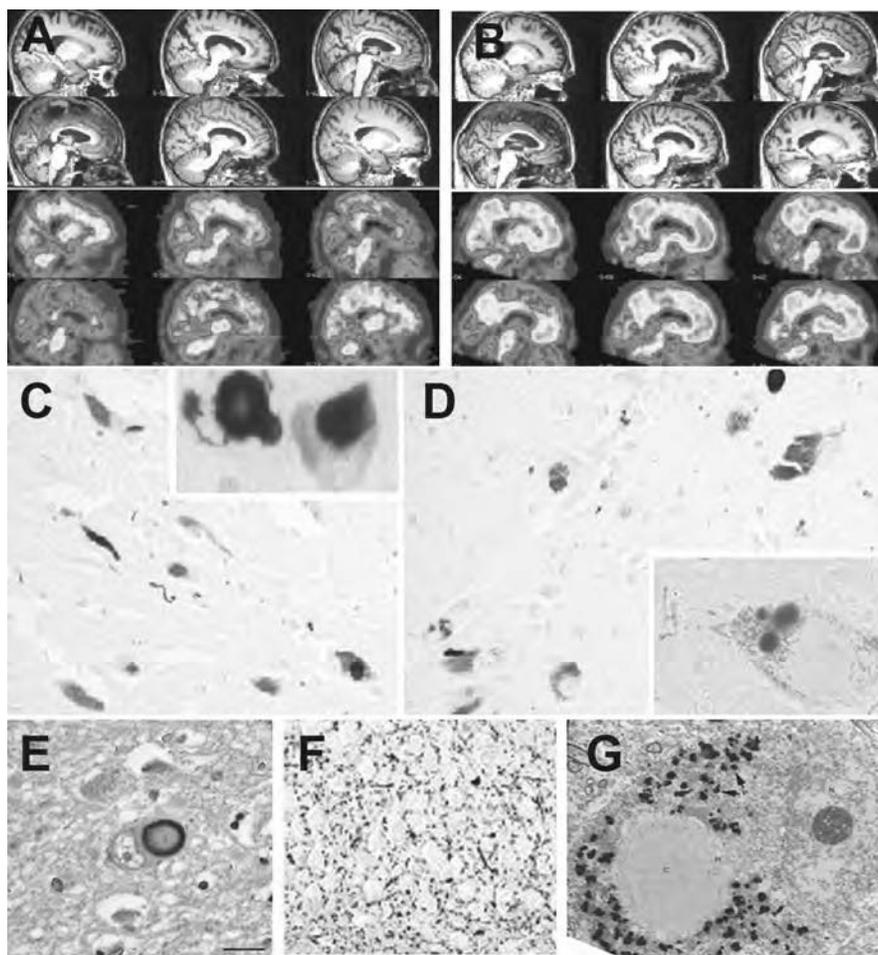

Figure 66.1 Imaging and pathology in lewy body dementia. (A) Sagittal sections of MRI and amyloid imaging in a case of PDD. There is mild cortical atrophy largely sparing the hippocampus. Amyloid imaging reveal minimal to no uptake of the PIB. (B) Sagittal section of MRI and amyloid imaging in a case of mixed LBD and AD. There is slightly more prominent atrophy of the hippocampus with significant uptake of PIB. (C) Photomicrograph of substantia nigra in DLB patient stained with α -synuclein. Note dystrophic neurites. Insert shows higher power magnification of two Lewy bodies in the nigral neurons. (D) Photomicrograph of substantia nigra in PDD patient stained with α -synuclein. Insert shows higher power magnification of a nigral neuron with multiple Lewy bodies. (E) Photomicrograph of Lewy body in the cingulate cortex of a LBD patient stained with α -synuclein. (F) Photomicrograph of dystrophic neurites in the CA 2–3 region of the hippocampus in a LBD patient. (G), Electron micrograph of a Lewy body. Note the dense core (gray) surrounded by a paler halo. (See color insert.)

in patients with both sporadic and familial DLB. From a susceptibility marker on chromosome 4q21-23 that segregated with the PD phenotype in Italian and Greek kindreds, A53T (Polymeropoulos et al., 1997) and A30P (Kruger et al., 1998) were the first two missense mutations in α -synuclein associated with familial Parkinson disease.

α -synuclein is a member of a larger family of synuclein proteins, which also includes β - and γ -synuclein. Like α -synuclein, β -synuclein has recently been implicated in PD and DLB pathogenesis, but its precise role in disease is still emerging. β -synuclein is highly localized to presynaptic sites in neocortex, hippocampus, and thalamus (Iwai et al., 1995) and it may act as a biological negative regulator of α -synuclein. Two novel β -synuclein point mutations, P123H and V70M, were found in highly conserved regions of the β -synuclein gene in respective familial (P123H) and sporadic (V70M) DLB index cases (Ohtake et al., 2004), where abundant LB pathology and α -synuclein aggregation was present without β -synuclein aggregation.

Unlike the other synuclein family members, γ -synuclein or persyn is largely expressed in the cell bodies and axons of primary sensory neurons, sympathetic neurons, and motor neurons as well as in brain (Buchman et al., 1998). γ -synuclein is the most recent synuclein member to be linked to LBD neuropathology and the least well understood. Single-nucleotide polymorphisms in all three synucleins have been associated with sporadic DLB, most prominently γ -synuclein (Nishioka et al., 2010).

STRUCTURAL MAGNETIC RESONANCE IMAGING

A diffuse pattern of global gray matter atrophy including temporal, parietal, middle, and inferior frontal gyri and occipital lobe has been reported in DLB, similar to AD (Beyer et al., 2007; Burton et al., 2004). Most volumetric studies have not found a significant occipital structural change in DLB

(Burton et al., 2002, 2004); this contrasts with the reported occipital hypometabolism/hypoperfusion noted with PET/SPECT studies, respectively. Longitudinal rates of whole-brain atrophy in PDD and DLB are probably intermediate between healthy aging and AD (O'Brien et al., 2001; Whitwell et al., 2007).

A robust MR finding in DLB and PDD is that of relative preservation of the medial temporal lobe when compared with AD (Barber et al., 2001; Burton et al., 2002; Whitwell et al., 2007); this holds promise as a diagnostic marker in differentiating AD from DLB (see Fig. 66.1).

Subcortical changes in terms of striatal atrophy have also been described in DLB. Putamen atrophy has been reported in DLB relative to AD (Cousins et al., 2003), but no significant differences were detected in caudate nucleus (Almeida et al., 2003; Cousins et al., 2003).

FUNCTIONAL IMAGING

OCCIPITAL HYPOPERFUSION AND HYPOMETABOLISM

Single-photon emission computed tomography (SPECT) studies in PD (Matsui et al., 2005) and DLB (Donnemiller et al., 1997) indicate reduced occipital perfusion relative to other cortical areas. It has been suggested that reduced flow in the medial occipital lobe, including the cuneus and the lingual gyrus, can discriminate LBD from AD, with a sensitivity and specificity of 85% (Shimizu et al., 2005). The possibility that parietal lobe perfusion is more severely reduced rather than occipital lobe hypoperfusion in DLB has also been raised (Ishii et al., 1998), which may be caused by the dopaminergic and/or cholinergic impairment in this region.

The use of PET scanning with markers such as [¹⁸F] fluorodeoxyglucose ([¹⁸F] FDG) shows metabolic reductions have been observed in the visual association cortex in DLB not evident in AD (Higuchi et al., 2000). A multicenter study examining ([¹⁸F] FDG) PET measures in the differential diagnosis of dementia, including AD, frontotemporal dementia (FTD), and DLB reported hypometabolism in the parieto-temporal and posterior cingulate cortices in AD, more prominent hypoperfusion in the occipital lobe in DLB, and more prominent hypometabolism in the frontal/temporal cortices in FTD. These cortical abnormalities discriminated DLB from AD with a sensitivity of 71% and a specificity of 95%. In another study, occipital hypometabolism and relative preservation of the posterior cingulate gyrus distinguished DLB from patients with AD with a sensitivity of 77% and a specificity of 80% (Lim et al., 2009). Greater metabolic decrease in the anterior cingulate has also been shown in DLB than PDD (Yong et al., 2007).

STRIATAL DOPAMINE LOSS

Nigrostriatal degeneration, with profound reductions in the striatal dopamine transporter, has consistently been found in patients with DLB at autopsy. Nigrostriatal integrity is assessed *in vivo* with specific ligands, such as ¹²³I-FP-CIT in SPECT

imaging, which binds to dopamine transporter and [¹¹C] dihydrotetrabenazine in PET imaging, which binds to the vesicular monoamine transporter T2 series.

Reduced striatal dopamine transporter uptake in DLB but not in AD has been shown in SPECT studies, which may aid in differential diagnosis (O'Brien et al., 2004; Walker et al., 2002). A large multicenter study examining ¹²³I-FP-CIT SPECT in DLB reported a sensitivity of 78% for detecting probable DLB and a specificity of 90% for excluding non-LBD, primarily AD (McKeith et al., 2007). In another study, ¹²³I-FP-CIT imaging was in line with postmortem diagnoses in 19 of 20 cases, and was more precise than clinical diagnosis (Walker et al., 2007). However, ¹²³I-FP-CIT is limited in that it does not discriminate DLB from other atypical parkinsonian syndromes. Nevertheless, head-to-head analyses comparing ¹²³I-FP-CIT imaging to other imaging modalities including ([¹⁸F] FDG)-PET have shown superior diagnostic accuracy with ¹²³I-FP-CIT imaging (Colloby et al., 2008; Lim et al., 2009).

Positron emission tomography studies have also been used to evaluate nigrostriatal dopaminergic degeneration in DLB. Reduction of striatal dopamine uptake was observed in patients with DLB using [¹⁸F] fluorodopa, with a sensitivity of 86% and a specificity of 100%, although this study was limited by a small sample size (Hu et al., 2000). These findings were confirmed in a later study using [¹¹C] dihydrotetrabenazine, which also showed significantly reduced uptake in caudate nucleus and anterior and posterior putamen in DLB and PD compared with patients with AD and normal controls (Koepp et al., 2008).

The latest revision of the International Consensus Criteria for DLB indicates that low dopamine transporter uptake in basal ganglia demonstrated by SPECT or PET imaging is a feature that in addition to a single core feature can support a diagnosis of probable DLB (I.G. McKeith et al., 2005). The National Institute for Health and Clinical Experience also recommends that ¹²³I-FP-CIT SPECT imaging may be particularly helpful when the diagnosis of DLB is unclear. Likewise, the European Federation of Neurological Societies (EFNS) guidelines also recommend the use of dopaminergic SPECT to differentiate between DLB and AD (Hort et al., 2010), the only imaging category to reach level A category of evidence.

CHOLINERGIC MARKERS

Brain cholinergic function can be estimated *in vivo* by measuring acetylcholinesterase (ACh) activity by PET using radiolabeled ACh analogues (Namba et al., 2002). Acetylcholinesterase is an enzyme that degrades ACh into the inactive metabolites choline and acetate. Several studies have demonstrated that cortical ACh activity is more severely and extensively reduced in the cerebral cortex, especially in the medial occipital cortex in DLB and PDD in comparison with AD, in which deficits were more prominent in the temporal cortex (Bohnen et al., 2003; Shimada et al., 2009).

Nicotinic and muscarinic receptors are subclasses of ACh receptors, implicated in memory and cognitive processes. Imaging of muscarinic receptors (Colloby et al., 2006) and nicotinic receptors (O'Brien et al., 2008) with SPECT has revealed

decreases in the frontal and temporal lobes of PDD and DLB, and relative increases in the uptake of both ligands in the occipital lobe, with the nicotinic ligand uptake being higher in DLB subjects with recent hallucinations (O'Brien et al., 2008). However, these changes are likely not specific to DLB because an increase in nicotinic binding in the occipital lobe has also been observed in vascular dementia (Colloby et al., 2011) and decreases have been noted in the frontal and temporal lobes in AD (O'Brien et al., 2007). The data are not yet compelling enough to suggest that PET and SPECT imaging looking at cholinergic activity could be used diagnostically in LBD.

METAIODOBENZYL Guanidine Myocardial Scintigraphy

[¹²³I] Metaiodobenzylguanidine myocardial scintigraphy is a noninvasive technique that was developed to evaluate the local myocardial sympathetic nerve damage, primarily in heart disease, and has only recently been used in LBD. The rationale for its use is that impairment of the peripheral sympathetic nervous system can occur even in the earliest clinical stage of PD (Spiegel et al., 2005). In addition, cardiovascular autonomic dysfunction is common in DLB (Allan et al., 2007). The early disturbance in the sympathetic nervous system can be detected by reduced MIBG uptake on myocardial scintigraphy independent of the duration of the disease.

A number of studies have demonstrated reduced MIBG uptake (heart to mediastinum ratio) in DLB relative to patients with AD and normal controls, with impressive accuracy for discriminating DLB from AD. Most studies performed measurement of both early (15- to 30-minute) and late (three- to four-hour) MIBG uptake, with the late image ratio typically resulting in better diagnostic accuracy. Several studies have found no correlation of MIBG scintigraphy with disease severity or duration of DLB or AD (Oide et al., 2003; Suzuki et al., 2006; Yoshita et al., 2001). Studies comparing MIBG scintigraphy and occipital hypoperfusion on SPECT have reported MIBG scintigraphy to be more sensitive in detecting DLB (Hanyu et al., 2006; Tateno et al., 2008). Also, MIBG scintigraphy has been reported to be more sensitive than cerebrospinal fluid (CSF) p-tau in terms of differentiating between DLB and AD (Wada-Isoe et al., 2007). No comparison with FP-CIT imaging has so far been carried out. However, one potential advantage of MIBG over FP-CIT is that myocardial MIBG can distinguish PD and DLB from atypical parkinsonian syndromes such as multiple system atrophy, corticobasal degeneration, and progressive supranuclear palsy (Spiegel, 2010), because in PD and DLB, the myocardial sympathetic damage is predominantly postganglionic, whereas in other parkinsonian syndromes, the preganglionic structures are mainly affected, resulting in normal MIBG uptake.

POSITRON EMISSION TOMOGRAPHY Amyloid Imaging

Over the past five years or so, amyloid imaging has emerged as important neuroimaging tool in studies of brain aging and dementia. Pittsburgh compound B (PIB) is currently the most

widely studied amyloid imaging agent. *In vitro*, PIB has been shown to bind specifically to extracellular and vascular fibrillar A β deposits in postmortem AD brains (Ikonomovic et al., 2008; Lockhart et al., 2007). At PET tracer concentrations, PIB does not significantly bind to other protein aggregates such as neurofibrillary tangles or Lewy bodies, and hence may be useful for diagnostically discriminating between AD and non-A β dementias (Rabinovici et al., 2007; Rowe et al., 2008).

As discussed, LBD is characterized at autopsy by the presence of subcortical and cortical LBs with a substantial burden of amyloid pathology also possible (Ballard et al., 2006). A limited number of PET studies have examined the amyloid burden in DLB and PDD *in vivo* (Edison et al., 2008; Gomperts et al., 2008). Edison et al. (2008) showed that in DLB, mean brain PIB uptake was significantly higher than that in controls, whereas uptake in PDD was comparable to controls and PD patients without dementia (Fig. 66.1). None of the patients with PD showed any evidence of increased cortical amyloid deposition. Gomperts et al. (2008) revealed that cortical amyloid burden as measured by PIB was higher in DLB than in PDD, but similar to that in AD. It may be that global cortical amyloid burden is high in DLB but lower and less frequent in PDD. Pittsburgh compound B imaging may prove to be useful to distinguish AD from PDD, but not AD from DLB.

CAREGIVER ISSUES

Lewy body dementia not only affects the individual diagnosed with the illness, but also has a profound impact on his or her caregivers, families, and friends. Those close to the patient have to learn to assist with the behavioral and emotional symptoms that accompany LBD, which are more pronounced and manifest earlier than in AD, as well as with the motor impairment, falls, and overall higher levels of disability than with other types of dementia (Ricci et al., 2009). Lewy body dementia caregivers also have to struggle through the often years-long challenge of obtaining an accurate diagnosis and adequate medical care for their relative.

The Lewy Body Dementia Association recently conducted an Internet survey of caregiver burden in LBD. Respondents were 611 people who stated that they were actively involved in the care of their relative with LBD. Results of this survey showed that in contrast to AD, many more LBD caregivers are women and are more often the spouse of the affected person. This difference likely reflects that fact that LBD is slightly more common in men than women, whereas AD is more common in women. Caregivers also reported many barriers in obtaining a diagnosis for their loved ones, with most having seen multiple physicians over more than a year before their relative was diagnosed with LBD and with more than three-fourths of persons with LBD given a different diagnosis at first.

Using these data from the Lewy Body Dementia Association, Leggett et al. (2011) were able to examine levels of stress and burden among caregivers of patients with LBD. Subjective burden was assessed with a 12-item short version of the Zarit Burden Interview. The results showed that caregivers

of patients with LBD experience significant perceptions of burden that is heightened by behavioral and emotional problems present early on in LBD (depression, irritability, hallucinations, delusions, sleep disturbances, nightmares, and unusual sleep movements), impaired ADLs, sense of isolation, and challenges with the diagnostic experience. Significantly, the level of subjective burden among this group of caregivers was noted to be higher than what is typically endorsed among caregivers of AD or mixed diagnostic groups. These data suggest that future interventions targeting each of these challenges are needed for caregivers of patients with LBD.

THERAPEUTIC APPROACHES

There are no approved therapies specifically for LBD; however, there is ample evidence in the literature regarding the use of medications approved for other disorders for the treatment of the various symptoms of LBD.

COGNITIVE SYMPTOMS

Acetylcholinesterase inhibitors (AChEIs) may be especially useful in the treatment of LBD. These medications, including donepezil (Aricept), rivastigmine (Exelon), and galantamine (Razadyne ER or Reminyl) block the breakdown of acetylcholine within the synapse, thereby prolonging its effect on post-synaptic receptors. AChEIs are generally well tolerated at their standard dosing. Primary side effects are gastrointestinal (e.g., nausea, vomiting, diarrhea, anorexia, weight loss); other side effects can include insomnia, vivid dreams, leg cramps, and urinary frequency.

It has been suggested that treatment with AChEIs may be more effective in DLB than AD because of early and prominent central nervous system cholinergic dysfunction in this group (Touchon et al., 2006). In one study, patients with DLB showed greater treatment improvement in cognition relative to AD patients, although the difference between the two groups was not significant (Samuel et al., 2000). Only a few clinical trials for the use of AChEIs in LBD have been conducted and most guidelines are based on case reports and extension of therapeutic trials in AD. Three independent clinical studies of AChEI treatment using donepezil, galantamine, and rivastigmine in patients with LBD suggest that AChEIs improve cognitive and neuropsychiatric measures, with no significant increase in EPS with AChEI use. Rivastigmine was the first AChEI to be given European and American marketing approval for patients with mild to moderate PDD. Currently, there is no compelling evidence that any one AChEI is better than the other.

The NMDA antagonist memantine, another treatment modality approved for use in AD, has not yet been tested in large, randomized, controlled studies in PDD. Results have been variable in a few case reports or case series in patient with DLB, with both worsening (Ridha et al., 2005) and improvement (Sabbagh et al., 2005) noted. Good tolerability and possible benefits have been reported in a small case series of patients with PDD.

MOTOR SYMPTOMS

There are no controlled clinical trials that have yet evaluated the treatment of motor features in DLB. There are reports of small series of patients with DLB whose motor impairments were successfully treated with L-dopa (Molloy et al., 2005). Levodopa is more effective in treating motor impairments in idiopathic PD than DLB. Dopamine agonists are associated with more side effects, especially drug-induced psychosis, even at low doses. Given this risk and because the motor impairments may be mild, the recommendation is to treat the movement disorder only if the motor symptoms interfere with function. Antiparkinsonism medicines should be initiated at the lowest possible dose and increased with caution. There have been reports of increased adverse events with the combined use of L-dopa and cholinesterase inhibitors in PD (Okereke et al., 2004).

Other PD medications such as amantadine, catechol-O-methyltransferase inhibitors, monoamine oxidase inhibitors, and anticholinergics tend to exacerbate cognitive impairment and should ideally be avoided. Furthermore, the cognitive impairment in DLB makes them poor candidates for DBS. Cholinesterase inhibitors can potentially worsen parkinsonism. In a study of rivastigmine in PD, approximately 10% of patients treated with rivastigmine had worsening of tremor (I. McKeith et al., 2000). However, their overall motor function was not significantly different between the treatment and placebo groups (I. McKeith et al., 2000).

BEHAVIORAL SYMPTOMS

As discussed, behavioral symptoms frequently accompany LBD. Clinical experience suggests that nonpharmacological treatment approaches should be considered first, including evaluating for physical ailments that may be provoking behavioral disturbances (e.g., fecal impaction, pain, or decubitus ulcers). Avoidance or reduction of doses of other medications that can potentially cause agitation should also be attempted. Both anxiety and depression are common occurrences in LBD. Generally speaking, when medications are needed to modify behaviors, they should be used for the shortest duration possible. Benzodiazepines are better avoided given their risk of sedation and paradoxical agitation.

There have been no randomized, controlled studies of antidepressants in patients with PDD. In one systematic review, amitriptyline was found to be the only compound with evidence of efficacy in PD depression; however, tricyclic antidepressants such as amitriptyline should be avoided in patients with PDD because of their anticholinergic effects.

ANTIPSYCHOTICS

Visual hallucinations have been considered predictors of a good response to AChEIs (I. McKeith et al., 2004). Classical neuroleptics (e.g., haloperidol) are best avoided in DLB because they may worsen motor function and even potentially result in life-threatening neuroleptic sensitivity. Experience with atypical antipsychotics in LBD has been mixed. Risperidone and

olanzapine have been shown to control psychosis and agitation in AD in randomized trials. Although low doses of risperidone (0.5 mg) and olanzapine (2.5 mg) are usually well tolerated and do not usually result in motor deterioration (Katz et al., 1999), motor deterioration may still be seen in advanced LBD (Walker et al., 1999).

Quetiapine and clozapine are preferred treatment options when pharmacological intervention is warranted. Randomized, placebo-controlled studies showing significant improvement of psychosis without worsening of motor symptoms has only been shown with clozapine (Friedman and Fernandez, 2002). However, given the potentially fatal adverse event of agranulocytosis and need for blood monitoring, it is not a first-line treatment. Apiprazole has not been studied in LBD but it has been shown to be effective in PD and AD and may be considered in LBD if needed. Quetiapine has become a popular treatment of psychosis in LBD given the low incidence of motor deterioration and its ability to control visual hallucinations at low doses. Efficacy and tolerability have been documented in both PD and DLB (Friedman and Fernandez, 2002). It is worth noting that hallucinations that are non-threatening to the patient and do not disturb function may not require pharmacological intervention. Rapid eye movement sleep behavior disorder generally responds to low doses of clonazepam before sleep.

ACETYLCHOLINESTERASE INHIBITORS FOR BEHAVIORAL SYMPTOMS

A metaanalysis of six large trials in AD showed a small but significant benefit for AChEIs in treating neuropsychiatric symptoms (Trinh et al., 2003). There also appears to be a differential effect of AChEIs on different psychiatric symptoms, with psychosis, agitation, wandering, and anxiety being the most consistently responsive. In a large multicenter trial, rivastigmine resulted in a 30% improvement from baseline in psychiatric symptoms (McKeith et al., 2000). In a case-control study of rivastigmine, treatment was associated with a reduction in NPI scores, hallucinations, and sleep disorders compared with AD. There were lower rates of apathy, anxiety, delusions, and hallucinations in the treatment group compared with controls. It is not clear whether this effect on behavior is owing to drug effect or more severe behavioral pathology in LBD.

AUTONOMIC DYSFUNCTION

Management of orthostatic hypotension includes relatively simple measures such as leg elevation, elastic stockings, increasing salt and fluid intake, and if not medically contraindicated, avoiding medications that can exacerbate orthostasis. Medications such as midodrine or fludrocortisone can be used in the event that such simple measures fail. Midodrine is a vasoconstrictor and side effects include urine retention and supine hypertension. Fludrocortisone has mineralocorticoid activity and causes fluid retention.

Medications with anticholinergic activity, including oxybutynin, tolterodine tartrate, bethanechol chloride, and

proprantheline can be used to treat urinary urgency, frequency, and urge incontinence. Because they can potentially exacerbate cognitive problems, these medications should be used cautiously. Because LBD is more common in men, the risk of producing urinary retention in the setting of prostatic hypertrophy should be considered.

Constipation can usually be treated by exercise and dietary modifications. Laxatives, stool softeners, and mechanical disimpaction may be needed. The prokinetic effect of cholinergic stimulation by AChEIs might improve these symptoms in some patients.

CONCLUSIONS

Lewy body disorders are a common cause of dementia in elderly people, characterized by varying degrees of cognitive, behavioral, affective, movement, and autonomic dysfunction in older adults. The LBD syndromes are associated with the accumulation of Lewy bodies in subcortical, limbic, and neocortical regions and are characterized clinically by progressive dementia, parkinsonism, cognitive fluctuations, and visual hallucinations. Whether or not PDD and DLB reflect the same underlying disorder whose differences in symptom presentation are merely the end product of the underlying brain region(s) affected earlier or later in the disease course is the subject of much controversy. For now, current diagnostic criteria for PDD and DLB advise that clinical distinctions be maintained (“one year rule”) even though they are pathologically similar. From a neuropsychological perspective, PDD and DLB are more readily distinguished from AD than from each other. It is hoped that the identification of a prodrome of PDD may improve our understanding of the earliest cognitive changes associated with LBD. This information can then be used in conjunction with biomarkers to diagnose these disorders earlier, as well as aid in the prediction and monitoring of treatment response and development of more selective therapeutic agents. Public awareness campaigns that specifically address LBD are also hoped for, as these may aid in generating interest and understanding of this group of dementias, and maybe even stimulate efforts to develop appropriate supportive programs and services for patients and their family caregivers.

DISCLOSURES

Dr. Karantzoulis has no conflicts of interest to disclose. She serves as co-investigator for one NIH grant (R01 AG040211-A1) and one Michael J. Fox Foundation for Parkinson Research award. She does not receive financial compensation or salary support from any pharmaceutical company.

Dr. Galvin is funded by grants from the NIH, Michael J. Fox Foundation, Alzheimer Association, New York State Department of Health, and Morris and Alma Schapiro Fund. Dr. Galvin serves as a consultant for Pfizer, Eisai, Baxter, Accera, Novartis, and Forest. He does hold stock or any equity in any pharmaceutical company.

67 | CLINICAL FEATURES AND PATHOGENESIS OF FRONTOTEMPORAL DEMENTIA

GEORGES NAASAN AND BRUCE MILLER

First described by Pick in 1892 as frontal lobe dementia, frontotemporal dementia (FTD) was neglected for almost a century before re-emerging as a clinically important neurodegenerative disease. It is the second most common dementia in patients under the age of 65 and the third, after Alzheimer's disease (AD) and dementia with Lewy bodies (DLB), in the elderly population. In neuropathological studies, frontotemporal lobar degeneration (FTLD) was found to be the third leading neuropathological diagnosis of neurodegenerative diseases with a prevalence of 4% after AD (42%) and vascular disease (VD; 23.7% isolated and 21.6% in combination with AD) (Brunnstrom et al., 2009).

Frontotemporal dementia (FTD) is used to describe a group of clinical syndromes that are caused by frontal and/or temporal lobe dysfunction with a relative preservation of the posterior brain structures that are typically involved in AD and DLB. The clinical presentation of FTD is insidious and slowly progressive. The predominant symptom can be behavioral changes (orbitofrontal, medial frontal, and/or anterior temporal lobe), executive function impairment (dorsolateral frontal), and/or language impairment (perisylvian, frontoinsular, or anterior temporal lobe) giving rise to various clinical subtypes that are summarized in Table 67.1.

The term frontotemporal lobar degeneration (FTLD) refers to the pathological syndrome associated with predominant frontal and/or temporal lobe atrophy (Cairns et al., 2007). Most FTLD cases show neuronal aggregates of tau, TDP-43, or FUS. Some FTD subtypes overlap with other neurological syndromes, including amyotrophic lateral sclerosis (ALS) in frontotemporal dementia with motor neuron disease (FTD-MND) (Caselli et al., 1993; Lomen-Hoerth et al., 2002; Neary et al., 1990; Neary et al., 2000) and parkinsonism in corticobasal syndrome (CBS) and progressive supranuclear palsy (PSP). Novel genetic mutations in familial and sporadic cases of FTD have been identified in the past decade and their implications continue to be a major subject of research.

Frontotemporal dementia represents a disorder of behavior that is caused by neurodegeneration, and this concept can be difficult for physicians to understand. Often, FTD is ascribed to conditions of the "psyche," without making an attempt to understand them as caused by degeneration in specific brain structures. In addition, patients with FTD may present fairly young, sometimes in their young adulthood, which is the

typical age at presentation for many psychiatric disorders such as schizophrenia and bipolar disease.

Many examples of FTD being misdiagnosed as a psychiatric disorder are reported in the literature and expose the medical and social burdens of a misdiagnosis on patients and their caregivers (Khan et al., 2012). Approximately 30% of patients with a neurodegenerative disease are initially erroneously diagnosed as having a psychiatric illness, especially when the predominant presentation is behavioral issues (Woolley et al., 2011).

EPIDEMIOLOGY AND DEMOGRAPHICS

The prevalence and incidence of FTD is variably reported and has been difficult to ascertain, partly because of the heterogeneity of the clinical syndromes and the pathological diagnoses that the terms FTD and FTLD encompass. It is likely that all of the previous studies have underestimated the true prevalence of FTD for a variety of reasons. First, many patients with FTD never get diagnosed and end up in mental institutions or prisons. Additionally, the co-association of FTD with memory difficulty, parkinsonian movement disorders, and amyotrophic lateral sclerosis means that even when a neurodegenerative disorder is recognized, many FTD patients are classified as having another neurodegenerative condition.

Studies conducted by European investigators suggested that the prevalence of a clinical frontal-lobe predominant dementia was between 12% and 16% at autopsy (Brun, 1987; Greicius et al., 2002). The release of the Lund-Manchester criteria for the diagnosis of FTD in 1994 (The Lund and Manchester Groups, 1994), followed later by the publication of the Neary criteria in 1998, helped to establish a clinical framework from which researchers could attempt to determine the epidemiology of the disease (Neary et al., 1998). By applying those clinical criteria, the prevalence of FTD in the United Kingdom was found to be similar to that of AD in the age group of 45 to 65 and was estimated at 15 per 100,000 (Ratnavalli et al., 2002). In the Netherlands, the prevalence of FTD was found to be lower and peaked between the ages of 60 to 69 at 9.4 per 100,000. It was roughly four in 100,000 for the age groups 50 to 59 and 70 to 79 (Rosso et al., 2003). For individuals age 85 and greater, the prevalence of the frontal variant of FTD according to the

TABLE 67.1. Clinical subtypes of frontotemporal dementia

	BVFTD	PNFA	SVPPA	LPA	CBS	PSP
Classical clinical presentation	Behavioral changes including disinhibition, lack of empathy, apathy, obsessions and ritualistic behavior, overeating, and executive problems	Non-fluent speech with agrammatism and apraxia of speech; usually with sparing of repetition, object, and word knowledge	Word finding difficulties with loss of individual word meaning and object knowledge; usually with fluent speech and spared grammar	Difficulty with spontaneous word retrieval and phonological memory loop with impaired repetition and intact grammar and semantic knowledge	Asymmetric parkinsonism, tremor, and rigidity with possible alien hand, dystonia, and apraxia	Postural imbalance, eye movement abnormalities, and parkinsonism
Patterns of atrophy on MRI	Bilateral frontal and/or temporal	Left frontoinsula and opercular	Left (and/or right) anterior temporal lobe	Left angular gyrus	Unilateral peri-rolandic dorsal	Midbrain atrophy
Associated pathology	Tau: 3R (Pick disease), 4R (CBD or PSP); TDP-43: Type A (in GRN mutations), B (in C9 mutations), C or D	Tau: 3R (Pick disease), 4R (CBD or PSP) TDP-43: Type A	TDP-43: Type C	AD pathology (plaques and tangles)	Tau: 4R (CBD most common, PSP) AD pathology TDP-43	Tau: 4R (PSP)

AD, Alzheimer’s disease; bvFTD, behavioral variant frontotemporal dementia; CBD, corticobasal degeneration; CBS, corticobasal syndrome; FTD, frontotemporal dementia; LPA, logopenic progressive aphasia; PNFA progressive non-fluent aphasia; PSP, progressive supranuclear palsy; svPPA, semantic variant of primary progressive aphasia; TDP, TAR DNA binding protein.

Lund-Manchester criteria was calculated at 3% (Gislason et al., 2003).

Frontotemporal dementia seems to peak in the sixth and seventh decades. The incidence of FTD was reported to be 2.2, 3.3, and 8.9 per 100,000 person-years in the age groups of 40 to 49, 50 to 59, and 60 to 69, respectively, as compared with 0.0, 3.3, and 88.9 for AD (Knopman et al., 2004). In the United Kingdom, the incidence of FTD in the age group of 45 to 64 was found to be 3.5 per 100,000 person-years as compared with 4.2 for AD (Mercy et al., 2008). The age of onset in FTD can vary according to the specific subtype of the disease. It is generally between 50 and 60 years of age and might be dependent on the underlying pathology and on genetic factors (Johnson et al., 2005; Rosso et al., 2003; Seelaar et al., 2008). Although patients with the bvFTD appear to have the earliest onset, patients with svPPA have an earlier onset than those with PNFA (Johnson et al., 2005).

In a study of the California State Alzheimer’s Disease Centers the frequency of FTD as a clinical diagnosis was different across ethnic differences: 4.2% in Asians and Pacific Islander and 4.7% in Caucasians, but was significantly less in Blacks (1.5%) and Latinos (2.4%) (Hou et al., 2006). Sadly most of this data was collected during the 1980s and 1990s when FTD was severely neglected and underdiagnosed in the United States, accounting for the low prevalence in this study.

The evidence for gender differences in FTD is conflicting. Although some studies report no significant differences (Hou et al., 2006; Ikeda et al., 2004; Mercy et al., 2008; Papageorgiou et al., 2009), others suggest that there is a male predominance in the behavioral and semantic subtypes and a female predominance in the non-fluent aphasia group (Ratnavalli et al., 2002; Johnson et al., 2005). Frontotemporal dementia is strongly familial, and patients with FTD were reported to have a family

history of dementia in 10% to 38% of the cases (Chow et al., 1999; Stevens et al., 1998). Psychiatric illnesses in these families, including major depression and schizoaffective disorders, were reported in 33% of patients with FTD (Chow et al., 1999).

Although the typical survival of patients with Alzheimer’s disease from the time of diagnosis to death is reported to be seven to 13 years from symptom onset (Garcin et al., 2009; Roberson et al., 2005), the survival of patients with FTD is shorter, ranging from 3.4 years for patients with bvFTD to closer to six years for those with semantic variant primary progressive aphasia (Roberson et al., 2005).

CLINICAL PRESENTATIONS AND DIAGNOSTIC CRITERIA

BEHAVIORAL VARIANT OF FRONTOTEMPORAL DEMENTIA

Behavioral variant of frontotemporal dementia (bvFTD) is the most common subtype of FTD (Johnson et al., 2005). An international consortium revised and published new criteria for the diagnosis of bvFTD in 2011 and compared their sensitivity with the previous criteria set forth by Neary in 1998 in 137 pathology confirmed cases of FTL (Rascovsky et al., 2011). The new criteria were superior to the previous ones in picking up possible and probable bvFTD when it corresponded to a pathological diagnosis of FTL. These criteria are summarized in Table 67.2.

Often bvFTD patients have little insight into their problems and interviewing an informant is essential in diagnosing bvFTD. In fact, in early stages, the diagnosis can be completely missed if patients are interviewed without an informant, and they can have an intact cognitive performance on routine neuropsychology testing (Miller et al., 1991).

TABLE 67.2. Diagnostic consensus criteria for FTD and PPA

BEHAVIORAL VARIANT OF FRONTOTEMPORAL DEMENTIA (bvFTD)
<p>I. Possible bvFTD (three out of the six following symptoms [a–f] should be present to meet criteria)</p> <p>A. Early behavioral disinhibition</p> <p>B. Early apathy or inertia</p> <p>C. Early loss of sympathy or empathy</p> <p>D. Early perseverative, stereotyped, or compulsive/ritualistic behavior</p> <p>E. Hyperorality and dietary changes</p> <p>F. Neuropsychological profile: executive/generation deficits with relative sparing of memory and visuospatial functions</p> <p>II. Probable bvFTD (all of the following [a–c] must be present)</p> <p>A. Meets criteria for possible bvFTD</p> <p>B. Exhibits significant functional decline</p> <p>C. Imaging results consistent with bvFTD</p> <p>III. Exclusion Criteria</p> <p>A. Pattern of deficits is better accounted for by other non-degenerative nervous system or medical disorders</p> <p>B. Behavioral disturbance is better accounted for by a psychiatric diagnosis</p> <p>C. Biomarkers strongly indicative of Alzheimer’s disease or other neurodegenerative process</p>
PRIMARY PROGRESSIVE APHASIA (PPA)
<p>I. Inclusion Criteria (All of a-c must be present)</p> <p>A. Most prominent clinical feature is difficulty with language</p> <p>B. Deficits are the principal cause of impaired daily living activities</p> <p>C. Aphasia should be the most prominent deficit at symptom onset and for the initial phases of the disease</p> <p>II. Exclusion Criteria</p> <p>A. Pattern of deficits is better accounted for by other non-degenerative nervous system or medical disorders</p> <p>B. Cognitive disturbance is better accounted for by a psychiatric diagnosis</p> <p>C. Prominent initial episodic memory, visual memory, and visuo-perceptual impairments</p> <p>D. --

BEHAVIORAL VARIANT OF FRONTOTEMPORAL DEMENTIA

Patients with the behavioral variant of frontotemporal dementia (see Case 1 later in chapter) often present initially to the psychiatry clinic with what appears to be a mania or depression, or to a marriage counselor because of marital problems. The first presenting symptom is often one of disinhibition and social inappropriateness (Miller et al., 1991). As an example, patients might become overly friendly, approaching strangers and starting conversations that are too personal or explicit. Excessive trust of strangers coupled with a difficulty in making sound judgments, can particularly make these individuals vulnerable to exploitation, both sexually and financially. In fact, many spouses may report that their loved ones were the subjects of an online or telephone prank involving investing suspicious amounts of money in unfounded organizations. Symptoms of disinhibition correlate mainly with a pattern of atrophy in the orbitofrontal cortex but can also involve the subgenual cingulate, medial prefrontal, and anterior temporal cortex, as well as the white matter tracts connecting those regions, as measured by voxel-based morphometry and diffusion tensor imaging analysis (Hornberger et al., 2011; Peters et al., 2006; Rosen et al., 2005).

Apathy, social withdrawal, and decreased motivation are often reported (Rosen et al., 2005). Informants may report a decrease in interest for previous hobbies and a general attitude of indifference. In an objective assessment of daytime activity using a wristwatch that measures motion, patients with bvFTD spent 25% of their day immobile compared with their caregivers, who spent 11% of their day immobile (Merrilees et al., 2012). Apathy was found to correlate with reduced gray matter density in the right dorsolateral prefrontal cortex, right ventromedial superior frontal gyrus, right anterior cingulate, right lateral orbitofrontal cortex, right caudate, right temporoparietal junction, and right posterior inferior and middle temporal gyri (Eslinger et al., 2012; Rosen et al., 2005; Zamboni et al., 2008). A subclassification of bvFTD presentations, separating between predominantly disinhibited and predominantly apathetic, was suggested in the past (Snowden et al., 2001); however, it was shown that most cases are often mixed, and if not,

they mostly progressed to mixed within four years of disease duration (Le Ber et al., 2006).

Patients with bvFTD can make rude remarks or gestures without regard for other people's feelings. They are often described as becoming self-centered and losing the ability to understand the feelings of others. Families often describe insensitivity to someone else's illness or injury. Patients become emotionally distant and detached. This often creates a toxic dynamic for couples. Also, because the majority of the patients present at a younger age, children who may be in their early teenage years, or even younger, may complain that their father or mother had become less affectionate and less involved in their schooling and upbringing. Neuroanatomical correlates of empathy include the right anterior temporal and medial frontal regions in a large-scale correlation study by voxel-based morphometry analysis of magnetic resonance imaging (MRI) data (Rankin et al., 2006). Also, by similar methods, an impaired recognition of emotions, and specifically negative emotions such as sadness, correlated with right lateral inferior temporal and right middle temporal gyri (Rosen et al., 2006).

Patients with bvFTD can become obsessed with specific thoughts and display compulsory behavior, which may be either simple or complex. For example, there may be repetitive picking, chewing, lip smacking, or pacing; there may also be constant locking and unlocking, as well as rituals that can be bizarre in nature. Compulsions can also manifest as hoarding. Mental rigidity occurs and patients may become less flexible to changes in plans or routines. Examples include exercising at a specific hour every day, eating specific types of food at specific times of the day, and taking the same route when walking their dogs.

Informants often describe hyperorality and inability to refrain from eating, even after satiety is achieved. A change in diet and more specifically a craving for sweets is often reported, as well as eating non-food items. The excessive, compulsive eating can result in weight gain. Hyperorality can also manifest in excessive drinking of alcohol, smoking, or chewing gum. Hyperorality despite reported satiety was found to correlate with right orbitofrontal, insular, and striatal regions, supporting the hypothesis that this circuitry is involved in higher gustatory integration and internal satiety signaling (Woolley et al., 2007). In another study, overeating correlated with loss of tissue in the posterior hypothalamus (Piguet et al., 2011).

Neuropsychological testing in patients with bvFTD primarily reveals deficits in executive functions (Kramer et al., 2003), with a relative sparing of verbal and visual memory and performance that is error prone and perseverative. It is important to recognize that episodic memory can be impaired in bvFTD (Hodges et al., 2004), even in early stages, and especially in some genetic forms of the disease that involve the progranulin gene (van Swieten and Heutink, 2008). Rule violation errors on neuropsychological testing correlated with tissue loss in the right lateral prefrontal cortex (Possin et al., 2009). In contrast, executive function tasks seem to be more diffuse and invoke attention, and visuospatial and language networks. Specific tasks of the executive function testing can localize to a specific region of the brain. Verbal fluency, in which patients are asked to generate the maximum number of words they can think of that start with a specific letter in one minute, correlated with

tissue loss in the left perisylvian cortex, while card-sorting tasks with the left dorsolateral prefrontal cortex (Huey et al., 2009). Set shifting tasks such as trails-making correlated with tissue loss in prefrontal and posterior parietal regions (Pa et al., 2010). Patients with bvFTD usually have relatively spared performances on verbal and visual memory tasks as well as visuospatial tasks.

With new emerging neuroimaging techniques, it is proposed that neurodegenerative diseases may involve various regions of the brain that operate together and are collectively referred to as brain networks. For example, the default mode network, including the posterior cingulate, medial temporal, lateral temporoparietal, and dorsal medial prefrontal regions, is thought to be involved in Alzheimer's disease (Greicius et al., 2003; Buckner et al., 2005). Seeley and colleagues have shown prominent deficits in functional connectivity in other networks such as the salience using task free functional MRI and this promising technique is likely to become standard in the assessment of patients with bvFTD (Seeley et al., 2009; Seeley et al., 2012; Zhou et al., 2010).

FRONTOTEMPORAL DEMENTIA AND MOTOR NEURON DISEASE

The co-association of FTD and ALS is now accepted at a clinical, neuropathological, and genetic level (Caselli et al., 1993; Lomen-Hoerth et al., 2002; Neary et al., 1990; Neary et al., 2000). Patients with frontotemporal dementia and motor neuron disease (FTD-MND) have the typical features of bvFTD that are either preceded or shortly followed by typical features of ALS. Perhaps one of the features that should make the clinician suspicious of MND with bvFTD is the lack of weight gain that classically comes with hyperorality, but instead, there is loss of weight resulting from muscle atrophy and diminished desire to swallow. Also, patients with FTD-MND have the highest frequency of concomitant psychotic symptoms, including delusions and hallucinations, which are less common in more classical forms of bvFTD. Familial FTD-MND was found to correlate with a genetic mutation on chromosome 9 and, in recent years, the culprit gene, C9ORF72, was discovered (see next section).

BEHAVIORAL VARIANT OF FRONTOTEMPORAL DEMENTIA "PHENOCOPY"

After the publication of diagnostic criteria for bvFTD, a group of patients was identified that fulfilled the criteria without necessarily progressing to a clinically defined dementia state, frequently plateauing at mild stages of the disease (Davies et al., 2006). These patients are referred to as bvFTD "phenocopies" because they display the "phenotype" of the disease, presumably without evidence of an underlying neurodegenerative process. These patients also score better on measures of activities of daily living as compared to patients with bvFTD (Mioshi et al., 2009). On neuropsychology testing, executive functions that are usually impaired in bvFTD may be spared in patients with the phenocopy (Hornberger et al., 2008). Magnetic resonance imaging is usually normal and does not reveal the typical pattern of frontal lobe

atrophy seen in patients with the progressive type (Davies et al., 2006; Kipps et al., 2007). Further functional imaging with fluorodeoxyglucose-positron emission tomography (FDG-PET) displays no hypometabolism in frontal brain regions (Kipps et al., 2009). Patients with the phenocopy often have a much longer survival and seldom get institutionalized, as opposed to their progressive counterparts who usually advance to death or institutionalization within three to four years (Davies et al., 2006; Garcin et al., 2009). Few of these cases that have come to autopsy have been reported in the literature as lacking the pathological changes typically seen in FTLD (Kertesz et al., 2005), however, there is not yet a large number of autopsies to definitively classify these patients as lacking a clear neurodegenerative process.

Recently the discovery of the C9ORF72 gene as implicated in the pathogenesis of FTD led to some re-examination of patients previously labeled as phenocopy. It was found that two out of four patients with the bvFTD phenocopy diagnosis harbored the mutation, raising concerns that there might in fact be an underlying neurodegenerative process in at least a subset of these slowly progressive patients (Khan, Yokoyama et al., 2012b).

PRIMARY PROGRESSIVE APHASIA

Primary progressive aphasia should be diagnosed when a patient experiences a progressive decline in language in which other cognitive domains and behavior are relatively spared for two years (Mesulam, 1982). The hallmark of the PPAs is a predominant deficit in conversational skills and language with an initial relative sparing of other cognitive and behavioral domains such as memory, executive functions, and visuospatial skills (Mesulam, 1982, 2001). Care must be taken when assessing other cognitive domains in a patient who has a primary language deficit because language greatly influences virtually all other cognitive functions. As an example, a person who does not understand the meaning of words may have difficulty memorizing them on verbal learning tasks.

Initial studies found that a primary language deficit can be the presenting clinical syndrome of many underlying brain pathologies, including FTLD, corticobasal degeneration, progressive supranuclear palsy, Creutzfeldt–Jakob disease, and Alzheimer’s disease (Galton et al., 2000; Kertesz et al., 2000; Neary et al., 1998). In the past decade, a clearer understanding of primary language disorders divided their clinical presentation into three primary subtypes, each with a different clinical presentation and a distinct focal neuroanatomical correlate (Gorno-Tempini et al., 2004). Each subtype also provides clues for the prediction of the underlying pathological neurodegenerative process. The classification criteria for PPA set forth by an international group of PPA investigators are summarized in Table 67.2 (Gorno-Tempini et al., 2011).

NON-FLUENT VARIANT OF PRIMARY PROGRESSIVE APHASIA

Non-fluent variant of primary progressive aphasia (nfvPPA) is characterized by difficulties in speech production including

agrammatism, an effortful, slow speech and/or apraxia of speech, defined as presence of speech initiation difficulties, sound distortion or substitution, and deletion or transposition of syllables (Gorno-Tempini et al., 2004; Hodges and Patterson, 1996; Neary et al., 1998). This can be apparent in spontaneous speech or when patients are given a polysyllabic word to say multiple times in a row. Phonemic paraphasias such as faulty syllable sequencing (amadant for adamant) or improper usage of phoneme (bumble for mumble) can occur. Patients are usually aware of their deficits and may try to correct their pronunciation errors, which often leads to frustration.

In addition to these deficits in language production, difficulty in understanding complex sentences with difficult grammatical syntax may indicate agrammatism in comprehension. Single-word comprehension is typically preserved and patients with nfvPPA perform within normal limits on word comprehension tasks (Gorno-Tempini et al., 2004). Patients with nfvPPA are the most likely to have motor findings on their neurological examination consisting of rigidity, and slowing and reduced dexterity, usually observable in the right arm (Gorno-Tempini et al., 2004). Brain atrophy is mostly localized to the left perisylvian region, and more specifically to the pars opercularis and pars triangularis (Gorno-Tempini et al., 2004). The clinical presentation of nfvPPA usually points to an underlying pathology of CBD or TDP-43 type A (see the following).

SEMANTIC VARIANT OF PRIMARY PROGRESSIVE APHASIA

The semantic variant of primary progressive aphasia (svPPA) (see Case 2 later in chapter) was initially described in its left predominant form, which presents with a loss of knowledge of words and objects in the setting of a relatively preserved speech production (fluent speech) and grammar both in production and comprehension (Gorno-Tempini et al., 2004; Hodges et al., 1992). Surface dyslexia can occur and is defined as the inability to recognize (and correctly read) irregular words, sounding them out instead. For example, a patient with surface dyslexia might read choir as chore. Similarly, spelling errors resulting from the inability to recognize words also occurs: in a word such as orchestra, the “ch” is pronounced and yacht is spelled like “yat.” Patients with svPPA perform poorly on confrontation naming and word recognition tasks. In fact, their speech often contains non-specific words such as thing or animal to circumvent words that they have lost the meaning of (Gorno-Tempini et al., 2004). Conversational speech is usually comprehended, although patients may ask about the meaning of a specific word in conversation. Patients with svPPA usually exhibit no motor findings on their neurological examination (Gorno-Tempini et al., 2004).

Patients with svPPA often develop more behavioral changes in the course of their disease than do those with other subtypes of PPA (Rosen et al., 2006). Prominent features of these behavioral manifestations include loss of empathy, irritability, mental rigidity, and compulsive behavior, as well as disruption of sleep, appetite, and libido, likely speaking for the role of the anterior temporal lobe and the orbital frontal cortex (where

svPPA quickly spreads to) in the manifestation of these symptoms. When the predominant presentation is behavioral, then the syndrome is that of right-sided predominant svPPA. In a longitudinal study of patients with either the right or left predominant svPPA, it was found that the disease spread to the contralateral temporal lobe within three years so that patients with initial language problems develop the behavioral disturbances later on and vice versa (Seeley et al., 2005). Both progressed to a more frontal type of behavioral disturbance within seven years.

Brain atrophy in svPPA localizes to the anterior temporal lobes bilaterally and can involve both lateral and medial aspects of the temporal lobe, including the inferior, middle, and superior temporal gyrus (Gorno-Tempini et al., 2004). The clinical presentation of svPPA strongly indicates an underlying pathology of TDP-43 type C.

LOGOPENIC VARIANT OF PRIMARY PROGRESSIVE APHASIA

Patients with the logopenic variant of PPA (lvPPA) have a deficit in phonological memory, often erroneously termed echoic memory. Phonological memory allows a person to hold short-term information by “repeating” and “hearing” it in his or her mind, such as when given a phone number to dial. Patients with lvPPA have a slow and syntactically simple speech with many word-finding difficulties. They have difficulties repeating and comprehending long sentences, regardless of their syntactic difficulties. Patients with lvPPA can have difficulty with calculation and with memory tasks (Gorno-Tempini et al., 2004). Brain atrophy localizes to the angular gyrus and posterior aspects of the middle temporal gyrus (Gorno-Tempini et al., 2004). The underlying pathology of lvPPA appears to be that of plaques and tangles similar to that seen in classical Alzheimer’s disease (Alladi et al., 2007; Josephs et al., 2008). Also, neuroimaging using Pittsburgh compound-B PET demonstrated that these patients have an amyloid deposition pattern similar to that seen in classical Alzheimer’s disease (Rabinovici et al., 2008). In fact, lvPPA is now considered another “atypical” presentation of the more classically memory-predominant presentation of Alzheimer’s disease.

CORTICOBASAL SYNDROME

Corticobasal syndrome (CBS) is clinically characterized by asymmetrical basal ganglia symptoms manifesting as parkinsonism, rigidity, akinesia, tremor; and cortical symptoms manifesting as apraxia, myoclonus, cortical sensory loss, and alien limb (Gibb, Luthert, & Marsden, 1989b; Kompoliti et al., 1998; Boeve et al., 2003). The clinical syndrome and the pathological diagnosis of corticobasal degeneration (CBD, discussed in the following) were used interchangeably for decades. Yet, CBS and CBD are two distinct entities. Corticobasal degeneration, a neuropathologically defined entity, a four-repeat tauopathy with distinctive cortical and subcortical tau aggregates has variable clinical presentations; and, CBS, a clinical syndrome, is associated with a wide spectrum of underlying pathologies (AD, CBD, PSP, or TDP-43) (Lee et al., 2011). The clinical presentation of patients with CBD pathology is

variable but includes nfvPPA, bvFTD, and an executive motor disorder with prominent difficulties with gait. Patients who initially present with clinical bvFTD and are found to have CBD pathology on autopsy tend to be more apathetic than have florid disinhibition, are more anxious, and have a more dorsal and milder pattern of frontal atrophy when compared with patients with bvFTD who end up having a pathology of Pick disease (Rankin et al., 2011).

PROGRESSIVE SUPRANUCLEAR PALSY

Progressive supranuclear palsy is a neurodegenerative disorder that is pathologically defined by the presence of neurofibrillary tangles and neuropil threads in brainstem, basal ganglia, and cerebellar nuclei associated with abnormal four repeat tau protein deposition (Hauw et al., 1994). The most common clinical presentation is that of Richardson syndrome and includes postural instability, gait imbalance, multiple falls, and supranuclear gaze palsy that primarily affects vertical saccades. However, around 5% of patients may present with a behavioral syndrome similar to that of bvFTD without any sign of parkinsonism, falls, or eye movement abnormality until much later in the disease (Hassan et al., 2011; Josephs et al., 2011). These signs should be examined carefully in patients presenting with bvFTD because they may point to the diagnosis of PSP. Vertical saccade abnormalities in particular have been found to have a high predictability of PSP pathology (Boxer et al., 2012). Magnetic resonance imaging might reveal only mild frontotemporal atrophy with or without the classical decrease in midbrain size.

IMAGING AND OTHER DIAGNOSTIC METHODS

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (MRI) is pivotal in reaching a more objective and neuroanatomically guided diagnosis in FTD. Patients with bvFTD usually have bilateral frontal and temporal atrophy with the earliest changes apparent in fronto-insular structures and other regions of the salient network (Seeley et al., 2009, 2012; Suarez et al., 2009). Nearly all patients referred with bvFTD show prominent frontally predominant atrophy, a finding that is often ignored in reports from radiologists (Suarez et al., 2009). Non-fluent variant primary progressive aphasia shows atrophy in the left perisylvian region, whereas svPPA shows parenchymal volume loss in left (or right) anterior temporal lobe (Gorno-Tempini et al., 2004). Patients with CBS show asymmetrical peri-rolandic dorsal atrophy, whereas those with PSP may show midbrain atrophy and a “hummingbird” sign on sagittal T1 resulting from atrophy of the midbrain tegmentum with a relative preservation of the pons (Massey et al., 2012).

POSITRON EMISSION TOMOGRAPHY

Fluorodeoxyglucose positron emission tomography (FDG-PET) may help in confirming a diagnosis of FTD. In a

pathology-confirmed study, FDG-PET was found to be reliable among different raters and aid in the differentiation between FTD and AD pathology (Womack et al., 2011). In FTD, it shows hypometabolism of frontal, anterior cingulate, and anterior temporal regions, whereas hypometabolism of temporoparietal and posterior cingulate regions was observed in AD (Foster et al., 2007; Poljansky et al., 2011). With the advent of biomarkers such as Pittsburgh Compound-B PET for the detection of amyloidosis in the brain, it is imperative to recognize that co-pathologies can occur and the pathologic diagnosis of Alzheimer's disease should not be conclusive in patients with a positive PiB-PET and an otherwise clinical presentation of FTD (Caso, Gesierich et al., 2012).

ELECTROENCEPHALOGRAM

Electroencephalograms (EEG) may help distinguish FTD from AD, especially when using quantitative analysis and other computational methods (Caso et al., 2012; Lindau et al., 2003; Yener et al., 1996). Yet, EEG is not used in the routine diagnosis of FTD.

CEREBROSPINAL FLUID MARKERS

Measurement of tau and amyloid- β 42 in the cerebrospinal fluid (CSF) of patients with neurodegenerative diseases is helpful in differentiating FTD from AD. In AD, amyloid- β 42 levels are low with tau levels being elevated. In FTD, the ratio of tau/amyloid- β 42 is significantly lower than in AD because of preserved amyloid- β 42 levels. Using a cutoff of 1.06, the tau/amyloid- β 42 ratio has a 79% sensitivity and a 97% specificity in discriminating between the two neurodegenerative conditions (Bian et al., 2008); however, this finding has not been validated in neuropathology-confirmed series. Measurements of other biomarkers in CSF continue to be investigated, especially for the differentiation of different pathological subtypes of FTD such as FTD-TDP43 and FTD-tau (see the following) (Hu et al., 2010).

HISTOPATHOLOGY

The major pathological hallmark of FTLN is atrophy of the frontal and anterior temporal lobes with microvacuolation and astrogliosis observed in affected areas on hematoxylin and eosin staining. In early pathological studies, cases that lacked the Pick disease pathology were roughly 80% and formed a group of unknown pathological etiologies that did not have typical Alzheimer's disease pathology. This group was initially termed frontal lobe degeneration of non-Alzheimer type.

Over the past two decades, neuropathologists have deciphered many distinct histopathologies that can underlie a pathological diagnosis of what is now referred to as frontotemporal lobar degeneration. These can be broadly classified according to the predominant abnormal protein deposition found on immunohistochemistry, and more specifically categorized according to the pattern of protein deposition. The two major proteins with which FTLN is associated are tau

(FTLN-tau) and TAR DNA-binding protein 43 (TDP-43; FTLN-TDP).

TAU

3-R TAU

The term Pick disease now refers to an FTLN pathology with observable Pick bodies that consist of intraneuronal argyrophilic inclusions. Pick bodies are mainly composed of abnormal three-repeat tau protein aggregates and stain strongly with antibodies against the tau protein on immunohistochemistry. In pathological series, Pick disease is found in roughly 15% to 20% of patients with FTD (Brun, 1987; Rosso et al., 2003).

4-R TAU

Corticobasal degeneration was initially described as a Pick-like pathology of corticodentatonigral degeneration with neuronal achromasia (Rebeiz et al., 1967). Later, its specific histopathology was described as ballooned neurons, neuronal loss, astrogliosis, and tau-positive neuronal and glial inclusions with the presence of coiled bodies and axonal and dendritic threads consisting of four-repeat tau protein isoforms (Gibb et al., 1989a; Gibb et al., 1990; Komori, 1999; Houlden et al., 2001), associated with an H1/H1 haplotype (Houlden et al., 2001). Progressive supranuclear palsy is another pathology related to four-repeat tau protein depositions and is summarized in the preceding.

TDP-43

One of the major non-tau-related pathologies of FTLN was initially termed FTLN-U for the presence of ubiquitin. In the past decade, pathological studies uncovered the implication of a protein called TAR DNA-binding protein 43 (TDP-43) as one of the major pathologies in FTLN-U (for ubiquitin) and FTD-MND (Neumann et al., 2006).

Three distinct histological patterns of FTLN with TDP-43 pathology were recognized based on the morphology and anatomical distribution of neuronal inclusions (Mackenzie et al., 2006; Sampathu et al., 2006). A unified classification was proposed in 2011 and another category was added based on emerging studies (Mackenzie et al., 2011). Each of the four subtypes was found to correlate well with different clinical and genetic forms of FTD. FTLN-TDP 43 type A consists of many neuro-cytoplasmic inclusions (NCI) and short dystrophic neuritis (DN) predominantly in layer 2 of the cortex, and correlates mostly with the clinical syndrome of bvFTD and PNFA, especially in *GRN* mutation cases. FTLN-TDP 43 type B consists mostly of moderate NCI and only few DN found in all layers of the cortex, and correlates mostly with bvFTD and FTD-MND, especially linked to *C9orf72* mutation cases. FTLN-TDP 43 type C consists mostly of numerous long DN and only few NCI predominantly in layer 2 of the cortex, and correlates best with svPPA. Finally, FTLN-TDP 43 type D consists of many lentiform neuronal intranuclear inclusions and many short DN in all layers of the cortex, and correlates best with the familial syndrome of inclusion body myopathy with Paget disease of bone and frontotemporal dementia, which is

associated with mutations in the valosin-containing protein gene. Because different pathologies and genetic factors might invoke different treatment options in the future, it is important to recognize the diversity of these pathologies and the clinical clues that allow a differentiation between them.

FUS

A small number of patients with FTD have a pathology that stains positive with ubiquitin antibodies but lack a TDP-43 (or tau) pathology. These were found to have fused in sarcoma (FUS) protein (Neumann et al., 2009), which was later found to be the underlying pathology in 5% to 10% of patients presenting with bvFTD (Seelaar et al., 2008; Urwin et al., 2010). Patients with the FTLD-FUS pathology present with a severe behavioral syndrome at a younger age, with a mean of 41 years old, accompanied by a high prevalence of psychotic symptoms and very little motor symptoms until much later in the disease (Urwin et al., 2010).

GENETICS

The genetics of FTD was a focus of interest in the past decade. Although roughly 40% of the cases have a family history, around 10% have an autosomal dominant pattern of genetic heritability (Rohrer et al., 2009). The bvFTD group has the largest proportion of familial cases while svPPA has the least.

MAPT

The microtubule-associated protein tau gene (*MAPT*), located on chromosome 17, was identified in 1998 as a culprit for a subset of familial Pick disease then termed FTD and parkinsonism (Hutton et al., 1998). The gene was found to carry a mutation in 17.8% of patients with clinically determined FTD and 43% of those with a positive family history in the Netherlands (Rizzu et al., 1999). In other series, it was found in 32% of patients with FTD and a positive family history, whereas only rare in the absence of family history (Rosso et al., 2003). In more recent case series mutations in *MAPT* was found in roughly 3% to 14% of patients with FTD (Rohrer et al., 2009; Seelaar et al., 2008). In our series it accounts for approximately 17% of all our familial forms of FTD.

These patients tend to have symmetrical frontal and anterior temporal atrophy; therefore, bvFTD is the most common clinical presentation (Rohrer et al., 2009). The typical age at the time of presentation is around 50 years, although patients have been seen with much earlier and later years of onset. Gene carriers were found to exhibit alteration of the functional connectivity in the default mode network (DMN) similar to that seen in patients with bvFTD who are also carriers of the mutation. This finding, in the absence of clinical symptoms or evidence of atrophy on structural imaging, suggests that a change in functional connectivity may be an early sign of the disease (Whitwell et al., 2011).

GRN

Mutations in the progranulin gene (*PGRN*), also located on chromosome 17, vary in frequency and are found in 1% to 16% of patients with FTD (Rohrer et al., 2009). They account for approximately 8% of all of our familial forms of FTD. The mean age of onset in patients with a GRN mutation is usually higher than that of patients with an *MAPT* mutation averaging around 62 years of age (Seelaar et al., 2008). Most of the GRN mutations cause nonsense-mediated decay of granulin so that no protein is produced by one chromosome. This is called haploinsufficiency, and patients with the mutation produce approximately 50% of the normal levels of progranulin (Rademakers et al., 2007).

Patients with GRN mutations tend to have an asymmetrical neurodegenerative condition that begins in the frontal or temporal region and spreads out along one hemisphere. Many are diagnosed with bvFTD or nfvPPA, whereas others are suspected of having CBS or Alzheimer's disease because of the spread into posterior brain regions. Additionally, the parkinsonian features found in some individuals lead them to be diagnosed with Parkinson disease.

Studies in knockout rat hippocampal cultures show that low progranulin levels reduce neural connectivity by decreasing the number of synapses and length of axons (Tapia et al., 2011). Interestingly, the number of neuronal vesicles per synapse was increased, similarly to observations in brains of patients with FTD and harboring the GRN mutation. The whole progranulin molecule seems to work as a neuronal growth factor that works at the neuronal level via the sortilin receptor, whereas it is broken down into smaller granulin molecules that activate inflammation. Histone deacetylase inhibitors increase the production of progranulin from the normal chromosome offering hope for a therapy for FTD related to this mutation.

C9ORF72

In the past two decades, several families with FTD-MND were reported, the genetic culprit being an autosomal dominant mutation that linked to a locus on chromosome 9. In 2011, a noncoding GGGGCC hexanucleotide expansion in the gene called *C9orf72* was described and found to be strongly associated with the disease (DeJesus-Hernandez et al., 2011; Renton et al., 2011). It became the most common genetic mutation in familial FTD (11.7% of cases) and familial ALS (23.5% of cases). The expansion was found in 7% of Caucasians with sporadic ALS and 39.3% of Caucasians with familial ALS. In FTD, the expansion is found in 6% of individuals of European ancestry in the sporadic form and 24.8% in the familial form. It accounts for approximately two-thirds of our familial cases of FTD. Data for non-Caucasian ethnic groups is scarce but it has been reported in Asians. The mutation was found to have very strong penetrance with the typical age of onset in the sixth decade (Majounie et al., 2012).

Clinically, patients with the C9 mutation often present similarly to patients with sporadic bvFTD. In our series we found a higher prevalence of delusions in C9 carriers (approximately

21%) compared with patients with sporadic bvFTD (approximately 10%) (Sha et al., 2012). Measurements of gray matter atrophy by voxel-based morphometry analysis of MRI images of 76 subjects with bvFTD revealed differences in brain parenchymal volume loss across subjects with different genetic mutations: symmetric atrophy in dorsolateral, medial orbitofrontal, anterior temporal, parietal, occipital, and cerebellar regions was associated with mutations in the C9orf72, whereas anteromedial temporal atrophy was associated with mutations in the MAPT gene and temporoparietal atrophy with mutations in the progranulin gene (Whitwell et al., 2012).

TREATMENT

The treatment for FTD is complex and calls for a multidisciplinary approach. Perhaps the first approach for treatment focuses on the education of patients and their caregivers (Merrilees, 2007). The understanding that abnormal behavior stems from a brain dysfunction can be difficult to grasp and caregivers may become quickly tired and frustrated. It is crucial for caregivers to develop strategies to help effectively interact with patients suffering from FTD and to keep them safe from the faulty judgment that inherently accompanies their disease (Perry and Miller, 2001). Social support services including support groups, home health aides, and a day care center can provide a healthy environment in which patients with FTD, especially in more advanced stages, can continue to have a good quality of life, especially in the absence of more structured institutions and nursing homes to care for a young population with a dementing illness (Chemali et al., 2010; Chemali et al., 2012).

The pharmacological treatment of FTD can be divided into symptomatic or disease-modifying therapy. Disease-modifying treatments would ideally target the underlying molecule associated with the respective pathology. For that reason, specific clinicopathological correlations are important to differentiate among diseases that would respond to a specific disease-modifying agent. For example, if a drug were to target TDP-43 pathology, it would be crucial to differentiate between cases of bvFTD that have TDP-43 as their underlying pathology as opposed to tau. Such treatments are currently not available. The results of a large multicenter clinical trial of PSP (a tauopathy) with davunetide, a microtubule stabilizing small peptide, were reported in December of 2012. The study failed to detect an effect on primary outcome measures. Similarly, a trial for patients with progranulin mutations is contemplated for 2013.

Because FTD is associated with many aberrant behaviors that might be troublesome to patients, their caregivers, and their surroundings, symptomatic therapy, although not curative, is important for a healthy patient-caregiver dynamic. It also provides control to patients that might be considered disruptive to others, especially in assisted living and nursing home settings. Both selective serotonin-reuptake inhibitors (SSRIs) and antipsychotic medications have been used in the symptomatic treatment of FTD. Indeed, autopsy and imaging studies seem to suggest that there is a serotonergic deficit in

patients with FTD, possibly related to the neural projections from the raphe nuclei to the frontal cortex (Huey et al., 2006). There are also PET and SPECT studies that implicate deficiencies in the dopaminergic systems, especially in the striatum, in FTD (Huey et al., 2006).

From the SSRIs, paroxetine (Paxil®) was the most studied in FTD. It was shown to improve behavior symptoms such as disinhibition and compulsions at a dose of 20 mg per day (Kerchner et al., 2011); however, because of its anticholinergic effect, paroxetine may worsen cognitive symptoms (Deakin et al., 2004). On the other hand, citalopram (Celexa®) has very little anticholinergic effect and had been successfully used in the treatment of behavioral symptoms in AD patients (Pollock et al., 2002). It was also shown to decrease behavioral symptoms in patients with FTD at a dose of 30 mg daily (Herrmann et al., 2011). Trazodone at a dose of 150 to 300 mg daily also helps control agitation and eating disorders in patients with FTD (Lebert et al., 2004). Antipsychotic medications such as olanzapine and risperidone have been used in the treatment of agitation and disinhibition in FTD. However, there is little evidence-based support for their use and the high risk of extrapyramidal symptoms argues against their use (Kerchner et al., 2011).

CASE 1

Mr. X is a 73-year-old right-handed man who presented to the clinic with his daughter and his fiancée. He was at baseline an accomplished man, holding a PhD in sociology and working in an academic setting until retirement. His ex-wife was a biology professor and had been deceased for more than 15 years. He met his current fiancée eight years ago after flirtatiously following her into a restaurant. His daughter describes him previously as a sophisticated man. She feels that at baseline her father was gregarious and outgoing, while being respectful.

Four years ago, Mr. X started making rude remarks to friends and strangers who attended his weekly movie night. In fact, he ended a friendship with a long-term woman after insulting her and calling her derogatory names in front of other guests. His social decorum declined since and his daughter describes him now as having “no filter,” telling people rude remarks to their faces. During the renewal of his driving license one year ago, he quarreled with his examiner and failed the test. He has also been walking up to strangers, starting conversations and touching them inappropriately; for example, hugging them. Furthermore, he is losing interest in activities he usually enjoyed doing such as fishing. He does not enjoy movies anymore but watches TV shows. His symptoms have all been slowly progressive over time.

Mr. X has lost the ability to be empathic and attentive to other people’s needs and emotions. Once, his fiancée was having a bout of diverticulitis with severe vomiting and he simply

(continued)

told her that he will be waiting for her in the car to go visit his daughter. He has become more self-centered and cares less about others' needs.

His daughter also describes ritualistic behavior. For example, he enjoys saluting the sun and the moon. When he walks through a room, he high-fives the walls, the tables, and the chairs that are on his way, sometimes kissing the back of the chairs. His attention to grooming has diminished and he now wears the same clothes over and over again until they are worn down. He uses the bathroom frequently during the day without necessarily urinating. Moreover, he compulsively sticks his tongue out. He often repeats catch phrases as well as tunes that he sings or whistles constantly regardless of the social setting. He is described as impulsive. In addition, he has been having paranoid delusions for the past three years. He checks that all the doors are locked and there are no people hiding under the beds.

Regarding his eating behavior, at the onset of the disease he had a decreased appetite and lost some weight. He had decreased interest in the gourmet food he usually enjoyed. He started craving sweets and could eat candy all day. In addition, he was drinking more and smoking cigars.

In terms of memory complaints, Mr. X often asked the same question repeatedly. He forgot plans and errands. In terms of executive functions, he had difficulties with planning and organization, multi-tasking, concentration, judgment, and problem-solving. His fiancée in fact does all the finances and sorts his mail. His language and visuospatial domains were spared.

Mr. X does not report any memory, cognitive, or behavioral complaints when asked.

He has no pertinent family history except for alcoholism in his father and a non-specific behavioral syndrome in his paternal uncle with onset at 40 years old. His grandfather was diagnosed with Alzheimer's disease.

On physical examination, Mr. X was wearing a green sweater, worn-out jeans, and tennis shoes. His behavior was childish and he giggled throughout the exam. He asked to leave the room multiple times to use the bathroom. He stuck out his tongue multiple times at the examiner. His neurological examination was essentially normal except for a mild increase in tone of his left arm. On his neuropsychology testing, he had difficulties with tasks of verbal and visual memory, as well as a decreased performance on design fluency with relative sparing of other domains.

His MRI revealed bilateral orbitofrontal, bilateral insular, bilateral caudate, bilateral anterior temporal, and bilateral hippocampal volume loss, with generally worse parenchymal loss on the right than on the left (Fig. 67.1).

This case illustrates the typical presentation of a patient with bvFTD. Mr. X fulfills five out of the six criteria for the clinical diagnosis of bvFTD (see Table 67.2) with the exception of executive deficits on neuropsychology testing, possibly because of sparing of the dorsolateral structures. This case also demonstrates that patients with classical bvFTD can also have memory impairments and that the presence of short-term memory loss should not preclude the diagnosis.

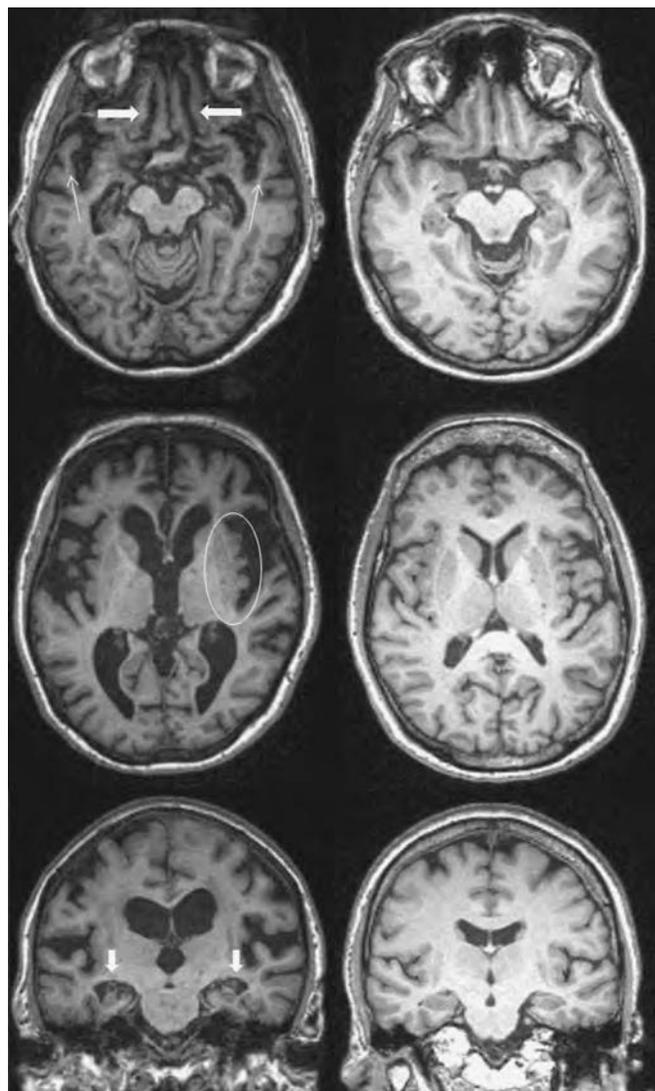

Figure 67.1 Mr. X magnetic resonance image (MRI) (left) as compared with a normal control (right) shows bilateral orbitofrontal (thick arrows) and anterior temporal (thin arrows) parenchymal volume loss (top images), bilateral insular volume loss (oval, middle images), and bilateral hippocampal volume loss (arrows, bottom images). In this figure, all sequences are T1-weighted and the right side of the MRI images corresponds to the right hemisphere.

CASE 2

Ms. Y is a 50-year-old right-handed woman who presented to the clinic with a chief complaint of "forgetting words and names," which started five years ago. This was first noticeable when she was reading stories to her two-year-old boy and she could not come up with the names of animals depicted in the story books, such as "rabbit" or "squirrel." She initially was able to describe the words she could not come up with, but became worse over time. For example, she would say "the word that starts with H and that pushes things against the wall as opposed to screwing." She also had difficulties recalling names of famous actors and names of cities. Moreover, she often asked about the meaning of words but had no difficulties comprehending and participating in general conversations.

(continued)

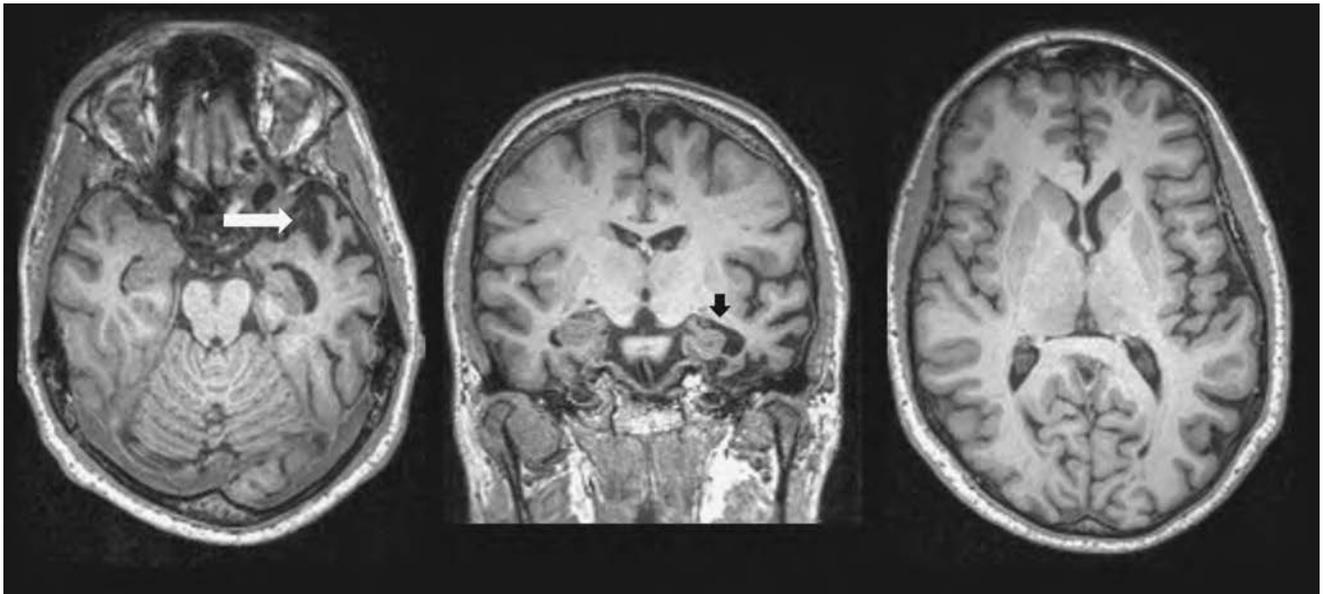

Figure 67.2 Ms. Y's MRI reveals left anterior temporal lobe volume loss in axial (right) and coronal (middle) planes on T1 sequences (arrows). There is relative preservation of other brain structures (left).

She had no memory, executive function, visuospatial, motor, or behavioral complaints. She continued to be independent in her activities of daily living. Her family history was unremarkable.

On exam, Ms. Y was appropriately groomed. Her speech output was increased, fluent, and grammatically intact, with word-finding difficulties and frequent questioning of the meaning of words. She had difficulties naming objects around the room. She spelled "cough" as "coff," "knot" as "naught" or "note," "choir" as "cwier," and she could not spell "yacht." She named only four out of 15 items on a naming test and could point to the correct picture describing a word in five out of 16 cases. Her visuospatial and executive functions skills were intact. She has mild difficulties on verbal learning tasks likely confounded by her inability to understand the meaning of the words. She performed well on visual memory tasks. Her neurological examination was otherwise unremarkable.

Her MRI is shown in Figure 67.2 and reveals left anterior temporal lobe parenchymal volume loss with relative preservations of other brain structures. There is only a slight volume loss in the right anterior temporal lobe.

This case illustrates the typical presentation of svPPA. The history and exam are usually focally localizing to the anterior temporal lobe through a predominant deficit of loss of word and object knowledge. Behavioral disturbances arise when more right anterior temporal lobe structures become involved. The underlying pathology is almost always that of TDP-43. Notice that in most cases the family history is unremarkable as this is the least genetic related disorder of all FTDs.

DISCLOSURES

Dr. Naasan has no conflicts of interest to disclose.

Dr. Miller receives grant support from the NIH/NIA and has nothing to disclose related to this chapter. Dr. Miller serves

as a consultant for TauRx, Allon Therapeutics and Siemens Medical Solutions. He has also received a research grant from Novartis. He is on the board of directors for the John Douglas French Foundation for Alzheimer's Research and for The Larry L. Hillblom Foundation.

68 | PATHOGENESIS, DIAGNOSIS, AND TREATMENT OF VASCULAR AND MIXED DEMENTIAS

HELENA CHANG CHUI

Cerebrovascular disease (CVD) is the second most common contributor to cognitive impairment in late life. Its impact on cognition and behavior is highly variable, depending on the location and extent of vascular brain injury (VBI) in relation to relevant functional networks. A diagnostic approach based on symptomatic profile (e.g., sudden onset, stepwise progression, executive dysfunction, apathy, depression) applies to a typical subset of patients. Alternative approaches based on structural imaging (e.g., MRI) have improved sensitivity for detecting presymptomatic VBI, thereby allowing earlier identification and treatment of vascular risk factors.

Vascular cognitive impairment (VCI) is currently the umbrella term encompassing both mild cognitive impairment and more severe dementia due to vascular brain injury and cerebrovascular disease. It subsumes other appellations including multiinfarct dementia, Binswanger's syndrome, poststroke dementia, vascular dementia (VD, VaD), ischemic vascular dementia (IVD), subcortical vascular dementia (SVD, SIVD), and vascular cognitive impairment not meeting criteria for dementia (Vascular CIND).

With advancing age, concurrent CVD and neurodegenerative pathologies (e.g., amyloid plaques, neurofibrillary tangles, synucleinopathy) become increasingly likely. Alzheimer pathology is associated with progressive loss of cognitive function, whereas the effect of VBI is variable. Sensitive and specific biomarkers for the major pathologies in late life are needed to identify each type of pathology. There is a widely held presumption that reduction of vascular risk will diminish vascular contributions to cognitive impairment.

Vascular cognitive impairment represents one manifestation in the larger realm of global vascular risk, including stroke, myocardial infarction, and peripheral artery disease (Fig. 68.1) (Sacco, 2007)). Ideally, reduction of global vascular risk should commence before the appearance of symptomatic clinical disease. In the case of VCI, neuroimaging offers a means of identifying the brain at risk. As imaging modalities become even more versatile and dynamic, they may offer new approaches to diagnosis as well as surrogate outcome measures for the prevention and treatment of VCI.

This chapter addresses five empirical questions of clinical relevance to VCI: (1) What is the pathogenesis of vascular cognitive impairment? (2) How accurate is the diagnosis of VCI? (3) What is the incidence and prevalence of vascular cognitive impairment? (4) What is the relationship between VBI and AD? (5) What is the best way to prevent or treat VCI?

The reader is also referred to a recent consensus statement for health care professionals on vascular cognitive impairment published by the American Heart Association/American Stroke Association (Gorelick et al., 2011) and the recommendations for Harmonization of Vascular Cognitive Impairment by the National Institute for Neurological Disease and Stroke and the Canadian Stroke Network (Hachinski et al., 2006).

WHAT IS THE PATHOGENESIS OF VASCULAR COGNITIVE IMPAIRMENT?

Vascular cognitive impairment embodies the construct that vascular risk factors (VRF) lead to cerebrovascular disease (CVD), which leads to parenchymal brain injury (VBI) that leads to cognitive impairment (VCI). There are a plethora of VRFs, CVDs, and mechanisms leading to VBI. There is also tremendous variability in the level of impact VBI imposes on cognition.

VRF → CVD → VBI → ?VCI

The most prevalent types of CVD are atherosclerosis, arteriolosclerosis, and cerebral amyloid angiopathy (CAA). Other less common forms include vasculitis, fibromuscular dysplasia, malformations, and the like. CADASIL (cerebral autosomal dominant arteriopathy subcortical infarcts and leukoencephalopathy) is a relatively rare but pure example of small vessel disease. The cerebrovascular tree may be compromised secondarily by heart disease (e.g., cardiac embolism or heart failure).

Substrate transport and barrier protection are two main functions of the cerebrovascular system. Inadequate delivery of oxygen and glucose to support the basic metabolic needs of brain cells (neurons, astrocytes, oligodendroglia) results in VBI. Narrowing or occlusion of blood vessels leads to ischemic infarction; leakage or rupture of blood vessels to hemorrhage. Clinical investigations focus predominantly on acute and focal stroke syndromes. Less is known about chronic, repeated, or widespread compromise of the cerebral vascular tree or to bidirectional molecular transport across the blood-brain-barrier at the microvascular level.

Ischemia refers to conditions in which tissue perfusion and supply of vital substrate (i.e., oxygen and glucose) are inadequate to support cell metabolism. The balance between supply and demand is influenced by: (1) differences in oxygen and glucose requirements of individual brain cells, (2) regional

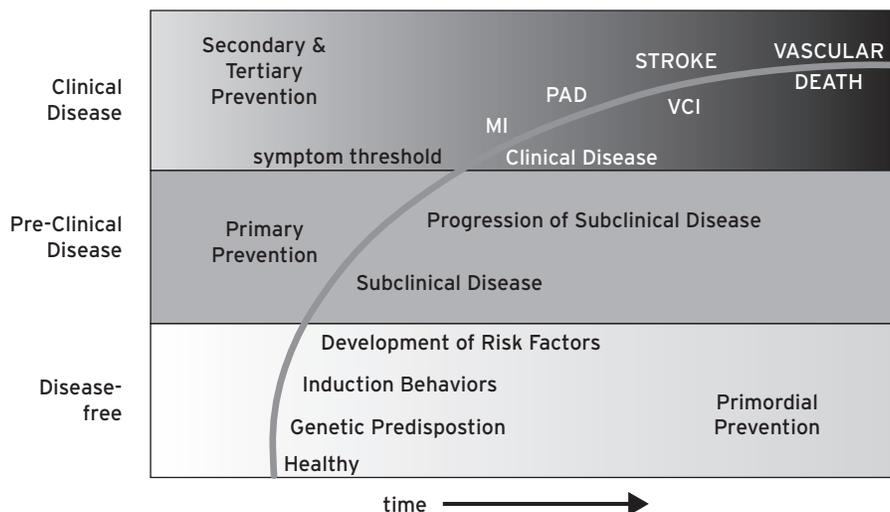

Figure 68.1 Global vascular risk. (Reproduced with Permission from the American Heart Association.)

differences in cerebral blood flow, assuming normal blood content of oxygen and glucose, and (3) the duration of hypoperfusion. Energy requirements are higher for neurons than glia. Blood flow declines as the length of the vessel increases and the radius of the vessel decreases. (Moody et al., 1991) Local cerebral blood flow is lowest in the periventricular and deep white matter—regions perfused by long, narrow, end-arterioles with no collaterals (Moody et al., 1991)

Two regional patterns of infarction are recognized. When a single artery is narrowed or occluded, the maximal extent of ischemic injury occurs in the *center* of the corresponding arterial territory. When perfusion pressure drops across several arteries, maximum injury takes place at the *border zones* between overlapping arteries and at the *end zones* of terminal arteries. This scenario may occur when: (1) systemic blood pressure drops below autoregulatory reserve, (2) intracranial pressure exceeds mean arterial pressure, or (3) there is severe stenosis of multiple arteries (e.g., hypertensive arteriolosclerosis or amyloid angiopathy). In cases of severe stenotic small artery disease, the periventricular and deep white matter border zones (despite lower oxygen requirements by oligodendroglia and axons) are at risk for chronic ischemia and incomplete infarction.

HETEROGENEITY OF CLINICAL PHENOTYPE

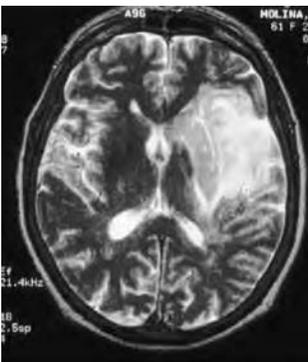

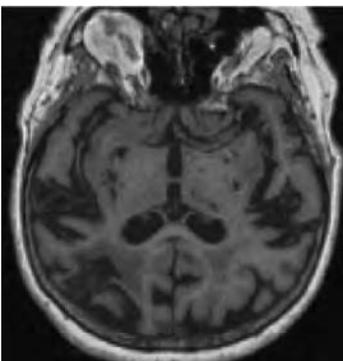

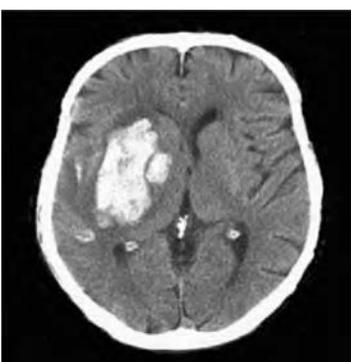

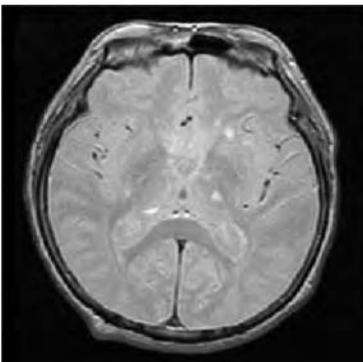

The phenotype of VCI and VaD is highly variable (Table 68.1). In the preimaging era, multiinfarct dementia was described as an abrupt onset and stepwise decline in cognitive function, with focal and patchy deficits in higher cortical function (e.g., aphasia, neglect, visual-spatial, executive). *Strategic infarct dementia* referred to cases where a single infarct in certain locations (e.g., anterior or dorsomedial nucleus of the thalamus; head of the caudate, genu of the internal capsule) resulted in impairment in multiple cognitive domains. *Binswanger's syndrome* represents a triad of slowly progressive dementia, early gait disturbance, and urinary incontinence caused by severe arteriolosclerosis of deep penetrating arteries, leading to demyelination of the periventricular and deep cerebral white matter.

The location of VBI is undoubtedly a major determinant of its impact on cognition and behavior. Subcortical lacunes and white matter changes disrupt frontal-subcortical loops and are associated with impairment in executive function. Left middle cerebral artery infarcts impact language faculties, whereas right middle cerebral artery infarcts cause neglect and deterioration of visual-spatial ability. Widespread small vessel disease (e.g., white matter encephalopathy) compromises the attentional matrix and processing speed (Schmidt et al., 2010). Newer imaging techniques such as fMRI and diffusion-weighted tractography promise more precise mapping of VBI onto relevant cognitive and behavioral networks (Duering et al., 2012), and future advances in understanding of the relationship between VBI and VCI.

POSTSTROKE DEMENTIA

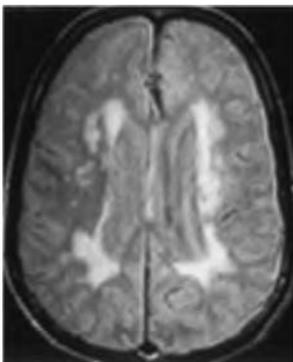

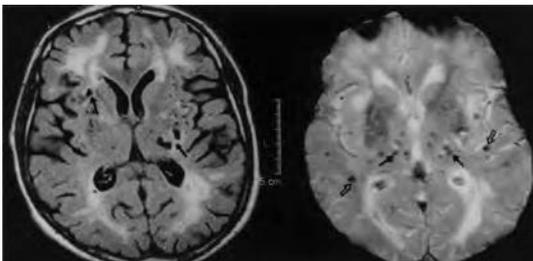

Approximately 25–30% of persons meet criteria for dementia three months after hospitalization for first stroke. In addition, the risk of developing dementia in the subsequent one to two years following a stroke is double the general population. In a community-based study of stroke, the prevalence of dementia was 30% immediately after stroke. The incidence of new onset dementia increased from 7% after one year to 48% after 25 years (Kokmen et al., 1996). Long-term mortality is two to six times higher in patients with poststroke dementia, after adjustment of demographic factors, associated cardiac diseases, stroke severity, and stroke recurrence (for review, see Leys et al., 2005). Risk of dementia was higher with increased age, fewer years of education, diabetes mellitus, atrial fibrillation, and recurrent stroke (Srikanth et al., 2006). Among neuroimaging findings, silent cerebral infarcts, white matter changes, and global and medial temporal lobe atrophy are associated with increased risk of poststroke dementia (Leys et al., 2005). Left hemisphere, anterior and posterior cerebral artery distribution, multiple infarcts, and strategic infarcts have been associated with greater risk of dementia (Allan et al., 2011). Thus, differential risk for cognitive impairment is not straightforward, but appears to be related to number, location, underlying

TABLE 68.1. VCI phenotype depends on pathogenetic mechanism and location of VBI

PATHOGENETIC MECHANISM	HISTORY	NEUROPSYCHOLOGICAL PROFILE	STRUCTURAL MRI	MRI EXAMPLE
Macrovascular occlusion	Sudden onset	Depends on location within functional networks Strategic locations include left angular gyrus, inferomesial temporal, mesial frontal, anterior and dorsomedial thalamus, anterior limb of internal capsule, left capsular genu, and caudate nuclei.	Wedge-shaped territorial infarcts	
Macrovascular stenosis or hypoperfusion	Sudden onset	Transcortical aphasias	Border-zone infarcts in major end arterial zones	
Macrovascular hemorrhage	Sudden onset Signs of increased intracranial pressure	Depends on location within functional networks	Location in basal ganglia, thalamus, brainstem and cerebellum suggests arteriolosclerosis Lobar location suggests CAA, malformations.	
Microvascular occlusion	May be clinically silent	Subtle changes on neuropsychological testing depending upon location within functional networks	Lacunar infarcts Incomplete infarcts Silent brain infarct (microinfarcts escape MRI detection at 1.5 or 3T MRI)

type of vasculopathy, coexisting neurodegenerative processes, and cognitive reserve.

SILENT BRAIN ISCHEMIA

Structural MRI reveals evidence of asymptomatic VBI, including silent brain infarcts (SBI), white matter hyperintensities (WMH), and microbleeds. The designation *subcortical ischemic vascular disease* (SIVD) describes cases of WMH and SBI located in subcortical gray and white matter. Gradient echo MR sequences may give evidence of small microbleeds, another often asymptomatic manifestation of VBI.

The prevalence of SBI on MRI in community-based samples varies between 5.8% and 17.7% with an average of 11%, depending on age, ethnicity, presence of comorbidities, and imaging techniques (Das et al., 2008). In the Framingham study, prevalence of SBI between the fifth and seventh decades of life is approximately 10%, but increases rapidly in the eighth decade to 17% and in the ninth decade to nearly 30%. Silent brain infarcts are most often located in the basal ganglia (52%), followed by other subcortical (35%) and cortical areas (11%) (Das et al., 2008). Risk factors for SBI are generally the same as those for clinical stroke (Das et al., 2008; Prabhakaran et al., 2008)

White matter hyperintensities are even more common and are generally present in most individuals older than 30 years of age (Decarli et al., 2005), increasing steadily in extent with advancing age. Also, WMH share risk factors with stroke (Jeerakathil et al., 2004). Age-specific definitions of extensive WMH can be created (Massaro et al., 2004) and prove useful in defining risk for VCI in a community cohort (DeBette et al., 2010).

Numerous studies have examined the cross-sectional relationship between MRI evidence of VBI and cognitive ability. A recent review (Mayda and DeCarli, 2009) of a large number of epidemiological studies summarizes cognitive and behavioral effects of both SCI and WMH on cognition. The presence of SBI more than doubles the risk of dementia and risk of stroke (Vermeer, Den Heijer et al., 2003a; Vermeer, Prins et al., 2003b). WMH are associated with decline in the modified Mini-Mental State Exam and the digit symbol substitution test (Longstreth et al., 2002, 2005), incident MCI, dementia, and death (Mayda and DeCarli, 2009).

Recent data suggests that progression of WMH is an even better predictor of persistent cognitive impairment than baseline white matter lesion burden (Schmidt et al., 1999; Silbert et al., 2009). In the Leukoaraiosis and DISability (LADIS) study the, severity of white matter lesions (WML) was associated with diminished executive function, depression, decreased balance and more falls, and urinary incontinence over 10 years of follow-up (Table 68.2) (Poggesi et al., 2011). Longitudinal quantitative MR studies in a relatively healthy elderly cohort showed that acceleration of WMH burden preceded the onset of mild cognitive impairment by a decade (Silbert et al., 2012).

SUBCORTICAL VASCULAR DEMENTIA

At a certain threshold, subcortical ischemic vascular disease becomes clinically symptomatic. The cognitive profile associated with subcortical vascular dementia (SVD) is said to be characterized by greater impairment in executive compared to memory domains, as well as apathy and depression (Roman et al., 2002). Indeed in CADASIL, a relatively pure form of

SVD caused by a relatively rare autosomal dominant mutation in Notch 3 gene (Dichgans et al., 1998), neuropsychological testing shows impairments in tests sensitive to speed and executive function (verbal fluency, digit symbol substitution, trails B) (Peters et al., 2005). In CADASIL, cognitive decline correlated with increased mean diffusivity, progressive atrophy, and infarct volume, rather than WMH or microbleeds (Jouvent et al., 2007). Among neuropathologically-defined cases followed prospectively with psychometrically-matched measures of executive and memory function, SIVD cases showed relatively similar levels of impairment in memory and executive function (only 9% showed predominant executive dysfunction) (Reed et al., 2004). In contrast, 67% of AD cases and 64% of mixed cases presented with a profile of predominant memory impairment. This autopsy study

suggests that although executive dysfunction is common, predominant dysexecutive profile (i.e., greater than memory impairment) may not be a sensitive diagnostic marker for sporadic SVD.

HOW ACCURATE IS THE DIAGNOSIS OF VASCULAR COGNITIVE IMPAIRMENT?

CLINICAL CRITERIA

Diagnostic criteria for VCI have evolved as new imaging modalities have come on line. In 1975, the likelihood that dementia was caused by multiple infarctions (vs. primary neuronal degeneration), was operationalized using the Hachinski Ischemic Score (Hachinski et al., 1975). Points were assigned

based on features of the clinical history and examination (e.g., abrupt onset, stepwise progression, emotional incontinence, focal neurologic signs and symptoms) associated with clinical stroke.

The threshold for detecting VBI was lowered dramatically with the arrival of MRI in the 1980s. Numerous second generation criteria for VaD appeared, incorporating results of neuroimaging: DSM, ICD, ADDTC, and NINDS-AIREN criteria. These criteria share several elements in common, but differ in operational definition: (1) requirement for cognitive impairment, (2) evidence of vascular brain injury, and (3) operational criteria linking VBI to cognitive impairment.

A diagnosis of probable VaD by NINDS-AIREN criteria requires a temporal association between the onset of stroke and cognitive decline (Roman et al., 1993). Evidence of two infarcts outside of the cerebellum suffices for a diagnosis of probable IVD by ADDTC criteria (Chui et al., 1992; Lopez et al., 2005). The number of subjects classified as VCI may differ two- to fourfold depending upon diagnostic criteria, (Knopman et al., 2002; Lopez et al., 2003, 2005) with NINDS-AIREN criteria being most conservative and ADDTC criteria most liberal. ICD-10 and DSM-5 feature minor variations on these past themes.

Clinical criteria have also been proposed for subtypes of VCI, including subcortical vascular dementia (SVD) (Erkinjuntti et al., 2000) and Binswanger syndrome (Bennett et al., 1990). Recently, criteria have been proposed for the clinical diagnosis of vascular cognitive impairment not meeting criteria for dementia (Vascular CIND) (Gorelick et al., 2011).

In evidence-based medicine, accuracy of clinical criteria is measured against a reference standard. Accuracy of clinical criteria for AD is assessed against a neuropathological gold standard (e.g., CERAD criteria, NIA-Reagan criteria). In the case of VCI, there is still no agreed upon gold standard for the diagnosis. Bearing these limitations in mind, comparisons between clinical criteria versus neuropathological criteria for VaD (e.g., evidence of VBI in three lobes of the cerebral hemisphere) show limited sensitivity, but high specificity. Positive likelihood ratios range from 3 to 5 (Gold et al., 2002), wherein modest changes in pre- to posttest probability may be seen.

NEUROPATHOLOGICAL EVALUATION

Although neuropathology excels in the characterization of CVD and VBI, there is lack of consensus about how to apportion cognitive impairment to evidence of VBI, AD, or other pathologies found on neuropathological evaluation. Thus, as mentioned in the preceding, there are no consensus criteria for the neuropathological diagnosis of VCI (Hachinski et al., 2006). On the other hand, guidelines to harmonize the neuropathological evaluation for VBI have been published (Hachinski et al., 2006), hopefully laying the foundation for future diagnostic paradigms.

Neuropathological examination provides valuable information regarding the presence and severity of CVD, VBI, neurodegenerative and mixed pathologies. Neuropathologic evaluation elucidates the type and severity of CVD (e.g., atherosclerosis,

arteriolosclerosis, amyloid angiopathy), and the severity, location, and size of VBI, including microinfarcts (too small to be seen by current 1.5 or 3 tesla MRI). Neuropathological examination greatly enhances our ability to identify cases with relatively pure versus mixed vascular and neurodegenerative pathologies by disclosing the presence and severity of amyloid plaques, tau-associated neurofibrillary degeneration, alpha-synuclein associated Lewy bodies, and TDP-43 intracytoplasmic inclusions. Better methods are needed to quantify the severity of diffuse white matter lesions, multiple microinfarcts, which are hallmarks of VBI, as well as synaptic loss, which may be a common underlying denominator of cognitive decline.

DYNAMIC AND FUNCTIONAL NEUROIMAGING: FUTURE ADVANCES IN DIAGNOSIS?

The advent of new structural and dynamic MRI sequences (e.g., diffusion tensor, fMRI, perfusion) promises additional advances for the detection and characterization of VCI. Diffusion tensor imaging/tractography provides a measure of white matter integrity. Resting fMRI provides a noninvasive measure of functional brain connectivity. Arterial spin labeling allows noninvasive and readily available measure of cerebral perfusion (compared with contrast arteriography or H₂(¹⁵O) PET. This may advance characterization of vasoreactivity in response to physiologic stressors (e.g., hypercapnea, orthostasis). With these additional advances in neuroimaging, we anticipate new approaches to the prevention and diagnosis of vascular cognitive impairment that include measures of vascular endothelial cell function and earlier recognition of the brain at risk.

WHAT IS THE INCIDENCE OF VCI AND MIXED VBI/AD?

Vascular brain injury is the second most common cause of dementia, after Alzheimer neurodegeneration. In the Cardiovascular Health Study 69% of cases with incident dementia were classified as Alzheimer's disease (AD), 11% as vascular dementia (VaD), 16% as both, and 4% as other types of dementia (Fig. 68.2) (Lopez et al., 2003). There is considerable variability in the incidence rates of vascular dementia (VaD) reported in the literature, depending upon methodological differences (e.g., diagnostic criteria, neuroimaging, neuropathology), threshold for cognitive impairment, as well as demography (e.g., age, ethnicity, education, and gender). Although neuroimaging increases the detection of VBI (McKhann et al., 2011), the cost may become prohibitive for large-scale epidemiology studies. Neuropathology improves the diagnosis of AD, VaD, and especially mixed pathology. Few studies have set the threshold for diagnosis of VCI at the level of mild cognitive impairment.

The Hisayama study (Matsui et al., 2009) stands out as a rare population-based study in Japan with a high autopsy rate (80%), where diagnostic classifications were informed by clinical, neuroimaging, and neuropathologic findings. Between ages 80 to 85 years, the annual incidence of AD, VD, and mixed AD/VD were approximately 4, 2, and 1 per 100 person years, respectively;

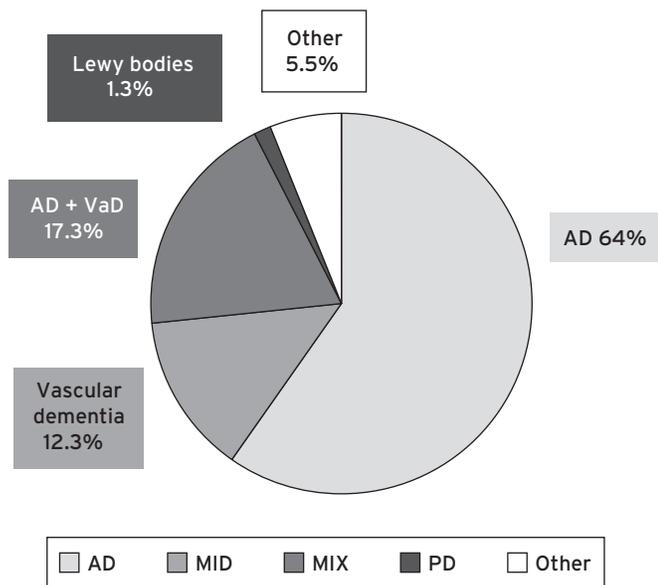

Figure 68.2 Causes of senile dementia.

after age 85, the rates were 7, 1, and 4 (Fig. 68.3). Thus, the incidences of AD, mixed dementia, and other types of dementia (but not VD) rose with increasing age, particularly after the age of 85 years (Matsui, et al., 2009). Similar incidence rates of AD and VaD (2/100 person years and 1/100 person years at age 85) were reported in Conselice, Italy, based on clinical diagnostic classifications (i.e., did not include mixed cases) (Ravaglia et al., 2005). Lower rates for VaD were reported in Rochester, MN (0.3 per 100 person years at age 85 years), as well as in earlier European metaanalysis without neuroimaging studies (Fratiglioni et al., 2000), which also did not include mixed cases.

In a poststroke dementia study (Allan et al., 2011), the incidence of delayed dementia was calculated to be 6.32 cases per 100 person years. The most robust predictors of dementia

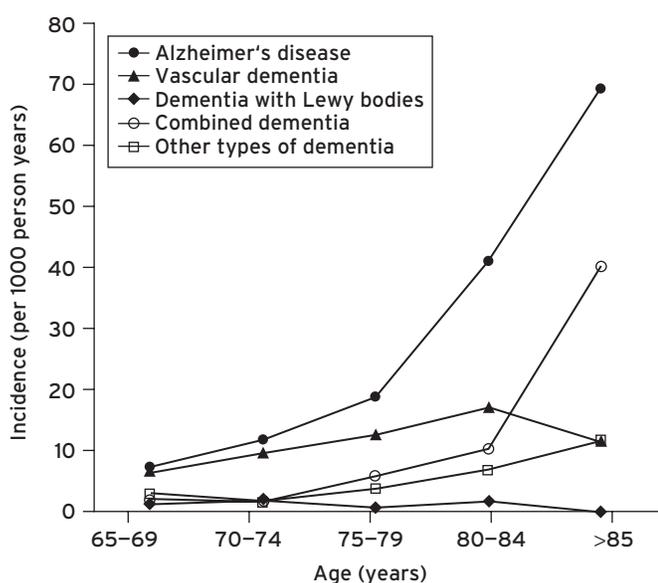

Figure 68.3 Incidence of dementia subtypes. (Reproduced with permission from BMJ Publishing Group Ltd.)

included low baseline Cambridge Cognitive Examination executive function and memory scores, Geriatric Depression Scale score and three or more cardiovascular risk factors. Autopsy findings suggested that 75% or more of the demented stroke survivors met criteria for VaD. But demented subjects tended to exhibit marginally greater neurofibrillary pathology, including tauopathy and Lewy bodies and microinfarcts, than non-demented stroke survivors, again underscoring the relevance and contributions of mixed pathologies.

WHAT IS THE RELATIONSHIP BETWEEN CVD AND AD?

MIXED VASCULAR BRAIN INJURY/AD PATHOLOGIES

Mixed vascular and neurodegenerative pathologies are commonly found in community-based autopsy studies. In the Honolulu Asia Aging Study of Japanese-American men, 25% of dementia cases had mixed pathologies, compared with 57% with primarily AD, and 53% with primarily microinfarcts (White et al., 2002). In the Religious Orders Study (Schneider et al., 2007) and community-based elderly autopsies series (Schneider et al., 2009), mixed pathologies was more common than AD or infarcts alone. Among the first 209 autopsy cases from the Cognitive Function in Aging Study (CFAS), both cerebrovascular (78%) and Alzheimer type (70%) pathologies were common.

The frequent concurrence of VBI and AD in the same person, especially with advancing age, prompts several questions. Does the concurrence of two distinct pathologies (VBI and AD) represent the chance occurrence of two common age-associated pathologies? How do CVD and AD influence or interact with each other, in terms of pathogenesis, presentation, diagnosis, prognosis, and treatment. Do vascular risk factors increase the risk of AD? Can treatment of vascular risk factors prevent AD?

In the following discussions of CVD and AD we refer to arteriosclerosis, the most prevalent form of CVD, and to VRF for stroke associated with arteriosclerosis (e.g., hypertension, diabetes mellitus, hyperlipidemia, smoking). We do not include cerebral amyloid angiopathy, a common vasculopathy, which shares with parenchymal AD pathology a strong association with the apolipoprotein E ε4 allele (Smith and Greenberg, 2009).

PATHOGENESIS OF VBI AND AD: CROSSING OR PARALLEL PATHWAYS?

Recently, the concept that risk factors for arteriosclerosis are also risk factors for Alzheimer's disease has gained traction. This hypothesis has been driven largely by some (Qiu et al., 2010; Reitz et al., 2010), but not all (Ronnemaa et al., 2011), epidemiologic studies wherein recognized risk factors for arteriosclerosis (e.g., diabetes mellitus, hypertension, hyperlipidemia, and aggregated vascular risk factors) are associated with increased risk of incident clinically-diagnosed Alzheimer's disease. These data suggest two possibilities: Are vascular risk factors also

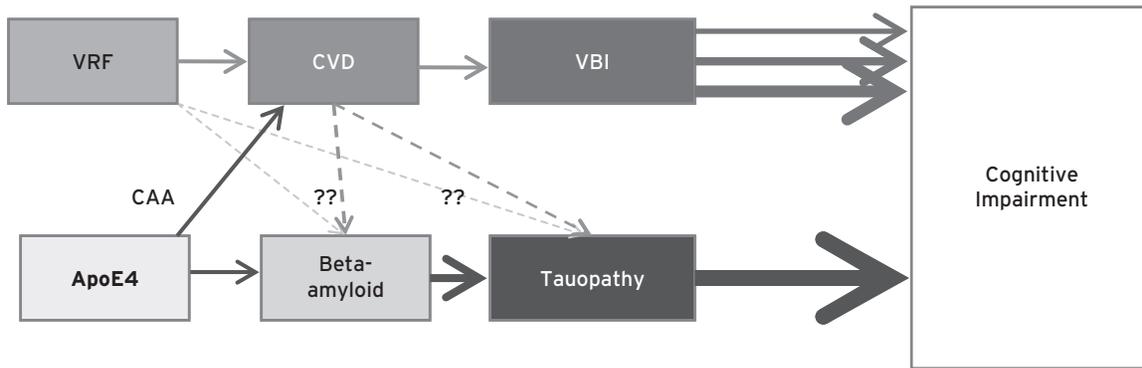

Figure 68.4 Impact of vascular risk factors and Alzheimer's disease on cognition.

risk factors for plaques and tangles, or are they promoting subclinical VBI that make symptoms of dementia appear earlier? (Fig. 68.4).

Positive associations between intracranial atherosclerosis and severity of plaques and tangles have been reported from several Alzheimer's disease brain banks (Beach et al., 2007; Honig et al., 2005). However, in a recent evidence-based review (Chui et al., 2012), no representative, prospective autopsy studies have shown significant positive associations between diabetes mellitus, hypertension, or intracranial atherosclerosis and AD pathology (i.e., plaques or tangles) (Table 68.3). The authors concluded that at the present time, there is no compelling evidence to show that vascular risk factors increase AD pathology. The alternate, but also unproven possibility remains that arteriosclerosis promotes *subclinical* VBI, thereby increasing the likelihood of dementia and in some cases making symptoms present earlier.

It is difficult to determine to what extent cognitive impairment may be caused by stroke versus concomitant AD. Estimates of the proportion of patients with poststroke dementia who also have underlying AD vary widely between 19% and 61%. (Leys et al., 2005) About 15% to 30% of persons with poststroke dementia have a history of dementia before stroke (Pohjasvaara et al., 1999; Cordoliani-Mackowiak et al., 2003) and approximately one-third have significant medial temporal atrophy. In the Lille study, the incidence of dementia three years after stroke was significantly greater in those patients with versus without medial temporal atrophy (81% vs. 58%) (Cordoliani-Mackowiak et al., 2003). Taken together, these findings suggest that approximately one-third of cases AD may contribute to dementia in patients poststroke.

COGNITIVE IMPACT OF VBI AND AD: ADDITIVE OR SYNERGISTIC?

Converging evidence suggests an additive effect of VBI and AD on cognitive function. In the Cognitive Function in Aging Study some degree of neocortical neurofibrillary pathology was found in 61% of demented ($N = 100$) and 34% of non-demented individuals ($N = 109$). Vascular lesions were equally common in both groups, although the proportion with multiple vascular lesions was higher in the demented group (46% vs. 33%). In the Religious Order study ($N = 153$),

each unit of AD pathology increased the odds of dementia by 4.40-fold and the presence of one or more infarctions independently increased the odds of dementia by 2.80-fold. There was no interaction between AD pathology and infarctions to further increase the likelihood of dementia ($p = 0.39$) (Schneider et al., 2004). In the Baltimore Longitudinal Study of Aging Autopsy Program (BLSA) ($N = 179$), a logistic regression model indicated that AD pathology alone accounted for 50% of the dementia, and hemispherical infarcts alone or in conjunction with AD pathology accounted for 35% (Troncoso et al., 2008). In a longitudinal study of SIVD, severity of AD pathology and presence of hippocampal sclerosis were the strongest predictors of dementia, whereas subcortical VBI exerted a significantly weaker effect (Chui et al., 2006). In the Honolulu Asia Aging Study, microinfarcts and neurofibrillary tangles were the strongest predictors of cognitive status, with microinfarcts having a greater impact in persons without dementia and tangles exerting the stronger influence in dementia (Launer et al., 2011).

Taken together, these findings suggest a model in which the attributable risk of cognitive impairment is the sum of various pathological lesions (including aging, and vascular and neurodegenerative changes) weighted by their differential impact on cognition minus cognitive reserve:

$$CI = \text{age} + (A \cdot AD + B \cdot VBI + C \cdot \text{Other pathology} \dots) - (A1 \cdot \text{Edu} + A2 \cdot \text{Other reserve})$$

Alzheimer's disease pathology has a relatively large and consistent impact A on cognition, whereas VBI has a highly variable impact B on cognition, depending on location, size, and number. Strategic infarcts by definition are associated with high impact on cognition. Of interest, microinfarcts (which may be numerous and widespread) also appear to contribute relatively greater deleterious effects (Fig. 68.5).

WHAT IS THE BEST WAY TO PREVENT OR TREAT VASCULAR COGNITIVE IMPAIRMENT?

At the present time, there are no medications specifically approved by the Food and Drug Administration for

TABLE 68.3. Correlations between CVD and AD: longitudinal aging cohort with autopsy

FIRST AUTHOR/ STUDY	ORIGINAL SAMPLE	AUTOPSY SAMPLE	AD PATHOLOGY	CEREBRAL INFARCTS
Peila, 2002 Honolulu Asia Aging Study 1991	Community-based Japanese-American males N = 3734	216 autopsies/ 521 deaths (42.5%)	Negative: Type 2 diabetes was not associated with cortical neuritic plaques (RR 0.8, 95% CI [0.5,1.4] or tangles (RR 1.0 [0.6–2.4])	Positive: Type 2 diabetes was associated with higher risk of large infarcts (RR 1.8, 95% CI [1.1, 3.0]).
Arvanitakis, 2006 Religious Orders Study	Older Catholic nuns, priests, or brothers N = 1060	233 autopsies (94%)	Negative: Diabetes was not related to global AD pathology score, or to specific measures of neuritic plaques, diffuse plaques or tangles, or to amyloid burden or tangle density.	Positive: Diabetes (present in 15% subjects) was associated with an increased odds of infarction (OR = 2.47, 95% CI [1.16, 5.24]).
Wang, 2009 Adults Changes in Thought	Health Maintenance Organization N = 2581	250/1167 deaths (21.4%)	Negative: Hypertension in mid-life was not associated with plaques and tangles	Positive: Among persons < 80, each 10 mmHg increase in SBP was associated with 1.15 [1.0–1.33] increased risk of ≥2 microinfarcts.
Ahtiluoto, 2010 Vaanta 85%+ Study	Community-based, elderly longitudinal study N = 553	N = 291 (48% of total cohort) (Age = 92+ years)	Negative: History of diabetes mellitus was less likely to have beta-amyloid (OR = 0.48 [0.23–0.98]) and tangles (OR 0.72 [0.39, 1.33])	Positive: History of diabetes mellitus was more likely to have cerebral infarcts (OR [95% CI] 1.88 [1.06, 3.34])
Dolan, 2010 Baltimore Longitudinal Study on Aging	Longitudinal cohort study with autopsy N of incident dementia cohort = 1236 (Kawas, 2000 ⁶)	N = 200 (16% of incident cohort) (87.6 ±7.1 years)	Negative: No relationship between the degree of atherosclerosis in intracranial, aorta, or heart and the degree of Alzheimer-type brain pathology	Positive: Intracranial atherosclerosis significantly increased the odds of infarcts (OR = 1.8 [1.2, 2.7]) and for dementia, independent of cerebral infarction
Richardson, 2012 Cognitive Function and Ageing Study (CFAS)	Community-based Longitudinal cohort study with autopsy N = 18,231	N = 456 Age range 66–103 years	Negative: Medicated hypertension was associated with less severe neocortical tangles (OR = 0.5, 95% CI = 0.3–0.8) and cerebral amyloid angiopathy (OR = 0.5, 95% CI = 0.3–0.8).	Positive: Medicated hypertension was associated with increased microinfarcts (OR = 2.1, 95% CI = 1.3–3.7). Heart attack was associated with increased microinfarcts (OR = 2.1, 95% CI = 1.2–3.9).

(Chui, H.C., Zheng, L., Reed, B.R., et al. (2012). Vascular risk factors and Alzheimer’s disease: are these risk factors for plaques and tangles or for concomitant vascular pathology that increases the likelihood of dementia? An evidence-based review. *Alzheimers Res. Ther.* 4(1):1.)

the symptomatic treatment of VCI. Clinical trials of cognitive-enhancing medications approved for the treatment of AD (e.g., acetylcholinesterase inhibitors and memantine) have also shown beneficial effects in subjects with VCI (Kavirajan and Schneider, 2007). But it was unclear whether these beneficial effects result from the concomitant presence of AD pathology or specific effects on VCI. Vascular brain injury is commonly associated with depression (Alexopoulos et al., 1997; Kales et al., 2005). Treatment with antidepressant medications (e.g., selective serotonin uptake inhibitors) is warranted, although responses in patients with VBI may be less gratifying (Sheline et al., 2010).

Overwhelming evidence indicates that early identification and reduction of VRF is effective for the primary or secondary prevention of stroke. Interventions include antihypertensives, statins, glycemic control, antiplatelet medications, revascularization procedures, and lifestyle modification (smoking cessation, exercise, and diet education). Recommendations for primary prevention (American Heart Association/American Stroke Association Guidelines [Goldstein et al., 2011]) and secondary prevention of ischemic stroke (Table 68.4) (Acciarresi et al., 2011; Ovbiagele, 2010; Spence, 2010) have been recently reviewed. Among the very elderly, targeted reduction of vascular risk factors (e.g., hypertension and hyperlipidemia)

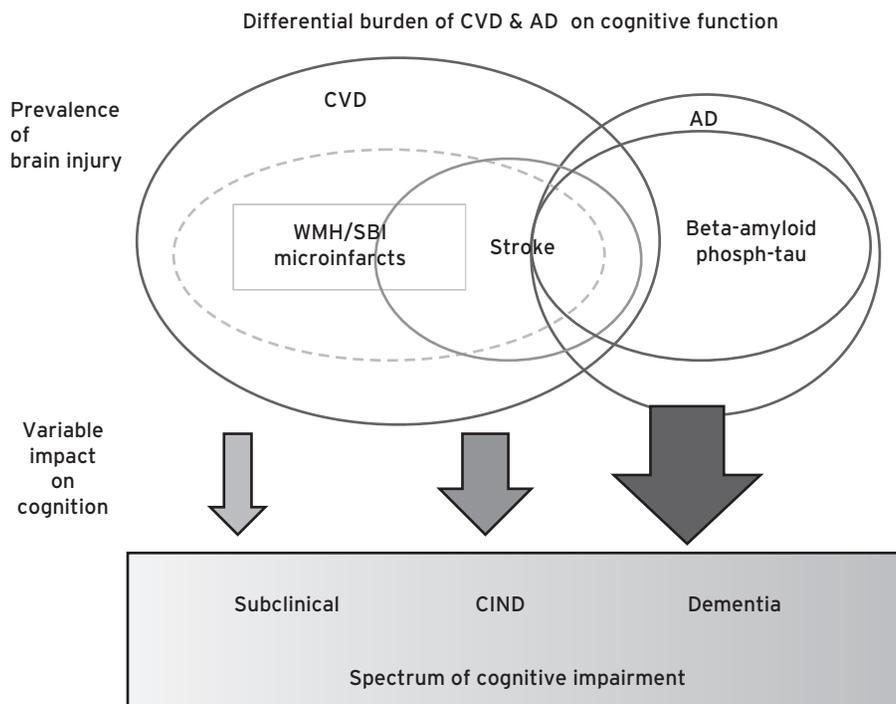

Figure 68.5 Differential burden of CVD and AD on cognitive function.

through clinical trials shows significant reductions in risk of stroke, although the benefits are not as large as among younger subjects (Table 68.5) (Sanossian and Ovbiagele, 2009).

Based on our understanding of the pathogenesis of VCI, it stands to reason that risk reduction for stroke will generalize to risk reduction for VCI. In fact, whereas the benefits of antihypertensive treatment in reducing the risk of stroke are

compelling, evidence-based data vis-à-vis reduction of VCI is relatively modest. Only small reductions in VCI were observed in a metaanalysis of four double-blind placebo-controlled primary prevention trials of antihypertensive medication (i.e., SHEP, Syst-Eur, HYVET, and SCOPE) (Table 68.6; Fig. 68.7) (McGuinness et al., 2009). In two anti-hypertensive trials for the secondary prevention of stroke, only modest differences

TABLE 68.4. Importance of secondary stroke interventions

INTERVENTION	REDUCTION IN RISK OF RECURRENT STROKE (%)	TIME FRAME FOR RISK REDUCTION	PROPORTION OF PATIENTS WHO WOULD BENEFIT (%)
Smoking cessation	≈50	6 months to several years	25
Mediterranean diet	60	4 years	100
Blood pressure control	40–50	3 years	60
Exercise	25–30	2 years	80
Antiplatelet agents	25–30	2 years	85
Lipid-lowering drugs	20–30	4 years	75
Pioglitazone for diabetes	47	3 years	20
Vitamins (B ¹²)	25–35	2–4 years	30
Carotid endarterectomy for severe symptomatic carotid stenosis	67	2 years	10
Anticoagulants for atrial fibrillation	50	1 year	15

Interventions are ranked in approximate order of importance (most important first), as determined by the combination of the magnitude of effect of the intervention and the proportion of patients presenting with transient ischemic attack or ischemic stroke who stand to benefit from each measure. (Spence, J. D. (2010). Secondary stroke prevention. [Review]. *Nat. Rev. Neurol.*, 6(9), 477–486.)

TABLE 68.5. Randomized clinical trials of antihypertensive drugs for prevention of stroke in the elderly

	N	MEAN AGE (SD, RANGE OR AGE CUT-OFF)	POPULATION STUDIED	INTERVENTION	FOLLOW-UP	RRR (95% CL) FOR STROKE	EFFECT IN ELDERLY	COMMENTS
PROGRESS	6105	64 (10, 26–91)	History of stroke or transient ischemic attack	Perindopril-based with indapamide add-on vs placebo-based	4 years	28% (17 to 38) for perindopril	Not reported	There was a 43% RRR in stroke for perindopril plus indapamide, which drove the positive result
LIFE	9193	67 (7, 55–80)	Essential hypertension and left ventricular hypertrophy	Losartan-based vs atenolol-based	4.8 years	2.5% (11 to 37) for losartan	Stroke reduction only seen in those aged ≥65 years	Equal reduction of blood pressure with losartan and atenolol
ACCESS	342	68 (9, 50–85)	Acute ischemic stroke	Candesartan vs placebo	12 months	32% (NS)	Not reported	Equal reduction of blood pressure in both groups but a 53% RRR for mortality and vascular events favoring candesartan
HOPE	9297	66 (7, >55)	Vascular disease or diabetes mellitus and one vascular risk factor	Ramipril vs placebo	4.5 years	32% (16 to 44) for ramipril	Elderly (>75years) had a 31% RRR of stroke ³⁴	Only modest reduction in blood pressure (3.8/2.8 mmHg)
ALLHAT	33357	67 (8, >55)	Hypertension and one other coronary risk factor	Chlorthalidone vs. amlodipine vs. lisinopril	4.9 years	7% (-7 to 18); NS	Not reported	Most required multi-drug regimen
SHEP	4736	71 (not reported, ≥60)	Isolated systolic hypertension and age ≥60 years	Chlorthalidone vs placebo with atenolol vs placebo add-on	4.5 years	36% (18 to 52) for chlorthalidone and atenolol	Stroke incidence was lower in the 13–7% aged ≥80 years	Active treatment was associated with fewer myocardial infarctions and a trend towards lower mortality
Syst-Eur	4695	70 (6.7, ≥60)	Isolated systolic hypertension and age >60 years	Nitrendipine with enalapril and hydrochlorothiazide add-on vs matching placebos	2 years	44% (14 to 63) for active treatment	33% risk reduction in stroke for those aged ≥80 years	Active treatment was associated with 50% reduction in dementia
MOSES	1405	68 (10, <85)	Hypertension and history of stroke	Eprosartan vs nitrendipine	2.5 years	25% (3 to 42) for eprosartan	Not reported	Equal reductions in blood pressure between the groups
PRoFESS	20332	66 (9, ≥55)	History of stroke or transient ischemic attack	Telmisartan vs placebo	2.5 years	None	Not reported	Largest secondary stroke prevention trial
HYVET	3845	84 (3, 80–100)	Systolic blood pressure >160 mmHg	Indapamide with perindopril add-on vs. placebo	1.8 years	30% (-1 to 51) for active treatment	All participants aged ≥80 years	Blood pressure with treatment 15.0/6.1 mmHg lower
SCOPE	4964	76 (not reported, 70–89)	Age 70–89 years and systolic blood pressure 160–179 mmHg or diastolic blood pressure 90–99 mmHg	Candesartan vs. placebo	3.8 years	28% (1 to 47) for candesartan	All participants aged 70–89 years	No difference in blood pressure reported among groups

TABLE 68.6. Primary and secondary prevention trials that included a cognition outcome measure

	ANTI-HYPERTENSIVE MEDICATION	FOLLOW-UP	OUTCOME	MAIN RESULTS FOR DEMENTIA	p VALUE
PRIMARY PREVENTION					
SHEP (1991) N = 4736	Diuretic (chlorthalidone) and/or beta-blocker (atenolol) or reserpine	4.5	--	16% reduction in dementia	n.s.
Syst-Eur (1998) N = 2418	Ca-channel blocker (dihydropyridine) with or without enalapril maleate and/or diuretic (hydrochlorothiazide)	2.0	MMSE	50% (0 to 76%) reduction in dementia	0.05
SCOPE (2003) N = 4937	ARB (candesartan cilexetil) and/or diuretics	3.7	MMSE	7% increased risk in active arm (but only 3.2/1.6 mmHg reduction in BP in treatment vs. control arm)	>0.20
HVET (2008) N = 3336	Diuretic (indapamide) with or without ACEI (perindopril)	2.2	MMSE	14% (-9 to 23%) reduction in dementia. (Trial stopped early because of significant reduction in stroke and mortality)	0.2
SECONDARY PREVENTION					
PROGRESS (2003) N = 6104	ACEI (perindopril) with or without diuretic (indapamide)	4.0	MMSE	12% (-8 to 28%) reduction in dementia	0.2
PRoFESS (2008) N = 20332	ARB (telmisartan)	2.4	MMSE	No reduction of the risk of dementia	0.48

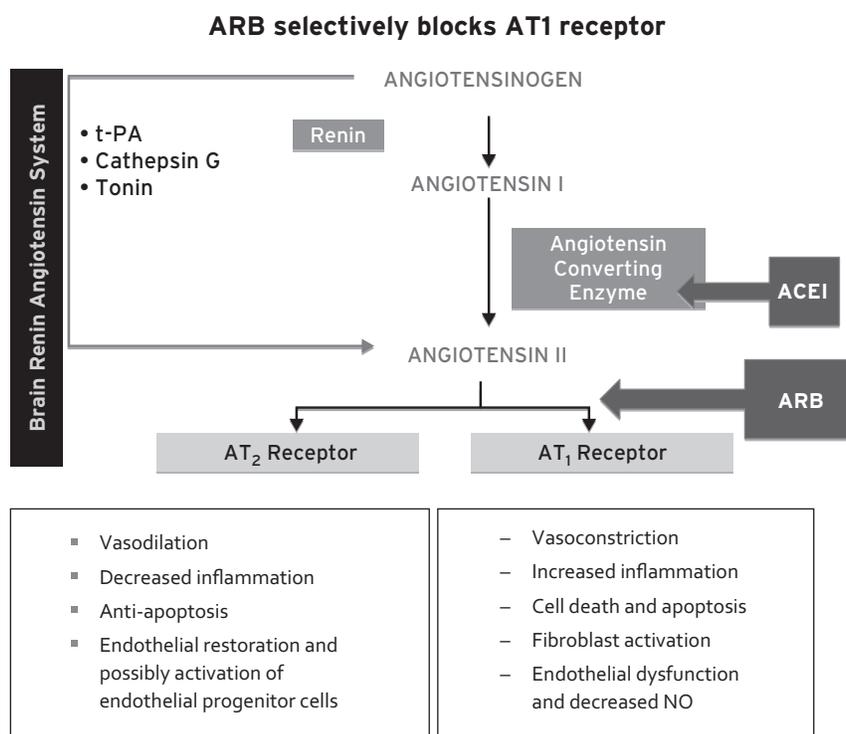

Figure 68.6 ARB selectively blocks AT1 receptor. (Reproduced with permission from The Cochrane Collaboration.)

in MMSE were noted in the active versus placebo arms (i.e., PROGRESS and PRoFESS) (Diener et al., 2008; “Randomised trial...,” 2001). This lack of evidence may reflect limitations in clinical trial design, because studies have been relatively short in duration (two–four years), have employed insensitive cognitive outcome measures (i.e., Mini-Mental State Examination), and have been stopped early because of effective but preemptive reduction of other vascular endpoints.

The Joint National Commission-7 (Chobanian et al., 2003) recommended more intensive blood pressure (BP) targets for patients with diabetes or kidney disease. The opposite may be true for individuals with extensive leukoaraiosis, in whom more liberal BP targets may be appropriate. Patients who have severe small-artery disease and compromised autoregulatory reserve may be at increased risk for ischemia, if blood pressure is abruptly lowered by postural changes (orthostatic hypotension) (Mehagnoul-Schipper et al., 2001) or overly aggressive

antihypertensive treatment. In a metaanalysis of 11 clinical trials, achieving an SBP less than 130 mmHg compared with 130 to 139 mmHg appears to provide additional stroke protection only among people with risk factors but no established cardiovascular disease (Lee et al., 2012). Higher risk of hemorrhage has been reported with administration of tPA (Palumbo et al., 2007) or anticoagulant drugs (Cervera et al., 2012) in patients with leukoaraiosis. Additional research using dynamic measures of vasoreactivity, cerebral perfusion, and integrity of the blood–brain barrier, may help set BP parameters for special subgroups of patients with significant white matter disease.

It is possible that beyond their effects on lowering blood pressure, angiotensin receptor blockers may have selective benefits for VCI. Angiotensin receptor blockers selectively block angiotensin receptor type 1 (AT1) and increase relative activation of AT2 receptors, which may protect endothelial cells and neurons (Fig. 68.6) (Armario and de la Sierra, 2009; Hajjar

Figure 1. Forest plot of comparison: 1 Incidence of dementia, outcome: 1.1 Number of cases of dementia

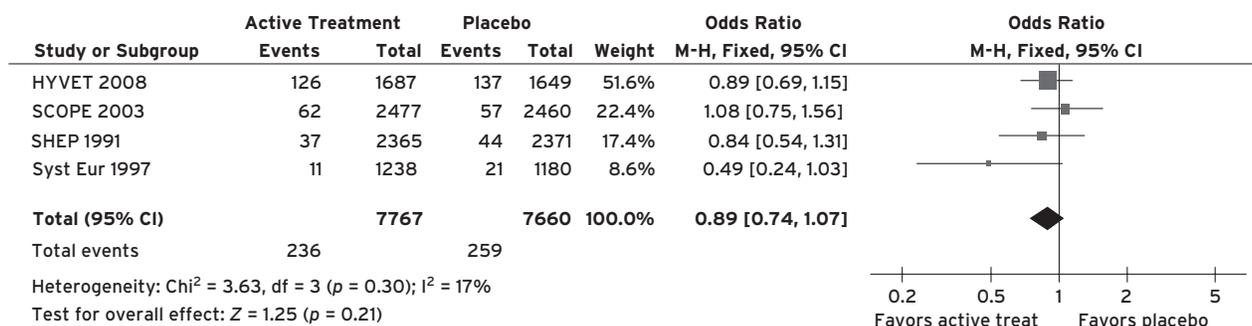

Figure 3. Forest plot of comparison: 2 Cognitive change from baseline, outcome: 2.1 Change in MMSE

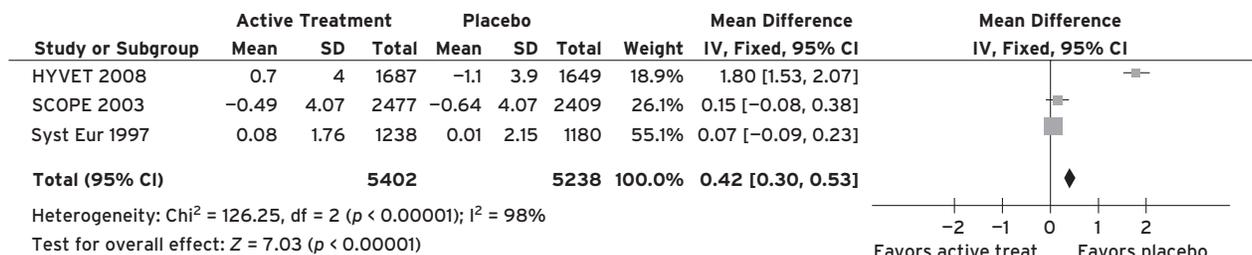

Figure 4. Forest plot of comparison: 3 Blood pressure level, outcome: 3.1 Change in systolic blood pressure level (mmHg)

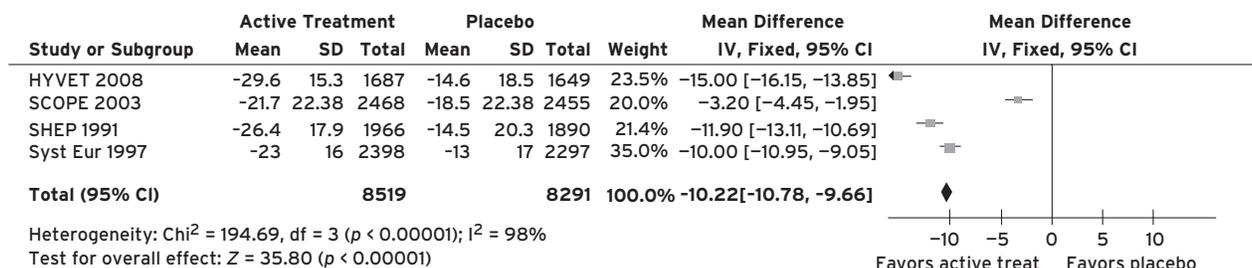

Figure 68.7 Forest plot of comparison. (Reproduced with permission from McGuinness, B., Todd, S., Passmore, P., and Bullock, R. (2009). et al., 2012; Horiuchi et al., 2010). In contrast, angiotensin converting enzyme inhibitors decrease activation of both AT1 and AT2 receptors. In a recent pilot study, candesartan was associated with greater improvement in tests sensitive to executive dysfunction than hydrochlorothiazide or lisinopril (Hajjar et al., 2012). Protection of endothelial and neuronal cells may represent promising new strategies to ameliorate VCI.

69 | CLINICAL FEATURES AND PATHOGENESIS OF PRION DISEASE

JOEL C. WATTS AND MICHAEL D. GESCHWIND

A BRIEF HISTORY OF PRION DISEASES

The first recognized prion disease in humans was Jakob–Creutzfeldt disease (CJD), a rapidly progressive neurodegenerative disorder of the central nervous system (CNS) in which patient death often occurs within a few months of the appearance of clinical symptoms. At the time of its first description in the early twentieth century by Alfons Jakob, who referred to a case originally described by Hans Creutzfeldt (see Nomenclature of Jakob–Creutzfeldt Disease), the cause of CJD remained completely unknown, and little research was conducted on CJD because of its rarity. The first clue toward the nature of CJD came when it was recognized that brains from patients who had died of CJD resembled the brains of patients with Kuru, a neurodegenerative disorder that affected the Fore tribe of Papua New Guinea (Prusiner, 1998). The neuropathology of both CJD and Kuru resembled that of scrapie, a neurodegenerative disease of sheep known to be transmissible between animals. This led to idea that CJD and Kuru might also be transmissible in a laboratory setting, and indeed it was demonstrated that brain extracts from CJD or Kuru patients could transmit disease to non-human primates after long incubation periods. This class of diseases is now often referred to as transmissible spongiform encephalopathies (TSEs) because of their infectious nature and unique neuropathological features. Other TSEs include bovine spongiform encephalopathy (BSE), also known as mad cow disease, in cattle, and chronic wasting disease (CWD), a TSE of deer, elk, and moose that occurs in free ranging animals. Although rare, TSEs are invariably fatal disorders. No treatment or vaccine exists for this class of diseases (Prusiner, 1998).

The nature of the infectious agent responsible for TSEs remained a scientific curiosity for many years. The vast majority of infectious human diseases are caused by exposure to parasites, bacteria, or viruses. All of these agents require an informational molecule such as DNA or RNA, which is essential for their persistence and spread. Because of the atypical nature of TSEs in that a prolonged period exists between exposure to the disease and the onset of clinical symptoms, it was assumed that a “slow” or “unconventional” virus was the cause of these disorders, and thus for many years they were considered to be caused by “slow viruses.” Mounting evidence, however, argued that procedures known to inactivate viruses, such as formalin treatment, nuclease treatment, or ultraviolet irradiation, had little effect on the TSE agent,

whereas procedures known to destroy proteins decreased the infectivity of the agent. Furthermore, no immune response was observed in patients with CJD, as would be expected if a foreign viral genome was present in the body. The critical breakthrough came in 1982 when Stanley Prusiner successfully purified the TSE agent from infected hamster brains and found that preparations that were highly enriched for infectivity contained a single protein but no nucleic acid. He coined the term prion to denote a *proteinaceous infectious* particle that replicates in the absence of a nucleic acid (Prusiner, 1998). This protein-only hypothesis was met with great skepticism because all previously known infectious agents, including bacteria and viruses, required a nucleic genome for replication. The concept of prions is now, however, widely accepted, and the protein-only hypothesis has been proved beyond a reasonable doubt. For his discovery of prions, Stanley Prusiner was awarded the 1997 Nobel Prize in Physiology or Medicine (Prusiner, 1998).

This chapter uses the general term prion disease instead of TSEs. This is for several reasons: (1) The term spongiform is not quite accurate neuropathologically because the pathological feature is actually vacuolation (see *Neuropathology of Human Prion Diseases*); (2) a few prion diseases have little or no vacuolation (Brown and Mastrianni, 2010); and (3) some prion diseases are either very difficult to transmit or have not been reliably shown to transmit (Tateishi et al., 1996).

PRION DISEASES: BASIC CONCEPTS

The protein-only hypothesis posits that infectious prions are composed of a single protein: the prion protein (PrP). The PrP is encoded by the *PRNP* gene, which is found on chromosome 20 in humans. Mutations in *PRNP* cause genetic prion diseases, often classified as familial CJD (fCJD), Gerstmann–Sträussler–Scheinker syndrome (GSS), or fatal familial insomnia (FFI). *PRNP* directs the synthesis of an approximately 250–amino acid protein that is posttranslationally modified by the removal of N- and C-terminal signal sequences and the addition of one or two asparagine-linked sugars. Following synthesis in the endoplasmic reticulum, PrP is transported to the cell surface, where it is tethered to the cell membrane of neurons by a glycosylphosphatidylinositol (GPI) anchor. In humans, there are two major polymorphic variants of PrP, with either methionine or valine residues encoded at

position 129 of the protein, giving rise to the M129 or V129 PrP allotypes. The codon 129 polymorphism is a critical determinant of susceptibility to a variety of prion diseases (Parchi et al., 1999). Under normal conditions, PrP is expressed at high levels in the brain and at lower levels in peripheral tissues but does not cause disease. This form of the protein is referred to as PrP^C (cellular PrP) and is a precursor of disease-associated forms of PrP. PrP^C is typically found in cholesterol-rich microdomains of the cell membrane referred to as lipid rafts. The N-terminal domain of PrP contains a series of octapeptide repeats that allow PrP^C to bind copper ions. Expansion of the octapeptide domain in PrP causes certain forms of genetic prion disease, called octapeptide repeat insertion (OPRI) mutations, classified clinically either as fCJD or GSS depending on the number of repeats present and their clinical–pathological features (see Genetic Prion Diseases). Although the function of PrP^C in the brain under normal conditions remains contentious, it appears to play roles in neuroprotection, olfactory behavior, and/or the maintenance of peripheral nerve myelination (Watts and Westaway, 2007).

During prion disease, PrP^C undergoes a conformational (structural) transition into a pathologically misfolded isoform referred to as PrP^{Sc} (PrP Scrapie) (Colby and Prusiner, 2011). PrP^{Sc} is the infectious, neurotoxic, and disease-causing form of the prion protein and has vastly different biochemical and structural properties than PrP^C. The atomic structure of PrP^C has been solved using nuclear magnetic resonance (NMR) spectroscopy, revealing that PrP^C is a predominantly α -helical protein with an intrinsically disordered N-terminal domain (Colby and Prusiner, 2011). In contrast, although the high-resolution structure of PrP^{Sc} has not yet been obtained, PrP^{Sc} is enriched in β -sheet content and is generally more insoluble, more prone to aggregate into higher-order structures such as amyloid fibrils, and more resistant to protease digestion than PrP^C. The fact that PrP can fold into at least two completely different conformations (PrP^C and PrP^{Sc}) was a highly novel assertion; it was previously believed that only a single tertiary structure was possible for a given amino acid sequence.

Several lines of evidence argue strongly that the protein-only hypothesis is the most reasonable explanation for the properties of prion disease. First, PrP is absolutely required for prion disease because mice that lack the prion protein are resistant to prions (Bueler et al., 1993). Second, transgenic mice over-expressing certain mutant or wild-type PrP molecules develop neuropathological changes reminiscent of prion disease and propagate infectious prions in their brains (Watts et al., 2012). The “final” proof of the protein-only hypothesis has recently been achieved via the generation of “synthetic prions” from recombinant prion protein produced in bacteria, proving that no nucleic acids are required for the creation of prion infectivity (Colby and Prusiner, 2011).

NOMENCLATURE OF JAKOB–CREUTZFELDT DISEASE

The naming of CJD is a bit confusing, and somewhat controversial, so it helps to briefly review some of the history. In 1921 and

1923 Alfons Jakob published four papers describing five unusual cases of rapidly progressive dementia. He stated that his cases were nearly identical to a single case report of a young woman published in 1920 by his professor Hans Creutzfeldt. This disease was referred to for many decades as Jakob’s or Jakob–Creutzfeldt disease until Clarence J. Gibbs, a prominent researcher in the field, started using the term Creutzfeldt–Jakob disease because the acronym was closer to his own initials, CJ (Gibbs, 1992). The patients whom Jakob described, however, were quite different from Creutzfeldt’s case, which did not have what we now call prion disease, and only two of Jakob’s five cases actually had prion disease (Katscher, 1998). Thus, the name of prion disease probably should be Jakob’s disease, or possibly Jakob–Creutzfeldt disease. We use the term Jakob–Creutzfeldt disease and the acronym therefore probably should be JCD, but in our experience we have noted that many clinicians mistakenly think the JC virus (the source of progressive multifocal leukoencephalopathy; PML) is the cause of or associated with prion disease and even test for the JC virus working up a suspected prion case. Therefore, unfortunately we continue to use the term CJD for Jakob’s disease. This chapter uses the term CJD.

FORMS OF HUMAN PRION DISEASE: MODES OF ACQUISITION

Human prion diseases are unique in that they can manifest through three completely distinct modes of acquisition (Table 69.1). The most common forms of human prion diseases, which accounts for approximately 85% to 90% of all cases, are the sporadic disorders, including sporadic CJD (sCJD). In sporadic cases, there is no evidence of a genetic cause (including no mutations in *PRNP*) and no evidence of any environmental and/or iatrogenic risk factors suggesting that the disease arose spontaneously. Although the exact molecular details underlying the cause of sporadic CJD remain unclear, it is thought to arise from the spontaneous misfolding of PrP^C into PrP^{Sc}.

This conversion likely happens on rare occasions in the healthy brain because the cellular quality control machinery is capable of degrading the newly formed PrP^{Sc} molecules and thus prevents the initiation of prion disease. As the brain ages, however, quality control mechanisms might begin to malfunction, increasing the probability that larger quantities of PrP^{Sc} form spontaneously. In rare cases, once a critical amount of PrP^{Sc} has been reached, the cellular degradation machinery is no longer able to keep up with prion replication, and the pathogenic cascade of prion disease commences. This explains why sporadic CJD occurs most frequently in older individuals and why the disease is very rare.

The second forms of human prion diseases, accounting for approximately 10% to 15% of all cases, are the genetic forms such as fCJD, GSS, and FFI. In these genetic prion diseases (gPrDs), a mutation in the *PRNP* gene results in the production of a mutant PrP molecule. These mutations are inherited in an autosomal-dominant fashion. Only a single copy of the mutant gene is necessary for prion disease to occur. Many different types of mutations in *PRNP* cause genetic prion disease, including point mutations, insertions, deletions, and

TABLE 69.1. Human prion diseases

CLASS	DISEASE	PRNP MUTATION	AVERAGE AGE OF ONSET (YR)	AVERAGE DISEASE DURATION	PROTEASE-RESISTANT PRP	PRP ^{Sc} NEUROPATHOLOGY
Sporadic	sCJD MM1/MV1	None	65	4 mo	Type 1	Predominantly non-amyloid “synaptic” PrP ^{Sc} deposition
	sCJD MM2	None	64	16 mo	Type 2	Perivacuolar PrP ^{Sc} deposits
	sCJD MM2-thalamic (sporadic fatal insomnia)	None	52	16 mo	Type 2	Mild PrP ^{Sc} deposition in the thalamus
	sCJD MV2	None	60	17 mo	Type 2	Kuru-like plaques
	sCJD VV2	None	61	6 mo	Type 2	Focal plaque-like PrP ^{Sc} deposits
	sCJD VV1	None	44	21 mo	Type 1	Mild “synaptic” PrP ^{Sc} deposition
	VPSPr	None	67	30 mo	Variable presence of smaller PrP ^{Sc} fragments	Granular and “synaptic” PrP ^{Sc} deposits
Genetic	gCJD	Many (i.e., E200K, D178N-V129, V210I)	39–59 (mutation dependent)	6–14 mo (mutation dependent)	Type 1 or Type 2	Similar to typical sporadic CJD
	GSS	Many (i.e., P102L, A117V, F198S, Y145Stop)	Mutation dependent	5–6 yr	Smaller PrP ^{Sc} fragments (~7–14 kDa)	PrP ^{Sc} amyloid plaques, PrP ^{Sc} amyloid angiopathy with certain mutations
	FFI	D178N-M129	49	11 mo	Type 2	Mild PrP ^{Sc} deposition in the thalamus
Acquired	Iatrogenic CJD	None	N/A	4 mo	Type 1 or Type 2	Dependent on source of contamination and route of infection
	vCJD	None	28	13 mo	Type 2	Florid PrP ^{Sc} plaques
	Kuru	None	N/A	12 mo	Type 1 or Type 2	Kuru plaques

truncations (Mead, 2006). Because the mutations are not clustered within a specific region of the PrP amino acid sequence, ascertaining the causal link between mutation and disease has been difficult. Although it is unlikely that all mutations act by the same mechanism, it is generally thought that mutant PrP^C is more likely to misfold and spontaneously adopt the PrP^{Sc} conformation than non-mutant PrP^C, greatly enhancing the probability of prion disease initiation. The clinical phenotype of the disease (i.e., CJD vs. GSS vs. FFI) is dependent on the mutation present in PrP and whether M129 or V129 is also present on the mutant protein. For instance, the D178N mutation in *PRNP* causes FFI if present in conjunction with the M129 polymorphism or vCJD if present in conjunction with the V129 polymorphism (Goldfarb et al., 1992).

The third forms of human prion diseases, which account for less than approximately 1% of all cases, are the acquired or infectious forms. Acquired forms of the disease occur when small amounts of PrP^{Sc} are introduced into the body by either dietary or iatrogenic (introduced by medical treatment) routes.

This PrP^{Sc} “seed” then prompts the conversion of PrP^C in the host, which initiates the process of prion disease. Currently, the most well-known human prion disease of this form is variant CJD (vCJD), acquired largely through the consumption of BSE (Brown and Mastrianni, 2010). Other examples include iatrogenic CJD caused by the implantation of prion-contaminated dura mater grafts, treatment with contaminated human pituitary hormones, such as growth hormone, and the use of improperly sterilized (i.e., treated in a way to kill viruses and bacteria, but not sufficient to denature prions) neurosurgical instruments (Brown et al., 2000; Brown et al., 2006; Will et al., 2004).

EPIDEMIOLOGY

The incidence of human prion diseases is about 1 to 1.5 per million per year in most developed countries, with some variability between countries and from year to year (Will et al., 1998).

From 1999 to 2002, mortality from CJD in Europe, Canada, and Australia was estimated to be 1.67/million for all prion cases and 1.39 for sCJD (Ladogana et al., 2005). In the United States, with about 300 million people, there are about 300 cases per year, but this number varies considerably from year to year (Holman et al., 2010). Because sCJD tends to fluctuate within a relatively narrow age range, and most persons in developed countries will live to the age at which CJD usually occurs (see sCJD: Clinical Features) a person's lifetime risk of dying from sCJD is estimated to be about 1 in 10,000s, much higher than the incidence (across all age groups) of 1 to 1.5 per million.

CLINICAL FEATURES

One of the difficulties in the diagnosis of prion diseases is that they may present with many varied neurological and psychiatric symptoms, and each patient presents differently, likely depending on where in that patient's brain the prions begin to accumulate. Most patients with sCJD and fCJD present with cognitive impairment (eventually dementia), movement disorders (e.g., myoclonus), and coordination problems (e.g., ataxia) (Brown and Mastrianni, 2010) and/or psychiatric symptoms (Brown et al., 1986). Visual symptoms are also common. Unfortunately, psychiatric features have been given a lower profile in much of the neurological literature and diagnostic criteria. The following section discusses the major clinical and laboratory aspects of various prion diseases.

sCJD: CLINICAL FEATURES

Sporadic CJD typically is characterized by rapidly progressive dementia, with a median survival of seven to eight months. (More than 90% of patients die within the first year of disease.) The typical age of onset, however, is generally quite narrow; the unimodal peak mean age of onset is around 68 years (Brown et al., 1986). Most persons with CJD are more than 65 years old (Holman et al., 2010). Occurrence of sCJD at less than the forties or later than the mid-seventies is uncommon (Corato et al., 2006; Will, 2004), but the range of onset of sCJD is quite wide, from teenagers (Murray et al., 2008)—the youngest to our knowledge is a 12-year-old diagnosed recently in Spain (M. Geschwind, personal communication)—to a 98-year-old in Italy (Buganza et al., 2009).

Diagnostic criteria for sCJD are often divided by increasing likelihood of diagnosis into possible, probable, and definite categories. The most commonly used criteria are World Health Organization revised criteria (WHO, 1998). For possible sCJD, they require dementia plus any two of the four combinations of symptoms:

1. Myoclonus
2. Pyramidal/extrapyramidal features
3. Visual/cerebellar features
4. Akinetic mutism (not moving, not speaking)

To meet probable criteria, patients must meet possible and also have positive laboratory evidence of either a characteristic electroencephalogram (EEG) (showing about one hertz periodic sharp wave complexes [PSWCs]) or a positive/elevated CSF 14-3-3 protein (see Diagnostic Tests for sCJD) (WHO, 1998). The pyramidal symptoms are motor findings on exam, such as hyperreflexia, focal weakness, or an extensor response. Extrapyramidal symptoms typically include rigidity, slowed movement (bradykinesia), tremor, or dystonia and are caused by problems in the basal ganglia or its connections. Akinetic mutism is the end stage of the disease when patients are mute and without purposeful movement (WHO, 1998). Definite sCJD diagnosis requires neuropathological evidence of CJD (Kretzschmar et al., 1996; WHO, 1998). One problem with WHO-based clinical diagnostic criteria for possible and probable sCJD is that they were designed for epidemiological purposes to identify cases by record review that had not had definitive pathological diagnosis. These criteria were not designed to diagnosis patients early or when first presenting to a physician's office. Thus, in our experience, many patients will not meet Revised WHO criteria until later in the disease course.

The addition of brain MRI to probable sCJD criteria was proposed in 2007 (Geschwind, Haman et al., 2007; Geschwind, Josephs et al., 2007), and in 2009, Modified European probable sCJD criteria allowed inclusion of brain MRI as a supportive ancillary test. Note that there are errors in the listed symptoms in these European criteria as initially published; dementia was supposed to be required for all cases and is not in the choice of four possible symptoms, and myoclonus was inadvertently left out (Zerr et al., 2009) (see Magnetic Resonance Imaging in sCJD).

The clinical presentation of sCJD is highly variable. Most commonly the first symptoms are cognitive or cerebellar (Brown et al., 1986; Rabinovici et al., 2006). Onset is typically subacute, but rarely is acute or strokelike (Hohler and Flynn, 2006). As noted by epidemiological diagnostic criteria, motor features such as ataxia and other cerebellar dysfunction and extrapyramidal and pyramidal symptoms are quite common. These are often the first symptoms that bring patients to medical attention. Symptoms of sCJD vary widely, but typically include cognitive changes (dementia), behavioral and personality changes, difficulties with movement and coordination, visual symptoms, and constitutional symptoms (Brown et al., 1986, 1994; Rabinovici et al., 2006). Although most patients with sCJD progress rapidly over weeks to months from the first obvious symptoms to death, a large minority survive for a year or longer, sometimes surviving for two to three years (Johnson et al., 2012; Parchi et al., 1999). The presentation and duration of sCJD are in part affected by the molecular classification of patients based on their polymorphism at codon 129 in PRNP (see Prion Diseases: Basic Concepts) and the prion typing based on Western blot of brain tissue (see Prion Strains and Strain Typing of Human Prion Diseases) (Parchi et al., 1999). The ultimate, final stage of sCJD is usually an akinetic-mute state (no purposeful movement and not speaking) (WHO, 1998). Most patients with prion disease, as with other neurodegenerative dementias, eventually die from aspiration pneumonia.

Cognitive problems are often among the first symptoms in sCJD, and typically include mild confusion, memory loss, and difficulty concentrating, organizing, or planning (Appleby et al., 2009; Rabinovici et al., 2006). Motor manifestations of CJD include extrapyramidal symptoms (bradykinesia, dystonia, tremor), cerebellar symptoms (gait or limb ataxia), and in many patients myoclonus (sudden jerking movements of the limbs or trunk) (Brown et al., 1986). Whereas the cognitive and certainly motor symptoms are obvious, behavioral/psychiatric features are common (Brown et al., 1986) and often early but are more subtle, and might not be what bring patients to medical attention (Rabinovici et al., 2006). These are discussed further in the section Neuropsychiatric Features of sCJD. Prodromal signs often include constitutional symptoms (i.e., fatigue, malaise, headache, dry cough, lightheadedness, vertigo), which occur in at least one-third of patients (Brown et al., 1986). Visual symptoms, such as blurred or double vision, cortical blindness, or other perceptual problems, occur as the first symptom in about 5% (Rabinovici et al., 2006), as early symptoms in about 15% (Brown et al., 1986), and in almost one-third of patients throughout the disease course (Brown et al., 1986). These symptoms likely are caused by problems with processing of visual information in the brain rather than retinal or cranial nerve abnormalities. Higher cortical signs, such as aphasia, neglect, or apraxia (inability to perform learned movements), owing to cortical dysfunction are present early in 15% and through the disease course in almost one-half of patients (P. Brown et al., 1986). Sensory symptoms, such as numbness, tingling, and/or pain are less well-recognized symptoms, and are probably under-reported given the magnitude of the other symptoms in sCJD. They occur about 10% of sCJD patients but often are very early symptoms (Brown et al., 1986; Rabinovici et al., 2006; Will et al., 2004). Painful dysesthesias, a more common feature (included in clinical diagnostic criteria for vCJD) might also occur in some patients with sCJD (Rabinovici et al., 2006).

Various clinical subtypes of sCJD also have been described, including a visual-onset form (Heidenhain variant; Kropp et al., 1999), an ataxic-onset form (Brownell-Oppenheimer; Brown et al., 2010), and recently an “affective variant” (Appleby et al., 2009). In the Heidenhain form typically the first symptom(s) are visual disturbances, such as blurred vision, visual field restriction, illusions, visual hallucinations, and even cortical blindness. Patients with the Heidenhain variant tend to have typical EEG findings, often have MM1 molecular classification, and shorter disease duration than other sCJD forms (Appleby et al., 2009; Kropp et al., 1999). In the Brownell-Oppenheimer variant of sCJD, patients have isolated ataxia at onset. These patients tend to not have classic EEG findings of PSWCs and the brain MRI often shows T2/FLAIR and DWI hyperintensity in the caudate and putamen (see Diagnostic Tests for sCJD) (Appleby et al., 2009). Behavioral/affective features of sCJD are discussed in Neuropsychiatric Features of sCJD.

NEUROPSYCHIATRIC FEATURES OF sCJD

Although sCJD generally is thought of as a cognitive and motor disorder, psychiatric symptoms often are prominent

and are under-recognized as early, if not the very first symptoms. Early behavioral and psychiatric symptoms in sCJD might include irritability, agitation, depression, apathy, aberrant motor behavior, aggression, anxiety, and unspecified personality changes (Rabinovici et al., 2006). Table 69.2 shows the frequency of a various neuropsychiatric behaviors from the Neuropsychiatric Inventory (NPI) (Cummings, 1997) occurring at least once per week in our UCSF cohort of 84 probable and definite patients with sCJD (M. D. Geschwind et al., 2007; Forner et al., 2011). Eating behaviors were the most common, occurring in about two-thirds of patients, and were usually eating less/losing weight (Tables 69.2 and 69.3). Apathy, anxiety, and sleep disturbances (typically insomnia) were the next most frequent neuropsychiatric behaviors, followed by aberrant motor behavior (repetitive behaviors, such as taking on/off clothes), agitation, and depression. When hallucinations occurred, they were usually visual. Table 69.3 shows details of five major NPI behaviors (change in eating habits, sleep disturbances, aberrant motor behavior, delusions, and hallucinations) occurring at any frequency (not just at least weekly, as in Table 69.2) in a UCSF sCJD cohort. More than half of sCJD patients had sleep problems, usually insomnia. Half of the patients had aberrant motor behaviors. Although only about 25% of subjects had hallucinations occurring at least once per week (see Table 69.2), 37% had hallucinations of any frequency (see Table 69.3). Auditory and tactile hallucinations occurred in less than 10% of patients. Some patients had multiple modalities of hallucinations. Delusions were even more common than hallucinations, and were often paranoid (Forner et al., 2011).

DIAGNOSTIC TESTS FOR sCJD

ELECTROENCEPHALOGRAPH IN sCJD

The diagnostic electroencephalogram finding in sCJD consists of sharp or triphasic waves (periodic sharp wave complexes or PSWCs) occurring every 0.5 to 2 seconds (Fig. 69.1) (Brown and Mastrianni, 2010). This electroencephalogram is found in only two-thirds of sCJD patients and often is present only late in the disease course. Other neurological conditions, however, such as Alzheimer’s disease, dementia with Lewy bodies (DLB), toxic-metabolic and anoxic encephalopathies, progressive multifocal leukoencephalopathy, and Hashimoto encephalopathy, also can have PSWCs on electroencephalogram (Seipelt et al., 1999; Tschampa et al., 2001). In most sCJD patients, the electroencephalogram typically first shows focal or diffuse slowing (Steinhoff et al., 2004).

CEREBROSPINAL FLUID TESTS IN sCJD

The clinical utility of cerebrospinal fluid biomarkers is somewhat controversial, in part because of varying degrees of sensitivity and specificity around the world. The 14-3-3 protein was one of the first CSF proteins touted as a diagnostic marker for CJD, but many feel it has limited sensitivity and specificity (Chapman et al., 2000; Geschwind et al., 2003) because it is found elevated in many non-prion neurological

TABLE 69.2. Frequency of UCSF sCJD cohort patients exhibiting behaviors from the neuropsychiatric inventory (NPI) at least once a week

BEHAVIOR FROM THE NPI OBSERVED ≥ ONCE/WEEK	PERCENT OF sCJD SUBJECTS (N = 84)

conditions (Sato et al., 1999). When initially published in 1996, the 14-3-3 was reported to have 100% sensitivity and 96% specificity, but this study was limited by small sample size and poor controls (Hsich et al., 1996). Subsequent larger European studies have found this protein to have a sensitivity and specificity of about 85%, but control patients might not have been sufficiently characterized in some of these studies (Collins et al., 2006; Sanchez-Juan et al., 2006). A more recent analysis in the United Kingdom showed cerebrospinal fluid 14-3-3 sensitivity of 86% and specificity of 74% in a pathologically confirmed cohort (Chohan et al., 2010). Recent data in a large US cohort from the US National Prion Disease Pathology Surveillance Center (NPDPS) showed the 14-3-3 Western blot only had a receiver operating characteristic area under the curve (ROC AUC) value of 0.68 (Hamlin et al., 2012), which is rather poor (a test with perfect sensitivity and specificity would be 1.0). Many feel that the 14-3-3 protein is merely a marker of rapid neuronal injury and has little specificity for sCJD. It is important to realize that cerebrospinal fluid 14-3-3 protein is elevated in many non-prion neurological conditions resulting in neuronal injury including multiple sclerosis, encephalitis, Alzheimer’s disease, and stroke (Geschwind et al., 2003).

Total-tau (t-tau), neuron specific enolase (NSE), and the astrocytic protein S100β are also used as cerebrospinal fluid biomarkers for sCJD diagnosis. The sensitivity and specificity of these biomarkers for sCJD varies greatly among studies. One large multicenter European study retrospectively examined the sensitivity and specificity of four biomarkers: 14-3-3, t-tau, NSE, and S100β. Because not all patients underwent all four tests, nor were the tests performed in the same cerebrospinal

TABLE 69.3. Analysis of frequency of any occurrence of five common behaviors in sCJD*

MAJOR AND MINOR BEHAVIORAL FEATURES	sCJD

fluid samples, this study did not allow for legitimate comparison between biomarkers. Nevertheless, they found the sensitivity and specificity of the 14-3-3 to be 85% and 84%, t-tau (cutoff greater than 1,300 pg/ml) 86% and 88%, NSE 73% and 95%, and S100β 82% and 76%, respectively (Sanchez-Juan et al., 2006). The same methodological problems were also present in a more recent 2010 survey of the UK surveillance

Figure 69.1 Diagnostic EEG in CJD. Electroencephalogram showing 1-Hz periodic sharp wave complexes (PSWCs) consistent with CJD.

center data; however, they did a separate analysis of cases in which both 14-3-3 and t-tau protein were tested in the same samples. The sensitivity and specificity for 14-3-3 and t-tau tested in the same samples were 85% and 74% for 14-3-3 and 81% and 85% for t-Tau (Chohan et al., 2010).

MAGNETIC RESONANCE IMAGING IN SCJD

Diffusion weighted imaging (DWI) MRI has higher sensitivity for sCJD than either electroencephalogram or 14-3-3 protein (Shiga et al., 2004; Vitali et al., 2008; Young et al., 2005; Zerr et al., 2009). Magnetic resonance imaging typically shows cortical gyral hyperintensities (cortical ribboning) on fluid attenuated inversion recovery (FLAIR) and especially DWI sequences (Vitali et al., 2011). These same sequences, as well as standard T2 sequences, also often reveal hyperintensities in the deep nuclei (the caudate, putamen, and less often the thalamus). Diffusion weighted imaging has a higher sensitivity than FLAIR for sCJD (Vitali et al., 2011). Figure 69.2C–H shows some typical MRI patterns in sCJD.

When CJD is suspected, a brain MRI with diffusion (DWI and attenuated diffusion coefficient map [ADC map]) and FLAIR sequences should be obtained (Vitali et al., 2008). Even at major medical centers, many radiologists are not familiar with the MRI findings indicative of CJD, and a majority of sCJD MRIs are misread (Geschwind et al., 2010). Diagnostic MRI criteria for sCJD have been proposed. Some allow the use of FLAIR or DWI and do not include abnormalities in the frontal lobes (Zerr et al., 2009), whereas others require diffusion abnormalities and do not exclude frontal lobe involvement (Vitali et al., 2008).

DIAGNOSTIC TESTS ON THE HORIZON FOR CJD

Although not yet in clinical practice, newer *in vitro* assays such as the protein misfolding cyclic amplification (PMCA) assay and modifications of this assay are on the horizon (see Prion Transmission and Detection). In these assays, a very small amount of fluid (e.g., blood or CSF) or brain tissue suspected to contain prions is mixed with PrP^C (recombinant or from normal brain) and subjected to alternating series of incubations and either shaking or sonication. PrP^{Sc} is amplified and more easily detected by transforming the PrP^C substrate into PrP^{Sc} (see Prion Transmission and Detection) (Atarashi et al., 2011; Brown and Mastrianni, 2010).

GENETIC PRION DISEASES

Genetic prion diseases (gPrDs) were discussed previously (Prion Diseases: Basic Concepts) More than 40 mutations, including point mutations, stop codons, insertions, and deletions, have been identified to cause gPrD (Fig. 69.3). Testing and diagnosis can be achieved through DNA testing of blood while a patient is alive or through autopsy tissue. Despite the typically high penetrance (100% for most mutations), more than 60% of patients with gPrD do not have a positive family

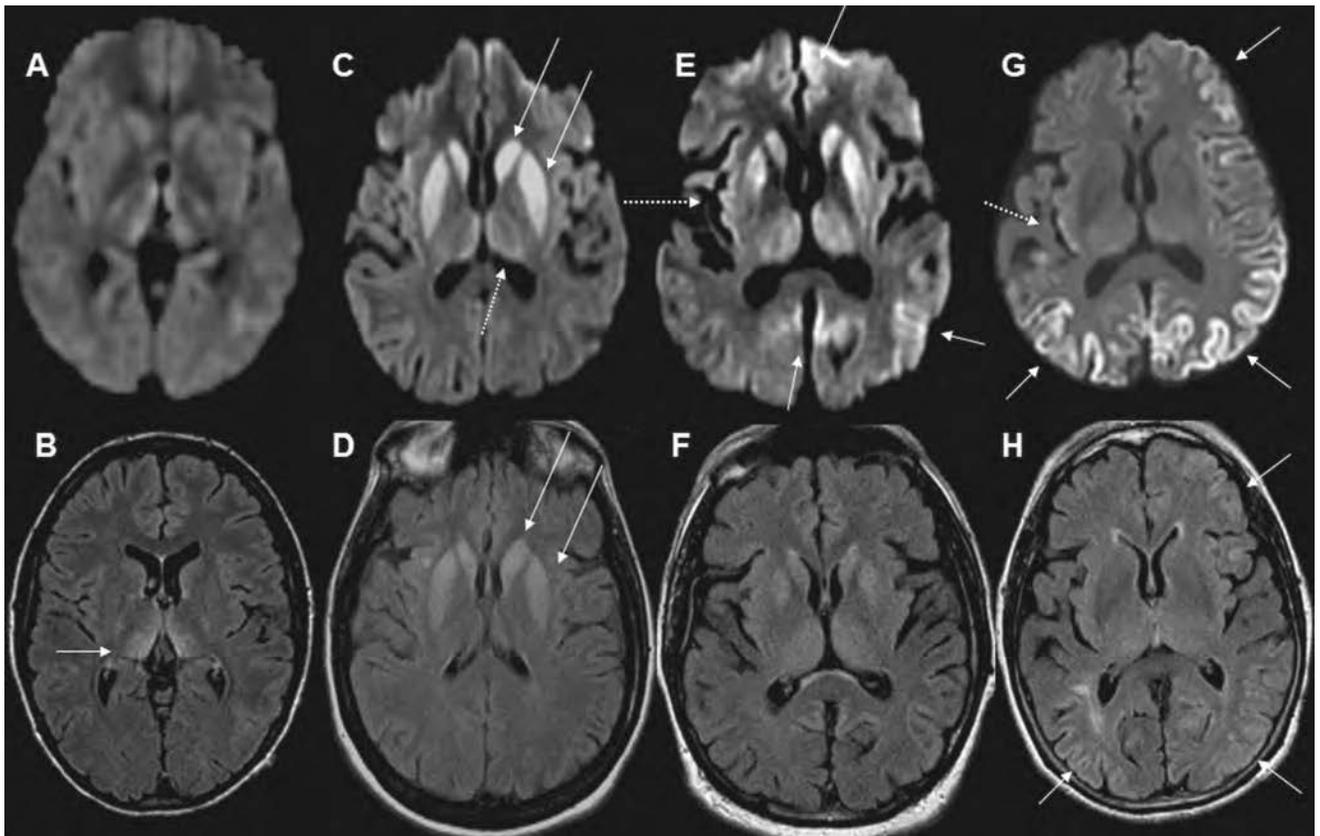

Figure 69.2 MRI findings in CJD. (A,B) A patient with probable variant CJD and three common MRI patterns in sporadic CJD: (C,D) predominantly subcortical, (E,F) both cortical and subcortical, and (G,H) predominantly cortical. Note that in sporadic CJD the abnormalities are always (C,E,G) more evident on DWI than (D,F,H) on FLAIR images. (A,B) An MRI of a 21-year-old woman with probable variant CJD showing bilateral thalamic hyperintensity in the mesial pars (mainly dorsomedian nucleus) and posterior pars (pulvinar) of the thalamus, the so-called double hockey stick sign. Also note the pulvinar sign, with the posterior thalamus (pulvinar) being more hyperintense than the anterior putamen. The three sporadic CJD cases are pathology proved. (C,D) An MRI of a 52-year-old woman showing strong hyperintensity in bilateral striatum (solid arrows, both caudate and putamen) and slight hyperintensity in mesial and posterior thalamus (dotted arrow). (E,F) An MRI of a 68-year-old man showing hyperintensity in bilateral striatum (note anteroposterior gradient in the putamen, which is commonly seen in CJD), thalamus, right insula (dotted arrow), anterior and posterior cingulate gyrus (arrow, L > R), and left temporal-parietal-occipital junction (arrow). (G,H) An MRI of a 76-year-old woman showing a diffuse hyperintense signal mainly in the bilateral parietal and occipital cortex, right posterior insula (dashed arrow) and left inferior frontal cortex (arrow), but no significant subcortical abnormalities. CJD, Creutzfeldt–Jakob disease; DWI, diffusion-weighted imaging; FLAIR, fluid-attenuated inversion recovery; MRI, magnetic resonance imaging. (Borrowed from Vitali et al. *Neuroimaging in dementia*. *Semin. Neurol.* Sep 2008;28(4):467–483 with permission from Thieme Publishing Group.)

history of prion disease; often this is because relatives were misdiagnosed with other neuropsychiatric or other conditions, such as alcoholic dementia. In some cultures, it is common for families to hide their medical history. In some mutations such as E200K in Slovakia, however, there is a negative family history because of reduced mutation penetrance (Kovacs et al., 2005).

As noted, historically, there have been three major classifications of gPrDs, largely based on clinical and pathological characteristics: fCJD, GSS, and FFI. These classifications are not absolute because some mutations have features that blend fCJD and GSS. More important, these classifications predate identification of the *PRNP* gene and thus genetic classification (Mead, 2006). Patients with gPrD typically have a younger age of onset (typically approximately in their forties to sixties), a slower progressive course, and a longer life span (typically a few years) than sCJD patients, but this varies greatly among mutations. Depending on the *PRNP* mutation and other genetic and epigenetic factors, some

gPrDs present virtually identically (clinically and pathologically) to sCJD, with rapid onset of clinical symptoms and short survival of weeks to months (Kong et al., 2004; Mead, 2006). In general, fCJD presents like classic sCJD with rapidly progressive dementia, with ataxia, other motor problems and myoclonus. GSS usually has a slower progression over a few years, often with early ataxia and other cerebellar features, sometimes early behavioral features, and dementia later in the course. The course of FFI usually presents with intractable insomnia, dysautonomia, hallucinations, and motor signs.

Some less common *PRNP* mutations, such as V180I, result in an older age of onset, in one's seventies or eighties. gPrDs often have variable presentations and disease courses within the same mutation, and sometimes, even within the same family. As noted, the codon 129 polymorphism within *PRNP* as well as other polymorphisms (see Fig. 69.3) often effect the presentation of gPrDs (Brown and Mastrianni, 2010; Kong et al., 2004; Mead, 2006; Mead et al., 2007).

POLYMORPHISMS

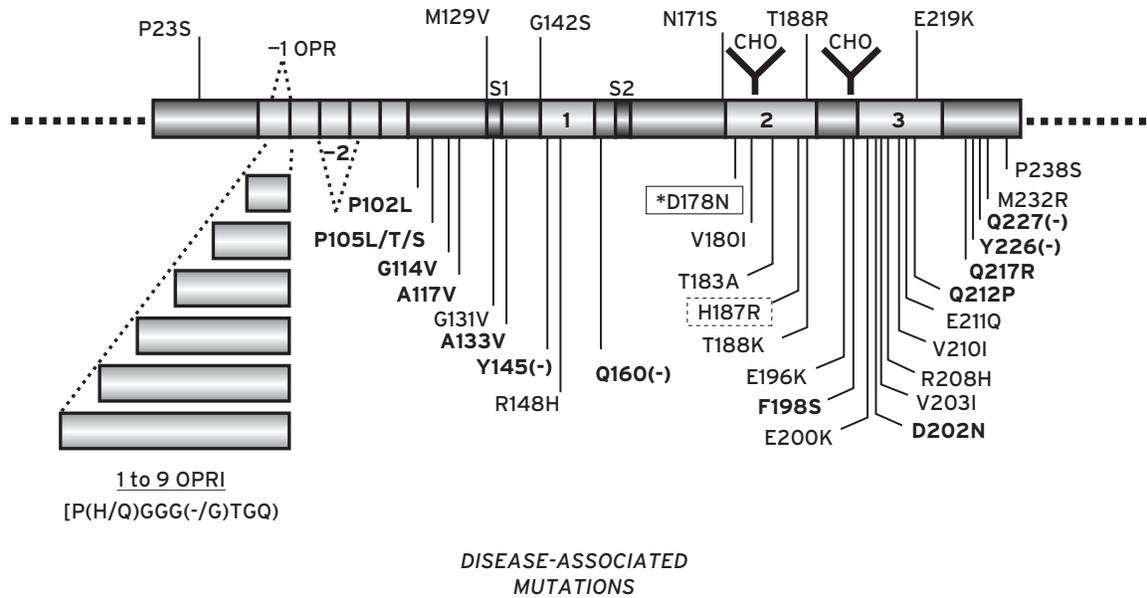

Figure 69.3 General organization of human prion protein (PRP) and related mutations and polymorphisms. The 762 base pair (bp) open-reading frame of PRNP encodes the 253 amino acid protease-sensitive, cellular isoform (Pr^{Sc}). Nuclear magnetic resonance (NMR) studies predict 3 α -helices (H1, H2, and H3), and 2 β strands (S1 and S2). Asn-linked glycosylation sites (CHO) occur at residues 181 and 197. The octapeptide repeat segment extends between residues 51 and 91. Pathogenic mutations and polymorphisms of the PRNP gene are represented below and above the schematic, respectively. A single octapeptide repeat deletion and a small number of single bp changes are considered non-pathogenic polymorphisms, some of which act as phenotypic modifiers, most notably, residue 129. Octapeptide repeat insertions (OPRI) of 1 to 9, excluding 3, are pathogenic, as are *30 bp changes. Letters preceding the numbers indicate the normal amino acid residue for the position and letters following the numbers designate the new residue caused by the mutation. Bold mutations are associated with Gerstmann–Sträussler–Scheinker syndrome (GSS); the remainder cause Creutzfeldt–Jakob disease (CJD). * D178N is associated with either CJD or familial fatal insomnia (FFI), depending on the allelic codon 129 sequence (Met = FFI; Val = CJD). H187R displays variable pathology in the limited cases reported. Amino acid letter designations are as follows: A, alanine; D, aspartate; E, glutamate; F, phenylalanine; H, histidine; I, isoleucine; K, lysine; L, leucine; P, proline; Q, glutamine; R, arginine; S, serine; T, threonine; V, valine; Y, tyrosine; (-), stop signal. (Borrowed from Brown and Mastrianni 2011 *J. Ger. Psych. Neuro* with permission from Sage Publications *The prion diseases. J. Geriatr. Psychiatry Neurol*, 23(4), 277–298.)

FAMILIAL CJD

More than 15 mutations cause familial CJD (fCJD). Most are point (missense) mutations, but some are insertion mutations and a deletion (Kong et al., 2004; Mead, 2006). Most fCJD patients present similarly to sCJD with overlapping clinical MRI and EEG findings. The most common fCJD mutation worldwide is E200K (Mead, 2006), found most commonly among Libyan Jews and Czechs (Kovacs et al., 2009). Many other PRNP mutations are presented in Figure 69.3.

GERSTMANN–STRÄUSSLER–SCHEINKER

Gerstmann–Sträussler–Scheinker (GSS) syndrome is caused by at least 10 PRNP mutations, including several missense mutations, a stop mutation, and insertion mutations (OPRI) (see Fig. 69.3). Generally OPRI mutations with five or more additional octapeptide repeats (repeats of 24 base pairs) present with a GSS phenotype with a long duration of several years, whereas OPRI mutations with four or fewer repeats present phenotypically as CJD, with lower penetrance as well. There are many exceptions, however (Kong et al., 2004; Mead, 2006). The age of onset for GSS mutations is often under the age of 65, typically in one’s fifties or younger. As noted, GSS often starts with a slowly progressive ataxic and/or parkinsonian disorder.

Cognitive impairment often comes later, although some mutations present with early dementia and/or behavioral abnormalities. There is, however, considerable phenotypic variability within and between mutations and families (Giovagnoli et al., 2008; Kong et al., 2004; Webb et al., 2008). Because of the slow course (up to several years), persons with GSS can be mistaken to have other neurodegenerative or even neuropsychiatric conditions such as multiple system atrophy, spinocerebellar ataxias, idiopathic Parkinson disease, AD, or Huntington disease (Alner et al., 2011; Laplanche et al., 1999; Mead, 2006).

Of the 8 OPRI mutations causing GSS, an atypical form of GSS caused by an 8-octapeptide repeat insertion mutation (OPRI-8) results in prominent early neuropsychiatric features, often in the patient’s late twenties, with a long disease course of several years. Patients are often hospitalized early in psychiatric institutions. Psychiatric features often include mania or mania-like features (Laplanche et al., 1999). Patients with 6-OPRI mutations often have a premorbid or early-onset psychological/personality disorder characterized by irritability, short temper, aggression, antisocial behavior, and aggression. Arrests and other involvement with police are common. These symptoms often predate onset of obvious neurological symptoms, which typically occurs in one’s thirties with quite variable survival of less than one year to more than a decade. Cognitive

testing typically shows frontal-executive impairment in almost all cases and many patients have visuospatial, naming, and memory difficulty (Alner et al., 2011).

Another gPrD of particular interest to this chapter is caused by the *PRNP* mutation H187R, of which only a few families have been reported. The first reported family presented with early-onset dementia and other motor features classic for CJD. Another family had childhood or adolescent onset of neuropsychiatric features in more than one-half of patients. Some of the common neuropsychiatric disorders include suicide attempts, pedophilia, pyromania, and kleptomania. Rarely there was developmental delay or mental retardation. Dementia often began in the early thirties, and progressed slowly over a decade or longer. Early cognitive features include frontal-executive dysfunction (including disinhibition) and poor insight. Later aphasia (often fluent), ideomotor apraxia, visuospatial dysfunction, extrapyramidal symptoms, as well as chorea and stereotypies occurred (Hall et al., 2005). This mutation sometimes presents with a more variable pathology that is not necessarily consistent with GSS (Brown and Mastrianni, 2010).

FATAL FAMILIAL INSOMNIA

Fatal familial insomnia (FFI) is one of the rarest gPrDs and is caused by a single *PRNP* point mutation, D178N, with codon 129 having methionine (129M) on the same chromosome (*cis*) (see Fig. 69.3). Patients with D178N but *cis* valine at codon 129 (129V) usually present with fCJD, clinically more similar to sCJD than to FFI. Fatal familial insomnia usually presents at a mean age of the late forties (48 to 49; range, 20 to 72) with progressive, severe insomnia occurring for several months before the onset of other features, such as dysautonomia (e.g., tachycardia, hyperhidrosis, hyperpyrexia), with motor and cognitive problems variably appearing later in the illness. Average survival is about 18 months (range, 7 to 33 months), slightly longer than most patients with sCJD (Brown and Mastrianni, 2010; Kong et al., 2004).

In our practice, after appropriate genetic counseling for autosomal-dominant neurological disease (<http://www.hdfoundation.org/html/hdsatest.php>), we test every patient suspected to have prion disease for gPrD by analyzing for a *PRNP* mutation. This genetic testing is usually done by blood test, or if done postmortem, by extraction of DNA from fresh-frozen tissue. Because many gPrDs appear similar to sCJD and can have obscured family histories, this testing is important after the appropriate genetic counseling.

DIAGNOSTIC TESTS IN GENETIC PRION DISEASES

In general, EEG, CSF, and MRI are less sensitive in gPrDs than in sCJD. In fCJD, depending on the mutation, the EEG often shows PSWCs (in later stages). The CSF biomarkers (14-3-3, NSE, t-tau) in fCJD often are elevated, but with typically lower sensitivity than in sCJD (Sanchez-Juan et al., 2006). Magnetic resonance images, again depending on the mutation, show

overlapping findings with sCJD. Some mutations, however, have particular patterns. E200K typically shows symmetrical, prominent striatal hyperintensity, with less prominent cortical ribboning (Vitali et al., 2008). The V180I mutation often shows cortical ribboning with minimal or absent deep nuclei hyperintensities. (The EEG typically lacks PSWCs.) In GSS, the EEG usually only shows slow waves and not PSWCs. Cerebrospinal fluid typically does not show elevated biomarkers (Sanchez-Juan et al., 2006), probably because GSS is not a very rapidly progressive dementia, like sCJD, and these biomarkers are probably more markers of rapid neuronal injury (Geschwind et al., 2003). Magnetic resonance imaging usually does not show the deep nuclei hyperintensities and cortical ribboning seen in sCJD and many patients with fCJD. There are GSS mutations, however, in which some patients have some of these CJD-like MRI findings, although for unclear reasons other patients with the same mutation might not have these MRI abnormalities (Vitali et al., 2011). In FFI, EEG usually just shows slowing, but not PSWCs. Brain MRI, including diffusion-weighted imaging, is usually normal, but FDG-PET imaging reveals thalamic and cingulate hypometabolism, often even before disease onset. Cerebrospinal fluid biomarkers in general have very low sensitivity in FFI.

ACQUIRED CJD

Acquired prion diseases occur because prion diseases typically are transmissible and infectious. Acquired forms include Kuru (now essentially extinct, occurring in the Fore tribe in Papua, New Guinea because of endocannibalism), iatrogenic CJD (iCJD), and the highly publicized variant CJD (vCJD), occurring primarily in the United Kingdom and France, caused by consumption of bovine spongiform encephalopathy (BSE or mad cow disease) contaminated beef and about five cases by blood transfusion (Brown and Mastrianni, 2010).

As prions are proteins, typical sterilization methods that kill viruses and bacteria do not denature proteins (Prusiner, 1998). Inactivation requires other methods or longer times at higher pressure and temperatures than typically used for standard sterilization (Peretz et al., 2006). Inadequate decontamination has led to approximately 400 cases of iatrogenic CJD (iCJD) from the use of cadaveric-derived human pituitary hormones (mostly human growth hormone), dura mater for grafts, cornea for transplants, as well as the re-use of “sterilized” EEG depth electrodes implanted directly into the brain and other neurosurgical equipment, and now blood transfusion from vCJD (Brown and Mastrianni, 2010; Brown et al., 2000; Will, 2003). Most of the pituitary-derived (human growth hormone [hGH]) cases occurred in France, the United Kingdom, and the United States. Methods have since been instituted to prevent prion transmission through such hormones (Brown et al., 2000). Fortunately, the number of iCJD cases is declining (Brown et al., 2006).

The most notorious form of CJD is variant CJD (vCJD), which was first identified in 1995 (Will et al., 1996). In most cases it is caused by inadvertent ingestion of bovine

spongiform encephalopathy (BSE or mad cow disease) or, in a few cases, blood transfusion from asymptomatic patients who were unknowing carriers of vCJD (Brown and Mastrianni, 2010). Cattle are thought to have contracted BSE from being fed scrapie-infected sheep products used as feed (Scott et al., 1999). Compared with sCJD, patients with vCJD are generally younger, with a median age of around 27 (range 12 to 74 years) and most patients have been less than 50 years old. The mean disease duration is longer, about 14.5 months, versus about seven months for sCJD. Relevant to this text, early psychiatric symptoms are quite prominent and more characteristic in vCJD than even sCJD (Wall et al., 2005; Rabinovici et al., 2006). Diagnostic criteria for vCJD are shown in Table 69.4 (Heath et al., 2010). Significantly, profound psychiatric features typically are an early and prominent feature of the disease, often occurring several months before obvious neurological symptoms. Painful paresthesias, usually persistent through the disease course, often occur in vCJD, although such pain rarely is seen in other prion diseases. The EEG does not show the classic periodic sharp wave complexes, except in rare cases at the end of the disease. Cerebrospinal biomarkers, such as 14-3-3, NSE, and t-tau, appear to be even less sensitive in vCJD than in sCJD (Sanchez-Juan et al., 2006). The best diagnostic marker currently is the brain MRI, which usually shows the “pulvinar sign,” in which the pulvinar (posterior thalamus) is

brighter than the anterior putamen on T2-weighted or DWI MRI (see Fig. 69.2A,B). This MRI pattern is very rare in the other prion diseases (Vitali et al., 2008). More specific tests are under development, including detecting vCJD prions in the blood and/or CSF.

The younger age of onset, MRI findings, prominent early psychiatric features, persistent painful sensory symptoms, and possible chorea help differentiate vCJD from sCJD. As with sCJD, definitive diagnosis of vCJD is based on neuropathological evidence of PrP^{Sc} in brain biopsy or autopsy. Unlike most other human prion diseases, in which prions are found primarily in the central nervous system, in vCJD prions are found in high numbers in the lymphoreticular system, including the appendix, tonsils, and other lymphoid tissue. Variant CJD is still exceedingly rare, with only about 226 cases identified worldwide through late 2012 (<http://www.eurocjd.ed.ac.uk>). Curiously, all but approximately two cases of vCJD have been MM at codon 129; two have been MV, suggesting that methionine homozygosity confers increased risk for vCJD (Brown and Mastrianni, 2010). It appears that the initial epidemic of vCJD has leveled off, with only a few new cases per year recently. There is, however, concern that an increase in cases will occur in the future either through blood transmission or longer latency, such as in MV or VV individuals (Brown and Mastrianni, 2010).

TABLE 69.4. Diagnostic criteria for variant CJD

DEFINITE 1A and neuropathological confirmation of vCJD ^a	I A Progressive neuropsychiatric disorder B Duration of illness >6 months C Routine investigations do not suggest an alternative diagnosis
PROBABLE I and 4/5 of II and IIIA and IIIB Or I and IV A ^b	D No history of potential iatrogenic exposure E No evidence of a familial form of prion disease
POSSIBLE I and 4/5 of II and III A	II A Early psychiatric symptoms ^c B Persistent painful sensory symptoms ^d C Ataxia D Myoclonus or chorea or dystonia E Dementia
	III A EEG does not show the typical appearance of sporadic CJD ^e in the early stages of illness B Bilateral pulvinar high signal on MRI scan
	IV A Positive tonsil biopsy ^b

^a Spongiform change and extensive PrP deposition with florid plaques throughout the cerebrum and cerebellum

^b Tonsil biopsy is NOT recommended routinely, nor in cases with EEG appearances typical of sCJD, but may be useful in suspect cases in which the clinical features are compatible with vCJD and MRI does not show bilateral I pulvinar high signal

^c Depression, anxiety, apathy, withdrawal, delusions

^d This includes both frank pain and or dysesthesia

^e The typical appearance of the EEG in sporadic CJD consists of generalized triphasic periodic complexes at approximately one per second. These may occasionally be seen in the late stages of vCJD (Borrowed with permission from Heath et al. *Ann. Neurol*, 67(6): 761–770.

NEUROPATHOLOGY OF HUMAN PRION DISEASES

There are four neuropathological hallmarks of prion disease: spongiform (vacuolar) degeneration, neuron death, reactive astrocytic gliosis, and deposition of misfolded prion protein in the brain (Budka et al., 1995). The signature pathology in these diseases is the presence of extensive vacuolation of the brain parenchyma (spongiform change), giving it a Swiss cheese–like appearance (see Fig. 69.4A). Although reactive astrocytic gliosis is a general marker for CNS damage, it is notable in that it is present to a much greater extent in prion diseases than in other neurodegenerative disorders such as Alzheimer’s disease and Parkinson disease (see Fig. 69.4B). Although PrP^{Sc} deposition is present in almost all cases of prion disease, the type and pattern of deposition can vary greatly among individual classes of human prion diseases (see Fig. 69.4C–F). For instance, cerebral amyloid plaques composed of aggregated PrP^{Sc} are found in patients with GSS and vCJD, whereas PrP^{Sc} deposition is more granular or “punctate” in nature in patients with CJD.

NEUROPATHOLOGY OF CJD

More than 95% of patients with sporadic CJD exhibit spongiform degeneration in the cerebral cortex. This is associated with an intense reactive astrocytic gliosis. In contrast to Kuru and GSS, only 5% to 10% of patients with sporadic CJD exhibit mature PrP-containing amyloid plaques. Non-amyloid PrP^{Sc} deposition, however, is much more common, with frequent evidence for “synaptic” or punctate deposition in the cortex

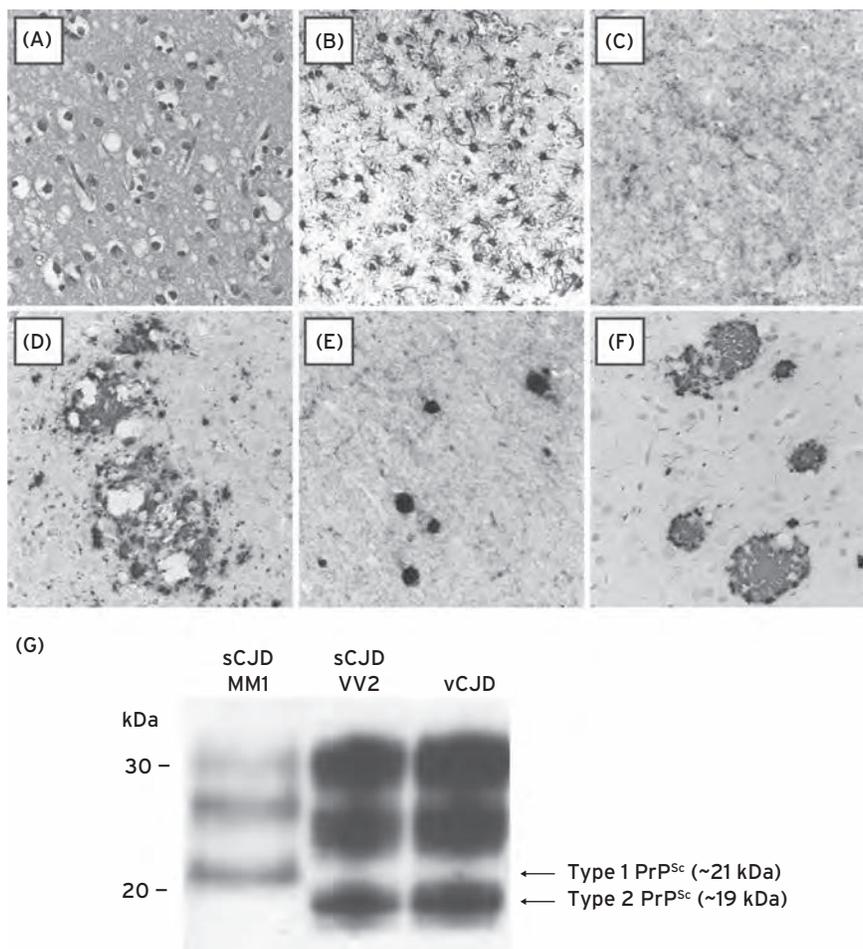

Figure 69.4 Biochemical and neuropathological hallmarks of human prion disease. (A–F) The neuropathological hallmarks of prion disease. Spongiform change (A) and reactive astrocytic gliosis (B) in the parietal cortex of a patient with sporadic CJD (subtype MM1). (C) The synaptic pattern of PrP^{Sc} deposition in the frontal cortex of a patient with sporadic CJD exhibiting the MM1 subtype. (D) Perivacuolar PrP^{Sc} deposition in the parietal cortex of a patient with MM2 sporadic CJD. (E) Kuru-like PrP^{Sc} plaques in the molecular layer of the cerebellum in a patient with MV2 sporadic CJD. (F) PrP^{Sc} amyloid plaques in the hippocampus of a GSS patient with the A117V mutation. (G) As revealed by immunoblotting, protease-resistant PrP^{Sc}, the biochemical signature of prion disease, is observed in the brains of patients with CJD. In sporadic CJD subtype MM1, type 1 PrP^{Sc} is present, whereas type 2 PrP^{Sc} is observed in sporadic CJD subtype VV2 and variant CJD. (See color insert.)

as well as perivacuolar PrP^{Sc} deposition in brain regions containing spongiform change. Spongiform change, PrP^{Sc} deposition, and reactive astrocytic gliosis tend to co-localize in the brain, arguing that PrP^{Sc} deposition is responsible for the neuronal damage. The location and intensity of the neuropathological changes vary between the different molecular subtypes of sporadic CJD. For instance, the “synaptic” pattern of PrP^{Sc} deposition is most common in the MM1 subtype of CJD, whereas focal plaque-like PrP^{Sc} deposits are typically found in the VV2 subtype. Likewise, Kuru-like PrP^{Sc} plaques are most commonly found in the MV2 subtype, but perivacuolar PrP^{Sc} deposits are found in the MM2 subtype. The neuropathology of most fCJD cases generally resembles that of sCJD. The most prominent feature of vCJD is the presence of large numbers of PrP-containing amyloid plaques in the brain, including so-called “florid plaques,” in which PrP^{Sc} deposits are surrounded by vacuolation, giving a flower-like appearance (Brown and Mastrianni, 2010). Intense vacuolation is also observed in patients with vCJD, allowing them to be further differentiated from GSS pathologically.

NEUROPATHOLOGY OF GERSTMANN–STRÄUSSLER–SCHEINKER SYNDROME

The defining neuropathological feature of GSS is the presence of PrP-containing amyloid plaques in the brain. The morphology and location of the plaques vary according to the specific GSS-causing mutation in *PRNP*. Although there is widespread neuronal loss in the brains of patients with GSS, there is minimal spongiform degeneration and reactive astrocytic gliosis is mostly associated with the amyloid plaques. Interestingly, neurofibrillary tangles (NFTs) composed of hyperphosphorylated tau protein are also found in some patients with GSS, such as those linked to the mutations F198S or Y145Stop. Neurofibrillary tangles are one of the two pathological hallmarks of Alzheimer’s disease. The amyloid plaques in GSS contain aggregated PrP; however, not A β as occurs in Alzheimer’s disease. Some GSS cases, such as those caused by the Y145Stop mutation, also exhibit prominent deposition of PrP amyloid along the walls of cerebral blood vessels, leading to a condition known as cerebral amyloid angiopathy (Bugiani et al., 2000).

NEUROPATHOLOGY OF FATAL FAMILIAL INSOMNIA

The most striking aspect of FFI is that the neuropathology is largely confined to the thalamus. In the anterior ventral and mediodorsal nuclei of the thalamus there is widespread neuronal loss and associated reactive astrocytic gliosis. Neuronal loss and gliosis are also observed in the inferior olives. Spongiform change is comparatively mild in FFI, but sometimes can be found in the cerebral cortex of patients with long disease duration. Compared with sCJD, the amount of PrP^{Sc} deposition in the brain is minimal (Gambetti et al., 1995). One form of sCJD, MM2-thalamic, has a similar pathological appearance to FFI, with some clinical overlap. Some have called this form sporadic fatal insomnia (sFI) (Barash, 2009).

NEUROPATHOLOGY OF KURU

Because the predominant clinical characteristic of Kuru is ataxia, it is not surprising that the most severely affected brain region in this disease is the cerebellum, in which large numbers of PrP-containing amyloid plaques can be found in the granule cell layer. These are associated with loss of granule cells, loss of Purkinje cells, and an intense activation of Bergmann radial glial cells. Milder neuropathological changes, including spongiform degeneration, are also observed in other regions of the brain.

PRION REPLICATION AND THE SPECIES BARRIER

Prions replicate using a process called template-directed misfolding. When a PrP^{Sc} molecule encounters a PrP^C molecule, it causes PrP^C to refold into an identical copy of PrP^{Sc} (Colby and Prusiner, 2011). These newly formed PrP^{Sc} molecules then serve as additional templates for converting more PrP^C molecules, allowing the infectious PrP^{Sc} form to propagate. This conformational conversion is thought to occur on the surface of the cell or within an endocytic compartment. The spontaneous (non-templated) conversion of PrP^C into PrP^{Sc} is an exceedingly rare event, likely owing to a large energy barrier between the two conformational isoforms of PrP.

Binding of PrP^{Sc} to PrP^C can be highly specific. For instance, hamster PrP^{Sc} is very ineffective at converting mouse PrP^C into mouse PrP^{Sc} and vice versa. When prions from one species are inoculated into an unrelated species, very inefficient disease transmission is observed, which is characterized by a low disease transmission rate and prolonged incubation periods. This is what is referred to as the species barrier for prion replication (Prusiner, 1998). The species barrier is encoded primarily by the amino acid sequence of PrP in a given species. For example, whereas normal mice are generally resistant to CJD prions, transgenic mice expressing human PrP in their brains are highly susceptible to CJD and other human prion strains (Telling et al., 1995).

The species barrier has important consequences for human health. Whereas there is no evidence that scrapie or CWD can be transmitted to humans (e.g., through the consumption of prion-contaminated meat from sheep or deer), consumption of BSE-contaminated meat has led to about 226 prion disease cases of variant CJD (vCJD), mostly in the United Kingdom and France (<http://www.cjd.ed.ac.uk/data.html>), as discussed earlier. Thus, BSE is one strain of prion that can more readily cross the species barrier. Indeed, BSE prions are also known to infect cats.

PRION TRANSMISSION AND DETECTION

The gold standard for demonstrating prion infectivity in a biological sample is to perform an animal bioassay. In a laboratory setting, the most efficient method for transmitting prion disease is to intracerebrally inject brain material from a sick animal into a young recipient animal (Watts et al., 2006). After a long incubation period (typically four to six months for various strains of mouse-adapted prions), the inoculated animals will exhibit clinical signs typical of prion disease and eventually progress to death within a few weeks. In mice, prion disease also can be transmitted via the oral and intraperitoneal routes of exposure, although the incubation times are longer than for intracerebral injections. Scrapie and CWD are known to be horizontally transmissible in nature (i.e., the disease can be transmitted from animal to animal under non-experimental conditions). Although the precise mechanism of inter-animal transmission remains to be established, prions are known to exist in the saliva and feces of CWD-infected deer. In contrast, there is little evidence to suggest that CJD is horizontally transmissible under normal conditions. Little or no prion infectivity has been found in biologically accessible fluids in CJD patients, including blood and urine. One notable exception is vCJD, in which secondary transmission of the disease through blood transfusion appears to have occurred (Brown and Mastrianni, 2010).

Although animal bioassays provide a definitive test for prions, they are time consuming and expensive. Consequently, numerous *in vitro* tests have been developed for detecting the presence of misfolded prion protein. Using a PrP-specific antibody, PrP^{Sc} deposits can be detected in formalin-fixed brain sections by immunohistochemistry, providing that a denaturing treatment has been performed to remove PrP^C and enhance the immunoreactivity of PrP^{Sc}. Similarly, protease-resistant PrP can be detected in brain homogenate by Western blotting using an anti-PrP antibody. More recently, two techniques have been developed that permit prions to be amplified in a test tube. Protein misfolding cyclic amplification (PMCA) and real-time quaking-induced conversion (RT-QuIC) can both be used to amplify and detect minute quantities of prions present in a sample, analogous to the polymerase chain reaction (PCR) technique that is used to detect trace amounts of specific DNA sequences (Atarashi et al., 2011).

PRION STRAINS AND STRAIN TYPING OF HUMAN PRION DISEASES

One of the greatest challenges to the protein-only hypothesis is derived from the existence of distinct “strains” of prions. Prion strains are defined as distinct prion isolates that exhibit differences in incubation period, neuropathological lesion profile in the brain, pattern of PrP^{Sc} deposition, and/or biochemical properties of PrP^{Sc} when propagated in a given species. In viruses or bacteria, different strains arise from mutations in their nucleic acid genomes, which confer novel properties to the infectious agent. Prion strains, however, can occur in the absence of any genetic material and without any changes to the amino acid sequence of PrP. Instead, it is thought that prion strains arise from distinct conformations of PrP^{Sc} (Telling et al., 1996). Thus, subtle changes to the “shape” of the PrP^{Sc} molecule can engender vastly different biochemical and neuropathological properties.

For human prion diseases, the most common way of differentiating different prion strains is by examining the biochemical properties of PrP^{Sc}. The biochemical hallmark of CJD is the presence of protease-resistant prion protein in the brain. Whereas PrP^C in healthy brain tissue is completely degraded by treatment with a protease such as proteinase K (PK), PrP^{Sc} is usually partially resistant to PK digestion, leaving behind the portion of PrP corresponding to the aggregated core of the protein. Protease-resistant PrP is most commonly detected in brain homogenate from CJD patients by immunoblotting using an antibody to detect PK-resistant PrP species. Following PK digestion, three PrP bands are typically visible, which correspond to di-, mono-, and un-glycosylated forms of PrP^{Sc}. Different prion strains can be ascertained by the relative ratios of the three PrP^{Sc} glycoforms as well as by the size of the unglycosylated PrP^{Sc} fragment. Using the most common nomenclature, there are two common sizes of PrP^{Sc} fragments, an approximately 21-kDa band referred to as type 1 PrP^{Sc} and an approximately 19-kDa band referred to as type 2 PrP^{Sc} (see Fig. 69.4G) (Parchi et al., 1999). For example, vCJD and FFI are classified as exhibiting type 2 PrP^{Sc}, whereas type 1, type 2, or both types of PrP^{Sc} can exist in sporadic CJD.

For sporadic CJD, prion strain types are classified according to the codon 129 genotype and the PrP^{Sc} type. There are at least six possible combinations (MM1, MM2, MV1, MV2, VV1, and VV2), where the two letters denote which polymorphic variant of PrP is present on the two copies of chromosome 20 (methionine [M] or valine [V]) and the number indicates whether type 1 or 2 PrP^{Sc} is present (Parchi et al., 1999). Of these six possibilities, at least five constitute distinct strains of sCJD (MM1, MM2, MV2, VV1, and VV2) (see Table 69.1). The MM1 and VV2 subtypes are the most common, whereas VV1 is by far the rarest. In general, sporadic CJD occurs more often in individuals who are homozygous for the codon 129 polymorphism (i.e., MM or VV). This is likely because the conformational conversion of PrP^C into PrP^{Sc} occurs more efficiently when identical PrP molecules are present. To complicate matters, although it was initially thought that patients with sCJD only had either type 1 or 2 PrP^{Sc} present in the brain, it is now known that some patients have both type 1 and 2 PrP^{Sc} (Polymenidou et al., 2005). How these MM1/2, VV1/2, and MV1/2 patients present is still not clear.

Protease-resistant PrP^{Sc} molecules that resemble those observed in sCJD are present in some but not all GSS cases. More common in GSS are smaller PK-resistant fragments of PrP that are approximately 14 and 7 kDa in size. These likely correspond to the protease-resistant core of the PrP amyloid plaques observed in GSS patients. A recently described sporadic prion disease in humans, termed variably protease sensitive prionopathy (VPSPr), is also characterized by atypical smaller protease-resistant PrP fragments, and might represent a sporadic version of GSS (Zou et al., 2010).

TREATMENT OF PRION DISEASES

Current management of prion diseases is largely symptomatic. Although many drugs have been effective at stopping or eliminating prion disease in cell culture and even in animal models when given before or near the time of prion inoculation, no drugs have been curative to date when given at a clinically meaningful time point after inoculation (to model sCJD). Drugs that are effective only before the disease has progressed, might however be helpful in presymptomatic gPrD or persons at high risk for acquired/variant CJD because of known exposure. A treatment trial in Germany with flupirtine showed some mild cognitive improvement in sCJD, but no effect on survival. Although quinacrine showed some promise *in vitro*, it failed to improve survival in an observational study of human prion disease in the United Kingdom and our own sCJD treatment trial in the United States (Geschwind, 2009). A treatment trial with doxycycline in Italy and France was completed in 2012 and showed no benefit. There is great effort to identify new treatments by high throughput drug screening, and other approaches, such as siRNA therapy to knock down the PrP^C substrate for PrP^{Sc}, are being actively studied in laboratories around the world (Brown and Mastrianni, 2010). Perhaps even more hopeful and exciting are recent data suggesting that other more common neurodegenerative diseases, such as Alzheimer’s disease, Parkinson disease, and frontotemporal dementia/ALS, might spread within the brain via a prion-like mechanism. Thus, drugs that work for one condition, might be helpful in other neurodegenerative diseases as well (Prusiner, 2012).

DISCLOSURES

Dr. Watts receives grant support from the NIH NINDS and NIA.

Dr. Geschwind receives grant support from the NIH NIA. Dr. Geschwind has served as a consultant for MedaCorp and Gerson Lehrman Group and has served on the advisory board for Lundbeck.

SECTION VIII | PSYCHIATRIC DISORDERS OF CHILDHOOD ONSET

JOSEPH D. BUXBAUM

There have been remarkable breakthroughs in our conceptualization of mental illness in the past few years, particularly in the areas of etiology and pathobiology. Nowhere is this more apparent than in neuropsychiatric disorders of childhood onset. The genomic architecture of these disorders includes rare genetic variation of major effect, allowing for the creation of cell and animal models with strong construct validity. In turn, results from these experimental model systems have provided the scientific basis for clinical trials using neurobiologically driven novel therapeutics. Given the current strengths of our research tools, genes are more tractable to discovery, but genes do not tell the entire story and the role of non-genic factors remains to be better elucidated. Important markers of environment, most broadly defined, are the epigenetic changes that regulate gene expression. Elegant and creative studies in this domain are leading to a better understanding of the interactions among environment, genes, and the epigenome and how the environment can sculpt the expression of genes in a manner with long-lasting and even trans-generational impact. Co-incident with these discoveries of molecular etiology, the advent of enhanced imaging and other techniques have not only increased our understanding of the neural processes underlying diverse mental disorders but are leading to important biomarkers for determining clinical subgroups, as well as monitoring clinical course and response to treatment, providing a window on the neural basis of successful and unsuccessful interventions, whether behavioral or pharmacological.

This section charts these advances, focusing on select disorders falling within the DSM-5 Neurodevelopmental Disorders group. We do not, however, wish to imply that there is necessarily an unambiguous distinction between the neuropsychiatric disorders of childhood onset discussed here and other disorders discussed elsewhere in this book. Many psychiatric disorders can onset either in childhood and adulthood (e.g., anxiety and mood disorders) or are likely to be neurodevelopmental in origin (e.g., anxiety, psychosis). Truly, as William Wordsworth said, “The Child is father to the man,” and processes that occur in early development and childhood and adolescence lay a foundation for mental health and mental illness in later life.

The chapters in this section can be arranged into two groups, reflecting either broad findings in neurodevelopmental disorders when viewed from a given perspective, or specific neurodevelopmental psychiatric conditions.

Chapter 70 presents the state of the art regarding the epidemiology of childhood onset psychiatric disorders, summarizing current knowledge related to epidemiology, heritability, and implied genetic architecture within each diagnostic category. One important theme discussed in this chapter is how reproductive disadvantage influences the genetic architecture of neurodevelopmental disorders associated with reduced fecundity, and hence a role for rare and spontaneously arising variation in such disorders. Such variation can be associated with intermediate or major effects, and occur on all genomic scales, from aneuploidy, through copy number variation (CNV), to single nucleotide variation (SNV), as discussed in by Mefford (see Chapter 71). The role of CNV in both human variation and mental illness was little known until just a few years ago and we have already reached a point at which CNV screening is a standard component in the clinical evaluation of individuals with unexplained intellectual disability (ID) and/or autism spectrum disorder (ASD). With the widespread availability of massively parallel sequencing (MPS; also termed next- or second-generation sequencing), the role of SNV in neurodevelopmental disorders will become clearer in the next few years, as will screening for such variation. Examples of CNV and SNV in specific disorders are found in the chapters on ID, ASD, Tourette syndrome, and tic disorders (TD), and attention deficit/hyperactivity disorder (ADHD).

Epigenetics, although difficult to study in disorders of the brain, likely has a great or greater impact on dynamic neural processes, when compared to genetic variation. In Chapter 72 Bale notes epigenetics encompasses change in gene function not associated with sequence variation and represents a means by which we can integrate a role for the environment to influence or “program” gene expression. Animal model systems demonstrate that epigenetics is a mechanism by which well-known associations of maternal stress, infection, or dietary challenges can increase risk for psychiatric illness at later times and be transmitted to subsequent generations, and we are learning about other important neuropsychiatric phenotypes modulated by epigenetics.

Animal models (see Chapter 73) provide opportunities for hypothesis testing and for evaluating novel therapeutics. In addition, these models have a special place in disorders of the brain for generating hypotheses because neuronal tissue from human subjects is not typically accessible before death, except in rare cases of neurosurgery (not typically associated with psychiatric illness). Given the growing genetic and molecular

discoveries in childhood-onset psychiatric disorders, many models are emerging with construct validity, which in turn provide manifest evidence for specific neuropathobiological substrates for such disorders.

Neuropathobiology in mental illness can be considered on both the micro and macro scale. Recurrent findings in the more severe neurodevelopmental disorders are pathological changes in synaptic structure and function that lead to disruption of plasticity and synchronicity (see Chapter 74). Dierssen and Martínez put these findings in a developmental perspective and examine additional neuronal mechanisms underlying neurodevelopmental disorders. These sorts of perturbations are reflected in changes in functional connectivity in many child psychiatric disorders (see Chapter 75). With enhanced neuroimaging modalities, coupled with advanced biostatistical algorithms, we now have the ability to interrogate and understand systems level processes in the brain. With magnetic resonance spectroscopy, molecular alterations can be mapped to other imaging changes in an entirely non-invasive manner, allowing for an examination of the neurotransmitter/synaptic (micro) and systems levels (macro) alterations at the same time.

Intellectual disability syndromes (see Chapter 76) and ASD (see Chapter 77) can arise from genetic variation as well as from prenatal and perinatal insults. Hundreds of genes and loci are implicated with these two disorders, and there is strong evidence for overlapping risk genes and loci, implying

shared origins of ID and ASD. Understanding how multiple genes come together in canonical and newly identified molecular networks is an exciting and challenging field of endeavor summarized in both Chapters 76 and 77. Such pathway analysis holds the promise of identifying “driver” genes that control the state of a neural network and, as such, these genes have potential to be optimal therapeutic targets.

Attention deficit/hyperactivity disorder (see Chapter 78), as well as tic disorders (see Chapter 79), represents disorders not associated with strong reproductive disadvantage and hence are likely to have differing risk architecture from disorders such as intellectual disability or ASD. However, more is known about specific neurobiological systems, with important roles for the attentional circuitry in ADHD and cortico-striato-thalamo-cortical circuitry in TD. Rare genetic variation has been associated with ADHD and TD, and has implicated specific neurotransmitter systems, including some unexpected ones, such as histamine in TD.

We end with a look forward. The emerging molecular insights into psychiatric disorders of childhood onset has led to important cell and animal models, which in turn have driven new neurobiological understandings of these disorders and identified potential novel therapeutic avenues. These potential treatments, previously unpredicted by the state of our knowledge but implicated from these translational approaches, are being evaluated in several clinical trials, summarized briefly in Chapter 80.

70 | EPIDEMIOLOGY OF NEUROPSYCHIATRIC AND DEVELOPMENTAL DISORDERS OF CHILDHOOD

ELISE B. ROBINSON, BENJAMIN M. NEALE, AND MARK J. DALY

Psychiatric and developmental disorders of childhood onset have been studied for much of the twentieth century. There is an emerging recognition, however, that neuropsychiatric conditions affecting children are rising in estimated prevalence and place an enormous burden on parents, educators, and the health care system (Charman, 2011a; King and Bearman, 2009). Although this rise in prevalence likely contains elements of diagnostic changes, greater awareness of these disorders, and true changes in incidence, there is little doubt that psychiatric and developmental disorders among children are a major concern to society today. A recent survey of more than 10,000 US adolescents concluded that there is nearly a 50% lifetime childhood prevalence of one or more DSM-IV mood, anxiety, or behavioral disorders (excluding eating and substance abuse disorders) and that more than 20% of children meet the definition of severe impairment (Merikangas et al., 2010).

It has become increasingly common for traditionally “adult” psychiatric disorders, such as bipolar disorder or major depression, to be diagnosed in children. However, the focus of this chapter is classical childhood neuropsychiatric conditions whose diagnosis requires the presence of symptoms before age 18 within the DSM-IV-TR framework (APA, 2000). We consider four major diagnostic categories falling within these specifications and highlight the major diagnosis within each—specifically, intellectual disability (ID; formerly referred to as mental retardation and referred to as learning disability in Europe), pervasive developmental disorders (autism spectrum disorders [ASDs]), hyperactive and inattentive behavior (attention deficit/hyperactivity disorder [ADHD]), and tic disorders (Tourette disorder [TD]). Within this first subsection, we address the epidemiology, heritability, and implied genetic architecture within each diagnostic category. We draw synergies and overlaps where appropriate and articulate the connection between traditional diagnostic categories and common behavioral and cognitive traits.

Some of these connections bear relevance to the fifth edition of the DSM, currently under development. In the DSM-IV, the central approach for disease classification is one of categorical symptoms without an empirical basis for diagnostic thresholds. In construction of the DSM-5, the recognition of a continuum underpinning some psychiatric illnesses is growing, exemplified by the planned adoption of autism spectrum disorder in place of a discrete diagnosis within the Pervasive Developmental Disorders category. This shift recognizes a

robust literature on more quantitative approaches to neuropsychiatric phenotypes and may influence estimates of disease prevalence. We discuss several implications of assessing psychiatric traits with a dimensional approach in the following, particularly as they relate to genetic architecture.

DEFINITION AND IMPACT OF CHILDHOOD PSYCHIATRIC AND DEVELOPMENTAL DISORDERS

INTELLECTUAL DISABILITY

Intellectual disability and the formal diagnosis of mental retardation in the DSM-IV are characterized by intellectual functioning that is substantially below average and significant limitations in adaptive behavior with onset before the age of 18 (APA, 2000). Approximately 2% of people worldwide meet criteria for IDs. Most individuals with a diagnosis require some level of assisted services throughout adulthood, although there is considerable inter-individual variability in the degree of impairment.

Intellectual functioning is most often assessed via IQ tests (e.g., the Wechsler Intelligence Scales for Children) (Wechsler et al., 1992). Intellectual disability is traditionally defined as a score below 70 (at or below two standard deviations below the mean). Although some people with IDs are not diagnosed until mid- or late-childhood, most are identified early in life subsequent to parental concerns about developmental delays (Leonard and Wen, 2002). The genetic sources of certain syndromic cases of ID have long been recognized (Lejeune et al., 1959), but in most cases the cause of cognitive impairment is unknown. Intellectual disability in general is accepted to have numerous genetic and non-genetic causes, representing the end result of a defect in any number of many possible elements of central nervous system (CNS) development.

AUTISM SPECTRUM DISORDERS

Autism spectrum disorders (ASDs) are a system of neurodevelopmental conditions with onset before age three, characterized by impairments in social interaction and communication, along with significantly restricted interests and repetitive behaviors (APA, 2000). Although ASDs vary widely in phenotypic expression, they are universally impairing and present an enormous burden to affected individuals and their families. Approximately

40% to 60% of children with ASDs have concomitant intellectual disabilities, and it is estimated that an even larger fraction require lifelong external supports (Chakrabarti and Fombonne, 2005; Charman et al., 2011b; Centers for Disease Control and Prevention, 2012). For each patient, the lifetime societal costs associated with an ASD diagnosis are estimated to be \$3.2 to \$5 million in the United States and £0.8 to £1.2 in the United Kingdom (Ganz, 2007; Knapp et al., 2009).

These costs become staggering in aggregate, especially given the growing frequency of ASD diagnoses. The prevalence of ASDs and their apparent rise in incidence has been a point of enormous contention in recent years and is discussed in the following section. Current estimates place the prevalence of ASDs at approximately 1% today in both the United States and the United Kingdom (Baron-Cohen et al., 2009; CDC, 2012).

ATTENTION DEFICIT/HYPERACTIVITY DISORDER

Excess levels of activity along with difficulties in attention and impulse control have been characterized in children for more than a century (Still, 1902). Three subtypes of ADHD are recognized in the DSM-IV: (1) hyperactive/impulsive, (2) inattentive, and (3) combined type, reflecting endorsed criteria in both categories. Examples of ADHD symptoms include interrupting, always being on the go, fidgeting and difficulty sitting still (which reflect the hyperactive/impulsive dimension), as well as difficulty completing tasks, an inability to maintain focus on an activity, and flipping focus (which reflects the inattention dimension). In developing the DSM-5, the psychiatric community is moving to abandon the distinction between the three subtypes in favor of a single construct. This is motivated in large part by the strong phenotypic correlation between the two dimensions, both among patients and the population at large (Larsson et al., 2011b).

Attention deficit/hyperactivity disorder is one of the most common psychiatric disorders of childhood, affecting an estimated 4% to 12% of children worldwide. Approximately 40% of cases are estimated to persist into adulthood, but method of assessment substantially impacts estimated adult prevalence. Self-report measures tend to be least reliable and yield the most restrictive estimates (Faraone et al., 2003). Attention deficit/hyperactivity disorder predicts a range of behaviors and outcomes in both childhood and adulthood that carry a societal cost. Children and adults with ADHD are more likely to be disruptive in school environments, have lower educational attainment, and higher rates of substance use, sexually transmitted diseases, criminality, incarceration, and incurred health care costs. In 2006, worldwide costs of ADHD were estimated to be between \$77.5 and \$115.9 billion annually because of the costs of treatment and more significantly lost productivity and indirect social costs (Barbaresi and Olsen, 1998; Leibson et al., 2001).

TOURETTE DISORDER

Tourette disorder (TD) and the related phenotype of tic disorder are characterized by uncontrolled movements, speech, or

actions. Tourette was originally proposed in 1885 by Georges Gilles de la Tourette as a phenotype that included multiple motor tics and at least one vocal tic (Gilles de la Tourette et al., 1982). Motor tics span from simple movements such as eye blinking to complex movements including jumping or body contortions. Vocal tics similarly vary from simple tics of throat clearing or sniffing to more complex tics, including syllables, words, coprolalia (undesired vocalization of profanities), echolalia (uncontrolled repetition of what other people say), and palilalia (repetition of one's own words) (Singer, 2005). In the DSM-IV, a Tourette diagnosis requires both motor and vocal tics persisting for a year or longer. When only vocal or motor tics are present, the patient is considered to have tic disorder, with presentation for less than a year considered transient and longer than a year considered chronic (APA, 2000). Onset of these phenotypes is primarily in childhood and is typically most severe during development.

Tourette Disorder and tic disorder are somewhat unusual as psychiatric phenotypes in that neither deficit nor difficulty resulting from the behaviors is necessary to define the disorder. Nevertheless, patients with these disorders experience increased average levels of anxiety and depression (Coffey and Park, 1997; Sukhodolsky et al., 2003). In addition to greater stress, patients with TD have higher rates of ADHD, obsessive compulsive disorder (OCD), and other neuropsychiatric phenotypes (Cavanna et al., 2009; Grados and Mathews, 2009). These comorbidities are well documented but poorly understood. (A discussion of the genetics of anxiety disorders including OCD is found in Chapter 41.)

TRAJECTORIES INTO ADULTHOOD FOR THOSE DIAGNOSED WITH CHILDHOOD PSYCHIATRIC DISORDERS

INTELLECTUAL DISABILITY

Although individuals with developmental disabilities can benefit from early intervention strategies (Charman, 2011c; Dawson et al., 2010), measured intelligence is, on the whole, stable following early childhood (Plomin et al., 2008). Recent evidence suggests that the common genetic influences on intelligence are highly consistent across the lifespan (Deary et al., 2012). The rare, sporadic genetic events associated with major cognitive impairment—e.g., Down syndrome and Fragile X syndrome—similarly influence cognition across the life course (Plomin et al., 2008). However, because of the great heterogeneity within the ID diagnostic category, there is also likely to be substantial variation in developmental trajectories both within and between etiologically distinct sets of cases.

AUTISM SPECTRUM DISORDERS

Studies in clinical populations have suggested that there is substantial heterogeneity in the developmental trajectory of ASDs (Eaves and Ho, 1996; Fountain et al., 2012; Lord et al., 2006; Starr et al., 2003). Improvements are common; for example, gains are often made in the domain of verbal fluency (Anderson et al., 2007; Shattuck et al., 2007; Szatmari

et al., 2000). However, even though some children with ASDs experience growth in specific skills (Fountain et al., 2012), the great majority continue to manifest the core symptoms of the disorder throughout their lives (McGovern and Sigman, 2005; Piven et al., 1996; Szatmari et al., 2009). The population of adults with an ASD diagnosis is growing rapidly, and further study is needed to understand their range of functioning and need for services (Shattuck et al., 2012).

ATTENTION DEFICIT/HYPERACTIVITY DISORDER

Longitudinal studies of ADHD have suggested that approximately 40% of patients continue to meet full criteria for ADHD in early adulthood and approximately 60% manifest residual symptoms (Faraone et al., 2006). Although the disorder as a whole is moderately stable over time, there is evidence for varying stability among ADHD's phenotypic domains. Multiple studies have noted greater persistence of inattentive as compared with hyperactive/impulsive symptomology (Biederman et al., 2000; Larsson et al., 2011b). However, few studies have assessed persistence beyond the age of 25. Children diagnosed with ADHD have significantly higher rates of arrest for both misdemeanor and felony charges than children without an ADHD diagnosis, although the samples in which this has been investigated are predominantly male (Barkley et al., 2004). In a longitudinal study of girls diagnosed with ADHD, higher rates of all major classes of psychopathology were found (Biederman et al., 2010).

TOURETTE DISORDER

Typically, vocal and motor tic symptoms peak during early puberty and tend to diminish in adulthood. Even though symptoms ease in adulthood, an estimated 90% of patients with Tourette continue to experience tics (Pappert et al., 2003). Tic severity in childhood has been shown to be inversely correlated with health-related quality of life (Cavanna et al., 2012).

HERITABILITY AND PREVALENCE OF CHILDHOOD PSYCHIATRIC DISORDERS

INTELLECTUAL DISABILITY

Unlike the other developmental phenotypes discussed in this chapter, intellectual disability is currently defined by a quantitative measure. Intelligence is assessed on a continuum in the general population, and IQ scores are standardized such that they are normally distributed around an empirically derived population average. The DSM-IV defines intellectual disability as an IQ score more than two standard deviations below the mean—accordingly corresponding with the lowest scoring 2.5% of individuals, an inherent marker of prevalence (APA, 2000).

Although the population rate of ID is stable under the DSM-IV definition, there can be fluctuation in the commonality of specific ID-associated syndromic conditions. For example, Down syndrome remains the most significant single, identified cause of major cognitive impairment (Mefford et al., 2012),

but its prevalence varies by time period and geographic region. Like many spontaneous genetic events, the incidence of chromosomal disorders like DS varies significantly with parental age and likely with other sociodemographic and environmental factors (Irving et al., 2008).

It is difficult to estimate the heritability of ID given its limited prevalence and etiologic heterogeneity. IQ itself is moderately to highly heritable (Haworth et al., 2010), and evidence suggests that at least mild ID represents the low end of typical variation (Plomin et al., 2008). However, the etiologic structure of ID is likely to vary across levels of severity (Nichols, 1984). The empirical basis for this model is drawn from family studies showing that the siblings of children with mild cognitive disabilities had, on the whole, below-average IQs themselves. The siblings of children with severe ID, by contrast, were on average IQ-normative. This pattern suggests that the genetic sources of rare and severe cognitive impairments are more likely to be sporadic, and the genetic sources of more common and mild cognitive impairments more likely to be familial.

On the whole, severe ID is considered to be significantly less heritable than most common neuropsychiatric conditions (or indeed nearly all medical and anthropometric traits in general) (Plomin et al., 2008). Although some inherited genetic causes have been identified (Lossie and Driscoll, 1999), there are a variety of clear environmental risk factors that can induce major cognitive impairment (e.g., trauma, infection, poisoning, or malnutrition before, during, or after birth, early childhood diseases). Furthermore, many of the documented genetic influences are large-scale spontaneous chromosomal anomalies, which themselves can be environmentally induced (Mefford et al., 2012). Such a heterogeneous etiology necessitates that inherited factors explain a smaller proportion of variance for ID than many other common medical phenotypes.

AUTISM SPECTRUM DISORDERS

The estimated prevalence of ASDs has increased dramatically over four decades in the United States and the United Kingdom, and is currently approximated at around 1% in both countries (Baird et al., 2006; Baron-Cohen et al., 2009; CDC, 2012; Elsabbagh et al., 2012). The increase in measured prevalence is at least in large part secondary to definitional expansion and greater diagnostic awareness. Neither Asperger syndrome nor pervasive developmental disorder not otherwise specified (PDD-NOS) were included in the DSM description of autism until the text's fourth edition (1994), and recent studies suggest that the probability of ASD ascertainment continues to grow within certain US populations (Pedersen et al., 2012; "Prevalence of autism spectrum disorders—Autism and Developmental Disabilities Monitoring Network, 14 sites, United States, 2008"). A recent UK study highlighted the probable importance of changes to the definition and study of ASDs in prevalence estimation. Using modern clinical criteria and research methods, Brugha et al. (2011) found that the prevalence of ASDs among UK adults was also approximately 1%. Because ASDs are typically lifelong phenotypes, this suggests that these adults would have met *current* clinical criteria as children but were not diagnosed because ascertainment

had yet to become common (Brugha et al., 2011). Studies such as these do not, however, preclude the possibility of a “true” increase in prevalence, and the degree to which current data may reflect such a trend is unknown.

The estimated prevalence of certain types of intellectual disability, discussed in the preceding, may also change with diagnostic climate. Although ID to ASD diagnostic substitution does not account for the majority of the increase in ASD prevalence, it has clearly made a substantial contribution. Using data from the California Department of Developmental Services, King and Bearman (2009) estimated that one-fourth of the observed increase in ASD prevalence in California between 1992 and 2005 was a direct consequence of diagnostic exchange between ID and ASD (King and Bearman, 2009). These changes are likely to have implications for the etiological structure and pathophysiological heterogeneity of ASDs.

The male to female ratio among individuals with an ASD diagnosis is approximately 4:1. The overall ratio, however, obscures a substantial sex by IQ interaction in the population distribution of the disorder. Among individuals with ASDs who have very low IQ, the male to female ratio is closer to 2:1. In cases with above average IQ, the ratio is much higher, likely 6:1 or above (Fombonne, 2003; Skuse, 2009). This trend has held constant across the period of prevalence increase (Lord and Schopler, 1985). Because much of the recent diagnostic expansion has occurred within the high functioning range (Rutter), several population-based studies have begun to report overall male:female ratios that are higher than 4:1 (Brugha et al., 2011; Williams et al., 2008). Although some of the sex by IQ interaction likely reflects greater ascertainment probabilities in boys (Russell et al., 2010), above average cognitive abilities do appear to confer greater ASD protection to women (at least as the diagnostic category is currently defined). Although the data are strong that some etiological overlap exists between ASDs and ID, ascertainment considerations do preclude a conclusive interpretation of population data. In fact, it has been proposed that the observed correlation between ID and ASD could be in part explained by the fact the presence of both in an individual dramatically increases the chance of the individual being ascertained owing to severe impairment (Skuse, 2007). This thesis is not inconsistent with the high rate of identification of IQ-normative ASD in adults who were not ascertained as children in the Brugha study (Brugha et al., 2011).

Autism spectrum disorders have long been considered among the most heritable of neuropsychiatric conditions. Through the period of diagnostic expansion, most twin studies of ASDs have suggested that the disease category is at least 60% heritable (Ronald and Hoekstra, 2011). However, the largest of those studies, both conducted recently, have noted a trend that reinforces the possibility of both genetic and environmental influence on autistic behavior (Hallmayer et al., 2011; Rosenberg et al., 2009). Rosenberg et al. (2009) and Hallmayer et al. (2011) reported that the dizygotic (DZ) twin of an individual with ASD has approximately a 30% chance of being diagnosed with autism him- or herself. This figure suggests that ASD recurrence in DZ twins may be higher than that estimated for regular siblings (Constantino et al., 2010; Ozonoff et al., 2011). This is notable because DZ twins are no more

genetically similar than regular siblings. Some of the estimated difference may be caused by higher ascertainment probabilities among twins (e.g., because twins are the same age, they are more likely to be assessed by the same clinician at the same time). There is also a possibility that the registries employed for these studies are not representative of the population as a whole, and families with multiple affected twins were more likely to participate than families with only one affected child. However, elevated DZ twin risk may also suggest that ASDs, in part, reflect environmental exposures during fetal development (Szatmari, 2011). The nature of such possible exposures, and the manner in which they interact with genetic vulnerability, are important areas of future research (Croen et al., 2011).

ATTENTION DEFICIT/HYPERACTIVITY DISORDER

The estimated prevalence of ADHD varies substantially based on age at assessment, informant (clinician, parent, teacher, self, or some combination), country, and diagnostic criteria. Using DSM-IV criteria, the estimated prevalence ranges from 5.8% in Brazil (Rohde et al., 1999) to 7.5% in Australia (Graetz et al., 2001) and 17% in Germany (Baumgaertel et al., 1995). In Sweden, using the Autism-Tics, ADHD, and Other Comorbidities inventory, prevalence was estimated at 1.8% with a 2.5-fold enrichment in boys compared with girls (Lichtenstein et al., 2010). In the United States, prevalence estimates range between 9.5% and 16% (Hudziak et al., 1998; Gimpel and Kuhn, 2000; Nolan et al., 2001), but can be lower when functional impairment is taken into consideration (Wolraich et al., 1998).

The estimated heritability of ADHD is consistently high. Faraone and colleagues conducted a metaanalysis of diagnostic and dimensional assessments of ADHD determining a mean estimate of 76% for heritability across 20 different twin studies conducted in the United States, the European Union, and Australia with point estimates ranging from approximately 60% to more than 95% (Faraone et al., 2005).

TOURETTE DISORDER

The prevalence of Tourette disorder is estimated between 0.1% and 1% with the expanded phenotype of tic disorder estimated to be between 3% and 12% (Kurlan et al., 2001; Lichtenstein et al., 2010; Singer, 2005). In a large population cohort of twins from Sweden, tic disorder is estimated to be significantly heritable, with a point estimate of 56% (95%; CI, 37–68%) (Lichtenstein et al., 2010). Some estimates for Tourette disorder alone are lower (32%) (Mathews and Grados, 2011).

CHILDHOOD PSYCHIATRIC DISORDERS AS THE EXTREMES OF NORMAL TRAIT VARIATION

A growing body of population-based studies suggests that, like mild intellectual disabilities, ASDs and ADHD may

exist as extreme positions of phenotypic continua (Larsson et al., 2011a; Lundstrom et al., 2012; Robinson et al., 2011a). This section reviews some of that evidence, concentrating on studies that link the genetic influences on major behavioral impairment to typical variation in traits of those disorders (e.g., autistic behavior, traits of hyperactivity/inattentiveness).

Because intelligence is measured on a continuum, much like height or weight, it is natural to think of intellectual disability as an extreme position on that distribution. The point below which an individual meets criteria for ID, however, is in many ways arbitrary, a problem common to categorical cutoffs superimposed on continuous distributions. Although an IQ of 70 is typically employed as the clinical threshold (APA, 2000), there is no clear biological or phenotypic break point that indicates where the boundary of “meaningfully” disordered cognition should lie. In other words, identifying the position on the IQ distribution below which a person has ID is no simpler than identifying the position on the height distribution above which a person is tall.

Only recently have researchers begun to consider the degree to which major psychiatric disorders may similarly exist as extreme positions on behavioral distributions. Diseases like autism and ADHD have traditionally been thought of as categorical clinical entities that one either has or does not have. However, traits typical of many behavioral disorders occur commonly at subthreshold levels in the general population as well as “deficits” characterizing many of these clinical phenotypes (Constantino and Todd, 2003; Goodman et al., 2000; Ronald et al., 2008; Skuse et al., 2005).

Autistic traits provide a useful example as they have been studied extensively over the last decade. Autistic trait measures are designed to capture the extent to which an individual manifests characteristics of the clinical ASD phenotype. These measures aim to assess the extent of social impairment, communication impairment, and restricted and repetitive behaviors and interests that a person displays (Constantino et al., 2003; Scott et al., 2002). When autistic trait scores are estimated in large samples of people in the general population, the distribution is typically skewed. The bulk of the population displays few if any autism-like behaviors, with a declining distribution to individuals that endorse a high number of traits, at or above the level that is on average associated with clinical ASD (Robinson et al., 2011a, 2011b). Using these trait measures, however, does not reveal a distinction between the clinical and subclinical levels of autism-like behavior. This pattern mimics the IQ distribution leading to intellectual disability (Constantino and Todd, 2003; Ronald et al., 2006).

Traits of ADHD can be measured in a similar way (Hansson et al., 2005) using a variety of instruments. The Conner’s Rating Scale, for example, aims to assess the presence and severity of symptoms recognized in the clinical phenotype. The Swan Rating Scale, in contrast, attempts to characterize individuals on a more normal scale of activity level, impulsivity, and attention. Consequently, the distribution of the Conner’s ADHD scale tends to be J-shaped, whereas the Swan is considerably more normally distributed. For each of these measures,

children with an ADHD diagnosis lie within the most affected tail (Larsson et al., 2011a).

The study of general population traits will only be informative with respect to disease processes if there is an etiological link between the extreme or categorical phenotype (e.g., ASDs) and the behavioral continuum (e.g., autistic traits in the general population). In the case of both ASDs and ADHD, evidence is building that such a link exists. Empirically, there is a high degree of consistency between clinically significant and subclinical levels of impairment. Much like the ASD diagnosis, autistic trait scores in the general population are highly stable over time (Robinson et al., 2011b; St Pourcain et al., 2011). Longitudinal studies of traits of ADHD suggest similar coherence with the clinical diagnosis (Biederman et al., 1996, 2000; Faraone et al., 2006).

On the whole, traits of ADHD are moderately stable across development (Kuntsi et al., 2005; Larsson et al., 2011b).

Many studies suggest a shared etiology between Robinson the clinical phenotypes of ASDs and ADHD and their respective behavioral continua. If autism and ADHD are extreme positions on quantitative distributions, two primary conditions should hold. The estimated heritability of traits of each disorder should be approximately equivalent to the estimated heritability of the clinical phenotype, and a clinical diagnosis should predict increased trait scores in family members of the proband. With respect to overall heritability, there is a substantial body of literature suggesting that this is the case. Like ASDs, autistic traits are moderately to highly heritable (Ronald and Hoekstra, 2011). Similarly, like ADHD, traits of hyperactivity and inattentiveness are consistently highly heritable (Larsson et al., 2011a). Autism spectrum disorders and ADHD also show the predicted pattern of increased trait burden in family members. In the case of ASDs, it has been noted for more than a decade that the family members of people with autism, on average, display more autistic traits than the family members of people without autism (Constantino et al., 2006, 2010; Piven et al., 1997). Twin studies can be used to examine the extent to which that pattern might be secondary to genetic influences that are shared between levels of affectation. Two large, general population twin studies recently reported evidence of strong genetic overlap between severely impairing autistic behavior and subclinical autistic traits (Lundstrom et al., 2012; Robinson et al., 2011a). In a similar analysis, Larsson et al. (2012) evidenced a genetic link between clinically diagnosed ADHD and traits typical of the disorder as they are distributed continuously.

These patterns can be interpreted in a number of ways and, in so doing, it is important to bear in mind the established etiological heterogeneity of neuropsychiatric conditions (Betancur, 2011). On the one hand, etiological overlap between the clinical (extreme) phenotype and the continuum could be interpreted as evidence that relevant *common* genetic variants act across the behavioral distribution, influencing both normal trait variation in the general population and the probability with which an individual will meet criteria for clinical disorder. On the other, these results are also consistent with the model in which *rare* (and potentially unique), familial genetic variants that increase risk for autism and ADHD can also predict

subclinical behavioral impairment. In other words, pleiotropy may extend to levels of affectation. It is believed that both common and rare genetic variants influence liability toward autism and ADHD, so these possibilities cannot be disentangled in the context of phenotypic family data.

PHENOTYPIC AND ETIOLOGIC RELATIONSHIPS AMONG CHILDHOOD PSYCHIATRIC DISORDERS

Neuropsychiatric disorders of childhood appear together far more often than predicted by chance. Among the phenotypes discussed in this chapter, most individuals with ASDs meet criteria for additional developmental or behavioral disorders such as ADHD, anxiety disorders, or intellectual disabilities (Gillberg and Billstedt, 2000; Lichtenstein et al., 2010; Simonoff et al., 2008; Volkmar et al., 1999). Intellectual disabilities themselves are similarly associated with an increased risk for a wide range of mental health conditions (Einfeld et al., 2011), and Tourette syndrome often co-occurs with ADHD and OCD (Mathews and Grados, 2011).

Twin and molecular genetic studies suggest that shared genetic risk factors are contributing substantially to the disorders' co-occurrence. Using the twin method, Lichtenstein et al. (2010) estimated that ASDs share approximately three-fourths of their genetic variance with ADHD, one-half of their genetic variance with intellectual disabilities, and one-third of their genetic variance with tic disorder. The authors further noted that the genetic influences on ADHD are highly correlated with those on tic disorder, a finding that has since been replicated in family studies (Mathews and Grados, 2011). Molecular genetic analyses have similarly indicated that the etiological influences on child neuropsychiatric disorders are unlikely to exclusively predict the phenotypes circumscribed by the DSM. For example, virtually every genetic variant that has been associated with ASDs is also associated with intellectual disabilities (Betancur, 2011); several of the notable rare variants are also risk factors for other major psychiatric disorders (McCarthy et al., 2009; Weiss et al., 2008).

Genetic relationships between the disorders raise questions about research approach. More often than not, investigations into ASDs, ADHD, and Tourette are conducted independently. This model is consistent with the classical approach to comorbidity, a term originally designed to indicate distinct, co-occurring medical problems (Feinstein, 1970). The etiological overlap described in the preceding section, however, suggests that conceptualizing multiple psychiatric disorders as comorbid could be "artificially splitting a complex clinical condition into several pieces" (Maj, 2005).

Large multidisorder research initiatives, such as the Psychiatric Genomics Consortium (PGC), are able to investigate etiological factors that may be shared across neuropsychiatric conditions. With the identification of genetic risk factors, broadly phenotyped samples provide the opportunity to potentially shed insight into the disorders' underlying biological and behavioral processes.

REPRODUCTIVE DISADVANTAGE AND GENETIC ARCHITECTURE

Reproductive disadvantage provides a major influence on the genetic architecture of disorders that are, on average, associated with reduced fecundity. In the simplest case, autosomal-recessive diseases that are lethal in childhood are defined by allelic spectra consisting of rare mutations. This occurs because of the consistently lower than chance probability of the alleles being passed on in each generation. Generally, such genetic variants are seen at less than 0.1% in population frequency, but they can be significantly more frequent in instances in which an advantage is conferred to heterozygote carriers (e.g., Hb mutations that confer resistance to malaria in heterozygotes but sickle cell disease in homozygotes). These alleles may also have been previously favorably selected in alternate environmental conditions or appeared recently in bottlenecked or isolated populations (e.g., Finns, Ashkenazi Jews, Quebecois from Saguenay-Lac St. Jean), where they received a chance boost to high frequency and are still early in the many hundreds of generations selection takes to inexorably push them down. As a consequence, gene mapping efforts in diseases associated with reproductive disadvantage are designed with a focus on rare and spontaneously arising variation.

By contrast, and consistent with classical theory (Kimura and Ota, 1973), humans have limited genetic variation. Considering two copies of the human genome, the heterozygosity rate for single nucleotide polymorphisms (SNPs) is approximately one in 1,000 bases (Sachidanandam et al., 2001) and roughly 90% of those heterozygous sites in each individual are common DNA variants. The variants are typically seen in multiple, diverse populations and show evidence of having existed for thousands of generations (Lewontin, 1972; International Hapmap Consortium, 2005). High frequency of an allele does not by any means rule it out as a contributing factor in diseases with reproductive disadvantage. However, it does indicate that the allele itself is not under strong selective disadvantage and limits the individual impact it could have in a reproductively deleterious phenotype. It is also important to note that mildly deleterious alleles can persist at intermediate allele frequencies, particularly under the conditions described that moderate the relationship between selection and frequency.

With these observations in mind, human genetics has been drawn to the common disease-common variant hypothesis, which suggests a role for common DNA polymorphisms (>1% in population frequency) in the genetic architecture of common and complex human diseases (Collins et al., 1997; Lander and Schork, 1994; Risch and Merikangas, 1996). This hypothesis produced the subsequent proposal that genome-wide association studies (GWAS) of common human diseases might yield, for the first time, specific genetic insights into complex human disease. Genome-wide association studies are powered by massively parallel array-based genotyping technologies that permit the evaluation of hundreds of thousands of common DNA variants simultaneously. Alongside the construction of maps of common variation and linkage disequilibrium patterns across the genome, GWAS has delivered myriad insights into common diseases. As of the end of 2011, more than 1,500

genetic associations have been defined since the first GWAS studies were initiated in 2005–2006 and, in the vast majority of cases, the associations were novel and therefore harbored unique insights into the pathogenesis of disease. It is noteworthy that most of these discoveries emerged in diseases and phenotypes only when very large sample sizes were assessed, often after initial smaller studies had not revealed any replicable, significant associations. Thus, a collective picture that has emerged from GWAS studies is one of extreme polygenicity for the complex disorders studied in which individual contributing alleles are of extremely modest effect and provide little predictive information about individual risk. Collectively, however, they can reveal novel insights into the pathways and processes of disease.

Negative reproductive selection is likely to be acting on severe forms of autism and intellectual disability (Uher, 2009). Although formal studies estimating the specific degree of reproductive disadvantage associated with these conditions have not been conducted, it is widely accepted that individuals with these phenotypes produce offspring far less often than the population average. Bolstered by classical examples of the role of major sporadic chromosomal anomalies in similar phenotypes such as Down syndrome, this observation has led to a substantial and sensible focus on the role of spontaneously arising (so-called *de novo*) DNA variants in ASD and ID. At the same time, large GWAS studies have also been undertaken, and draw considerable hope from the example of schizophrenia. Schizophrenia has a similar prevalence and estimated selective disadvantage (approximately 50% reduced fecundity) (Svensson et al., 2007). Genome-wide association studies of schizophrenia have proved, at large sample sizes, to be able to demonstrate specific compelling associations and to establish a significant global role for common as well as rare variation. It is not incongruous that common variation can be associated to a common and reproductively deleterious phenotype. In the case of extremely polygenic phenotypes, an obligate relationship between allele frequency and reproductive advantage is precluded by each of: the modest contributions of individual loci; unknown interactions that may exist among genes or between genes and environmental factors; and the other (perhaps positive) phenotypic outcomes that may be influenced by some of the risk variation. Take for example the predominant role of common variation in type I diabetes, and the mix of common, rare, and *de novo* variation in Hirschsprung disease—both conditions that had extreme selection against them owing to high lethality before modern medical interventions developed in the last century. The genetic architecture of these conditions does not stand in stark violation of fundamental principles but is likely representative of the mix of variation types that will be uncovered in childhood neuropsychiatric disease.

The insights attained to date from the early studies of both common and rare DNA variation are outlined in the next section and more thoroughly delineated in subsequent sections of the book. Of note, the accepted negative selection attributable to ID and ASD does not carry over into ADHD and TD, where no perceived reproductive disadvantage resides. As noted, however, strong etiological overlaps likely exist between each of these disorders. We fully expect that overlap to manifest

itself in considerable shared genetic risk factors of both a common and rare variety.

EMPIRICAL INSIGHTS INTO THE GENETIC ARCHITECTURE OF CHILDHOOD PSYCHIATRIC DISORDERS

The most compelling evidence compiled to date with respect to neuropsychiatric disorders of childhood onset surrounds the role of large and predominantly spontaneously arising chromosomal abnormalities and copy number variants. Down syndrome (trisomy 21) is the most common and widely recognized karyotypic abnormality associated with ID but, in recent years, many such findings have emerged as substantial components of both ASD and ID more broadly. Many additional syndromes (e.g., Prader–Willi/Angelman, Williams syndrome, DiGeorge/velocardiofacial syndrome) result from specific recurrent copy number variants. Genome-wide, gross chromosomal abnormalities (Sanders et al., 2011; Vorstman et al., 2006) and even balanced translocations (Talkowski et al., 2012) have been documented as strongly enriched in both ID and ASD. However, as most such events are rare and seen only in individual cases, certainty is generally lacking that individual events are causative. In addition, because these events are most often large and delete, duplicate, or disrupt many genes, biological insights have been slow to emerge in many cases.

Recent surveys (Girirajan et al., 2011) have clearly demonstrated that the burden of CNVs in ID is considerably greater than in ASDs. In particular, large CNVs (>1 Mb) are observed in four to five times as many instances of ID-related phenotypes than in ASDs, although the distinction between syndromic and non-syndromic forms of ID is not always made, and there could be more CNVs associated with syndromic ID (or ASDs). Overall, rare CNVs (seen in roughly 2% of the general population) are observed in 10% of ASD cases and 16% of IDs. A more modest, roughly twofold excess of rare CNVs has also been observed in ADHD (Williams et al., 2010, 2012). Thus, emerging data suggest a convincing role for rare, primarily spontaneous, CNVs but to significantly varying degrees. The highest frequency is in ID, then to lesser degrees respectively in ASD + ID, ASD alone, ADHD, and likely other less deleterious childhood phenotypes. Although it is still early in the use of many genomic analysis techniques (e.g., GWAS, genome sequencing), it seems plausible that these observations represent the relative contribution of extremely rare and *de novo* variation versus more common, older inherited variation across these phenotypes.

Two other important observations, which are also likely to extend to other variation types, have been made convincingly as sample sizes and studies have grown across many distinct clinical end points. First, the majority of CNVs that have been associated with ASDs have independently been demonstrated to confer risk to other, apparently unrelated phenotypes such as schizophrenia or epilepsy (Sebat et al., 2009). This suggests pointedly that most of these mutations confer risk to a very broad set of phenotypes, rather than a clinically specific one. Second, for most of these CNVs, healthy adult controls are

also occasionally seen bearing the mutations. Accordingly, although risk conferred is quite high (approximate odds ratios of 10 to 20), the penetrances for any specific outcome are generally less than 50%. In these two properties, the risk variants discovered in large case-control studies (generally focusing on large, idiopathic population samples of cases) seem distinct from those relevant to the rare mendelian genomic syndromes. Such syndromes usually are caused by high penetrance events and have an extremely specific set of comorbidities and features that make them clinically recognizable often in advance of conclusive genetic testing.

Related to this, a considerable number of specific, single-gene genetic syndromes have been described that feature unusually high rates of ID or ASD (Betancur, 2011). Although some of these are rare and apparently fully penetrant entities such as Rett syndrome, a severe form of autism most often caused by mutations in one copy of MECP2 or CDKL5 on one X chromosome in girls (these mutations are usually lethal prenatally in boys), most have far less than complete penetrance. Noteworthy examples among these in the case of ASDs include Fragile X and tuberous sclerosis complex (TSC) (Folstein and Piven, 1991), specific and long-identified Mendelian syndromes with high rates of ASD. Similar to the CNVs described in the preceding, however, fewer than 50% of cases manifest ASDs. Although many such rare genetic syndromes are now identified, taken in total they likely explain only a small percentage of idiopathic ASDs.

Figure 70.1 shows the relationship between effect size and frequency for CNVs associated to ASD and the first common variants identified in schizophrenia at genome-wide significance. The CNVs clearly confer much greater risk, but are only present in a small fraction of cases. The common variants are

selected from schizophrenia, to illustrate the effect sizes of common variants typical of psychiatric phenotypes. As sample sizes continue to increase for GWAS for these traits, further clues are likely to be revealed in the biological basis of these diseases.

The massively parallel genome sequencing technologies that have become available since 2010 have it possible to sequence the roughly 1% of the human genome that encodes proteins (the exome). Autism spectrum disorders are among the first disorders for which this approach has been utilized in substantial numbers of cases and indeed, by sequencing parents and children, recent studies have documented excesses of *de novo* loss-of-function mutations in cases when compared with either control individuals (Sanders et al., 2012) or mutational expectations (Neale et al., 2012; O’Roak et al., 2012). Although these early studies suggest that only a minority (<20%) of cases harbor relevant spontaneously arising mutations, they do have the ability to pinpoint specific genes relevant to ASD risk. Overall, however, these studies reinforce estimates from the CNV work that hundreds of genes likely contribute to ASD risk. Although large-scale studies have not yet been performed in the other childhood psychiatric disorders, earlier studies of X-linked mental retardation (Tarpey et al., 2009) similarly concluded that relevant mutations are likely distributed across many genes, resulting in a situation that will inevitably require considerable sample sizes on which to provide clarity.

As noted, GWAS has far and away been the most productive avenue toward insight into the genetics of unquestionably polygenic common diseases. Common variation, as assessed by GWAS, has yet to provide compelling findings in the case of any of the childhood neuropsychiatric disorders. Although the role of rare and spontaneous mutations may well dominate in the

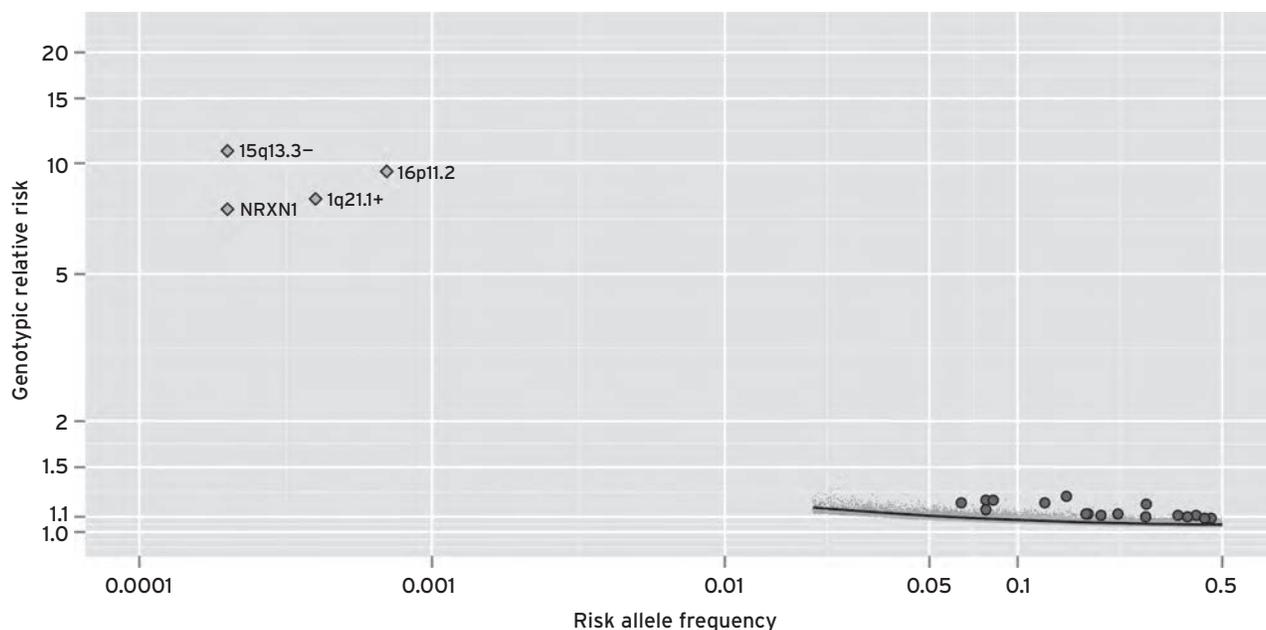

Figure 70.1 The risk allele frequency is plotted against the genotypic relative risk for the copy number variations identified in autism spectrum disorder along with single nucleotide polymorphisms associated at genome-wide significance for schizophrenia. The specific copy number variations identified are 15q33.3 deletion, deletions at NRXN1, 1q21.1 duplications, and both deletions and duplications at 16p11.2 (Malhotra and Sebat, 2012). These events confer strong risk to ASD in contrast to the identified genome-wide significant loci from schizophrenia (Ripke et al., 2011). (Thanks to P.F. Sullivan for concept and underlying data.)

case of severe ID, it appears to play a reduced role in idiopathic ASDs and has not been documented to contribute substantially to ADHD or TD. The high heritability of the latter three, particularly ASD and ADHD, suggests some substantial role for inherited and somewhat more common variation. If we contrast the published efforts to date in ASD, ADHD, and TD with those in schizophrenia (as well as particularly polygenic and complex non-psychiatric diseases and phenotypes such as type 2 diabetes, coronary artery disease, and adult stature), a consistent pattern emerges. In all of these cases with similar high heritabilities, early GWAS studies of one to a few thousand cases failed to reject the null hypothesis that any common variants were associated to disease risk. Much larger collaborative studies that followed, however, were able to define many distinct and replicated associated loci. In each case, these studies provided novel insight into the biology of the diseases in question. This is of course not proof that such insights will be forthcoming in childhood neuropsychiatric disorders, but the productivity of schizophrenia GWAS after early “failure” suggests that further investment may be warranted in tandem with the focus on rare variation.

CONCLUSIONS

Research approaches that integrate the levels of evidence introduced in the preceding sections are likely to improve the efficacy of genetic inquiries into child neuropsychiatric conditions. Behaviorally defined disorders are characterized by enormous genetic complexity, and inferences drawn from epidemiological and family data, as well as classic genetic theory, can be used in concert to begin parsing that variation. The ASD literature presented here provides an example of such a collaborative logical trajectory. Autism spectrum disorders as currently defined exist across a broad range of severities, including phenotypes that both do and do not confer substantial reproductive disadvantage. Although the etiological structure of the disorders is unlikely to fall cleanly along these phenotypic lines, family and twin data are consistent with such a pattern in that they suggest that ASDs exist in both familial and non-familial forms (and likely in the space in between). These patterns can be used to justify a tandem approach of genetic investigation, focusing on both common and rare variants, consistent with the relationship between genetic architecture and reproductive disadvantage, as it has been observed more broadly within genomic inquiry.

Large sample, multidisciplinary collaborations designed to uncover the biology underlying neuropsychiatric disorders in children are already in progress. Following lessons from the progress emerging from larger, adult psychiatric consortia, it is very likely that continued efforts along these lines will be necessary to elucidate the complete genetic architecture of each disorder, as well as to progress to a full understanding of the relationship between etiologically linked phenotypes.

DISCLOSURES

Dr. Daly’s research into childhood psychiatric disorders is currently funded through grants from the NIMH and NHGRI

and a philanthropic gift from the Gerstner Foundation. In the past year Dr. Daly has consulted with Pfizer, Inc. and Eisai Pharmaceuticals. Grant Support: R01 NS 059727 NIH; 1R01 DK083756-1 NIH/NIEHS; 2P30DK043351-21 NIH/NIDDK; R01AI091649-01AI NIH/NIAID; 1R01MH09443201 NIH/NIMH; 5R01DK064869-09 NIH/NIDDK; 1R01MH089208-01 NIH/NIMH; 1R01MH094469 NIH/NIMH; P40 RR12305 NIH/NCBI; U01HG006569 NIH/NHGRI; I5-A523 Starr Cancer Consortium.

Dr. Neale has no conflicts of interest to disclose. He is funded by the NIMH, the Gerstner Foundation, and the Stanley Center for Psychiatric Research. Grantsupport: 5R01MH080403-03S1 NIH/NIMH; 1R01MH09443201 NIH/NIMH; 1R01MH089208-01 NIH/NIMH; 1R01MH094469 NIH/NIMH.

Dr. Robinson has no conflicts of interest to disclose. She is funded by Massachusetts General Hospital.

71 | RARE VARIANTS OF SUBSTANTIAL EFFECT IN PSYCHIATRIC DISORDERS OF CHILDHOOD ONSET

HEATHER C. MEFFORD

Psychiatric disorders in children carry a significant financial and social burden for affected children and their families. Examples include autism, intellectual disability, attention deficit/hyperactivity disorder (ADHD), childhood-onset schizophrenia, and bipolar disorder. For parents, these diagnoses also carry a psychological burden as questions about etiology and recurrence risk arise. The evidence for genetic contribution to these disorders is extensive and stems from family and twin studies. In fact, early genetic studies focused on linkage analysis in rare, large families with multiple affected family members. However, for all of these disorders, such large families are rare; rather, the inheritance pattern for most psychiatric disorders is complex and does not follow a simple mendelian inheritance pattern.

Two hypotheses have been put forth concerning the genetics of such disorders. One suggests that multiple common genetic variants each contribute a small increased risk for disease. Genome-wide association studies (GWAS) are designed to identify common single nucleotide variants that are more frequent in affected versus unaffected individuals and have been carried out for many psychiatric disorders. Results of GWAS are varied, but in most cases, a single nucleotide change that is found to be associated with disease confers only a slight increased risk for disease. The rare variant hypothesis, on the other hand, puts forth that some rare genetic variants have a large effect on disease risk. Each variant may be individually quite rare—even absent from control populations—but the collection of rare variants together explain a large portion of genetic risk. This chapter focuses on the identification of rare variants that have a large effect on genetic risk for childhood psychiatric disorders.

GENETIC VARIANTS AND THE TECHNOLOGIES THAT DETECT THEM

Over the past five to ten years, advances in technology have enabled genome-wide discovery of both common and rare genetic variation. Here we consider two general classes of variation: single nucleotide variants (SNVs) and copy number variants (CNVs; Fig. 71.1). Single nucleotide variants are DNA changes involving a single base pair (e.g., an A to G change) that can be found in noncoding or coding regions of the genome. Single nucleotide variants that vary from the reference genome in 5% or more of the population are termed single nucleotide polymorphisms (SNPs) and occur at an average frequency of one per kilobase throughout the genome.

Copy number variants are defined as deletions or duplications of a stretch of DNA when compared with the reference human genome and may range in size from a kilobase (kb) to several megabases (Mb) or even an entire chromosome (trisomies and monosomies). Copy number variants can involve multiple, one or no genes. As with SNVs, some CNVs are polymorphisms. Multiple studies of large control cohorts have shown that some regions of the genome are tolerant of copy number changes, and that every individual carries many copy number changes that are, for the most part, benign (Iafrate et al., 2004; Itsara et al., 2009; Locke et al., 2006; Redon et al., 2006; Sebat et al., 2004). Copy number variants come in two basic flavors: recurrent and non-recurrent (Fig. 71.1). Recurrent CNVs are those that arise by non-allelic homologous recombination (NAHR) during meiosis. The breakpoints of recurrent CNVs lie in large duplicated blocks of sequence flanking the CNV event, so the breakpoints of recurrent CNVs in unrelated individuals will be essentially identical. In contrast, non-recurrent CNVs have breakpoints that generally lie within unique sequence and do not occur because of predisposing genomic architecture. There are several different mechanisms by which non-recurrent CNVs can arise including non-homologous end joining (NHEJ) and fork stalling and template switching (FoSTeS). Although two unrelated individuals may have overlapping non-recurrent CNVs, they are unlikely to have the same breakpoints. Significantly, comparison of overlapping non-recurrent CNVs in individuals with similar phenotypes can lead to narrowing of the critical region for a given phenotype (see Fig. 71.1).

Three technologies developed over the past several years have transformed our ability to efficiently detect genetic variation across the entire genome: array comparative genomic hybridization (CGH), SNP genotyping arrays, and massively parallel sequencing. Array CGH technology was developed to detect copy number changes throughout the genome. Although initial studies were performed in population controls to determine the “CNV landscape” in normal individuals, the technology was rapidly applied to large cohorts of individuals with ID, autism, and other disorders to detect disease-causing CNVs. Single nucleotide polymorphism genotyping arrays were developed to genotype up to several million common SNPs simultaneously and have been used extensively for GWAS. It was also recognized that SNP microarray data could be used to detect CNVs, facilitating CNV discovery in cohorts that had already been genotyped for GWAS. Both array CGH and SNP

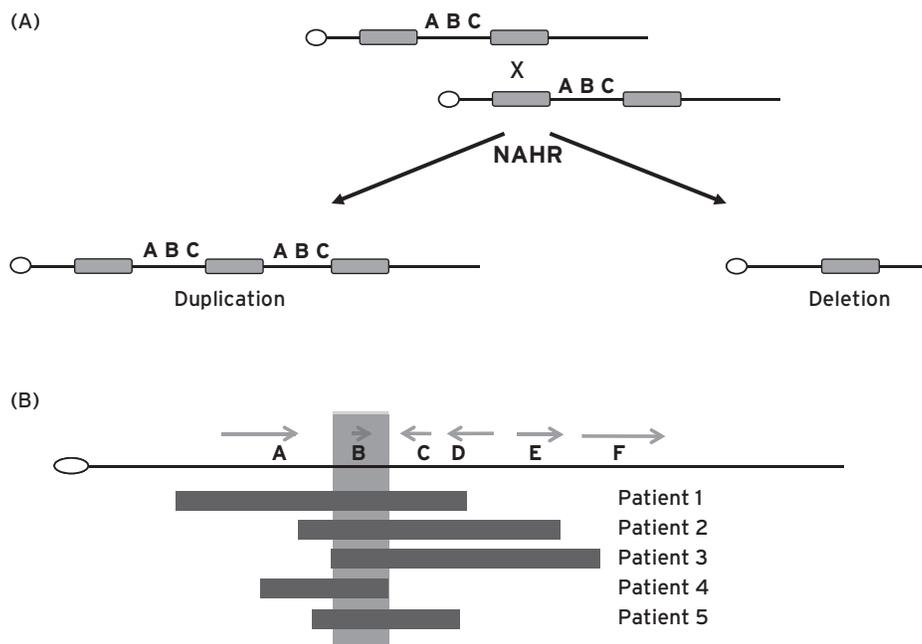

Figure 71.1 Schematic representation of recurrent (A) and non-recurrent (B) copy number changes. (A) Recurrent CNVs usually arise by non-allelic homologous recombination (NAHR) during meiosis. Light Gray blocks represent large duplicated blocks of sequence where mis-alignment can occur. Recombination, represented by the “X,” causes duplication or deletion of the sequence between the duplicated blocks. “A B C” represent genes within the region that are deleted or duplicated as a result. (B) Non-recurrent CNVs are represented by dark gray horizontal bars, each with different proximal and distal breakpoints. Comparison of overlapping, non-recurrent CNVs in individuals with similar phenotypes can lead to narrowing of the critical region for a given phenotype, represented by the gray shading over gene “B.”

microarrays have been used extensively to investigate the role of CNVs in disease and are also used in clinical laboratory settings for diagnostic testing.

Although common SNPs can be genotyped with SNP microarrays, rare SNVs cannot, although recurrent rare SNV are now being incorporated into microarrays. The technology that has enabled efficient detection of rare SNVs is massively parallel or “next-generation” sequencing. Massively parallel sequencing (MPS) involves highly parallelized sequencing of millions of short DNA fragments from the genome. Indeed, an entire genome can be sequenced using MPS in a matter of weeks. A more efficient approach, and one that has now been employed extensively for disease gene discovery, is to sequence only the approximately 1% of the genome that is protein-coding, termed the exome. There are two main reasons for sequencing the exome as opposed to the whole genome when looking for disease-associated variants. First, the majority of known variants that cause mendelian disorders occur in coding sequence, whereas a minority is found in non-coding regions of the genome. Second, variants within coding exons are readily interpretable. That is, it is fairly straightforward to determine whether a given nucleotide change will result in a change in the protein. Interpretation of variants in noncoding regions is much more difficult.

All of these technologies have been used to investigate the role of genetic and genomic variation in various neuropsychiatric illnesses, and three consistent themes have emerged. First, each disorder exhibits significant genetic heterogeneity. That is, the number of genes and genomic loci that confer disease risk is extensive, and unrelated patients are more likely to

have unique, rather than shared, genetic risk factors. A second and related theme is that the genetic factors involved in disease risks of large effect are rare, rather than common, variants. This is true for both SNVs and CNVs, with *de novo* variants playing an important role. Finally, large-scale studies across diverse disorders have revealed shared genetic susceptibility factors for disorders once thought to be distinct. In some respects, this shared genetic susceptibility is not surprising. Indeed, there is considerable comorbidity as children with ID often have autistic features; children with schizophrenia may exhibit ASD features before onset of psychosis; children with ASD may have ID or seizures, and so forth. With the technologies described earlier, genome-wide studies of rare variants in each of these disorders are illuminating specific genomic regions and genes that confer shared genetic susceptibility. This will shed light on common pathways for normal brain development and function, providing insight into potential therapies. This chapter discusses recent advances in the discovery of rare genetic variants that confer risk for childhood-onset psychiatric disorders including intellectual disability, autism, childhood-onset schizophrenia, attention deficit hyperactivity disorder, and Tourette syndrome.

INTELLECTUAL DISABILITY

Intellectual disability (ID) affects 1% to 2% of individuals and is characterized by significant limitations in both intellectual functioning and adaptive behavior that begins before the age of 18 years (American Psychiatric Association., 2000; Leonard

and Wen, 2002). Although a diagnosis of ID is usually made in late childhood or early adulthood when IQ testing reveals an IQ of less than 70, most individuals with ID are identified early in childhood with concerns about developmental delays that may include any or all of motor, cognitive, and speech delays. A thorough discussion of ID syndromes is presented elsewhere (see Chapter 76). Here, we will discuss more recent discoveries made possible by array CGH, SNP microarrays and exome sequencing.

COPY NUMBER VARIATIONS IN INTELLECTUAL DISABILITY

It has long been known that chromosomal copy number changes can cause ID. One of the earliest examples, and still one of the most important causes of ID, is the presence of an extra copy of chromosome 21 resulting in Down syndrome. Intellectual disability syndromes caused by recurrent deletions were recognized as cytogenetic techniques improved and fluorescent in situ hybridization (FISH) techniques became available. Examples of well-known ID syndromes cause by recurrent microdeletions include Prader-Willi syndrome (paternal deletion of 15q11-q13), Angelman syndrome (maternal deletion of 15q11-q13), Smith-Magenis syndrome (deletion of 17p11.2), and velocardiofacial syndrome (deletion of 22q11.2). Fluorescent in situ hybridization studies of subtelomeric regions near the ends of chromosomes highlighted the importance of unbalanced subtelomeric rearrangements, which cause 2.5% to 5% of ID (Ballif et al., 2007; Knight et al., 1999; Ravnan et al., 2006). These early studies were targeted to specific regions of the genome. In most cases, a suspected diagnosis could be confirmed or ruled out with a FISH study for a specific deletion. Subtelomeric studies targeted multiple regions at once, but still assayed only a small portion of the genome.

In approximately 2004, the introduction of array CGH and SNP arrays for CNV detection facilitated unbiased, genome-wide discovery of CNVs in patients with ID, paving the way for an unprecedented rate of discovery of novel ID syndromes associated with both recurrent and non-recurrent CNVs. Since 2006, more than 20 novel recurrent deletion and duplication syndromes have been described in patients with ID (Table 71.1), along with many more non-recurrent deletions and duplications. Two examples of recently described recurrent deletions that are highly penetrant and associated with syndromic features are microdeletions of 17q21.31 and 15q24. Heterozygous deletions of 17q21.31 are always *de novo* and are associated with moderate to severe ID, hypotonia, facial dysmorphic features, occasional cardiac and renal abnormalities, seizures, and a generally happy disposition (Koolen et al., 2006; Koolen and de Vries, 1993; Sharp et al., 2006; Shaw-Smith et al., 2006). The deletion is 500 to 650 kb in size, is not detectable by routine karyotyping, and has never been seen in healthy controls. The prevalence is estimated to be approximately 1/16,000 (Koolen et al., 2008). Deletions of 15q24 are much rarer, but patients with 15q24 microdeletions also appear to be syndromic (Andrieux et al., 2009; El-Hattab et al., 2009; Klopocki et al., 2008; Mefford et al., 1993; Mefford et al., 2011; Sharp

*Newly described syndromes since 2006. del, deletion; dup, duplication.

et al., 2007). All 15q24 deletions described to date are *de novo*, and common features include variable developmental delay and ID that is usually moderate to severe; severe speech delays or absent speech; dysmorphic features, including a high anterior hairline, prominent forehead, and downslanting palpebral fissures; joint laxity; and hypotonia. Many patients also have some features of autism spectrum disorders. The 15q24 deletions have variable breakpoints and range in size, but most include a region of 1.1-Mb that is thought to be the critical region for the phenotype.

In addition to the syndromic microdeletions described in the preceding, several recurrent microdeletions and duplications have been associated with ID but also with a wider range of phenotypic features and severity. Examples include 1q21.1 deletions and duplications (Brunetti-Pierri et al., 2008; Christiansen et al., 2004; Mefford et al., 2008), 16p11.2 deletions and duplications (Battaglia et al., 2009; Bijlsma et al., 2009; Hempel et al., 2009; Rosenfeld et al., 2009; Shinawi et al., 2010), 15q13.3 deletions (Ben-Shachar et al., 2009; Sharp et al., 2008; van Bon et al., 2009), 15q11.2 deletions (Mefford et al., 2009; Murthy et al., 2007; von der Lippe et al., 2011) and 16p13.11 deletions and duplications (Hannes et al., 2009; Mefford et al., 2009; Ullmann et al., 2007). Each of these CNVs is associated with a significant risk for ID, but is also associated with risk for at least one other psychiatric condition including schizophrenia, autism, ADHD, and/or epilepsy (see the following).

Numerous non-recurrent deletions and duplications have also been described in cohorts of patients with ID. Because they are non-recurrent—often unique—it can be difficult to accumulate a series of patients so as to identify common features. Pathogenicity is generally determined because of the inheritance (*de novo*), size (large), or gene content (many or at least one known disease gene) of a given CNV (Miller et al., 2010). In some cases, overlapping deletions are frequent enough to describe common features. Such is the case for overlapping deletions involving 1p36, 9q34, distal 22q11, 22q13 and others.

SINGLE NUCLEOTIDE VARIATIONS IN INTELLECTUAL DISABILITY

There are numerous single-gene causes of ID and syndromes associated with ID, many of which are discussed elsewhere in this volume. Early discoveries of genes responsible for ID relied on family-based genetic linkage studies and DNA sequencing. Because X-linked forms of ID can be transmitted through unaffected females in families, allowing pedigree analysis, a large effort has focused on identifying genes on the X chromosome, and mutations in more than 90 X-linked genes are now known to cause ID, accounting for about 10% of cases (Ropers, 2010). Autosomal genes have been more difficult to identify, because there are few familial forms of ID. Indeed, it is thought that the majority of moderate to severe ID is caused by *de novo* mutations, which cannot be detected by linkage mapping. However, new sequencing technologies are facilitating gene discovery in this previously intractable form of inheritance.

Exome sequencing has been used to identify the genes responsible for many disorders since 2009, including Kabuki syndrome (Ng et al., 2010), Schinzel–Giedion syndrome (Hoischen et al., 2010), Sensenbrenner syndrome (Gilissen et al., 2010), and others. One approach that has been quite successful is exome sequencing in “trios” of one affected child and two unaffected parents. The goal of trio analysis is to identify the small number of *de novo* sequence changes that are present in the affected child but not in either parent. The trio approach is efficient because, on average, it is predicted that each exome will have less than one *de novo* mutation that changes an amino-acid (Lynch, 2010). At least one study has applied exome sequencing in trios to identify causes of nonsyndromic ID (Table 71.2) (Vissers et al., 2010). In 10 affected individuals without a family history of ID, they identified nine true *de novo* variants (in nine different genes) in six individuals. Two patients each had a *de novo* mutation in a known ID gene. In four other cases, patients had a *de novo* variant in a plausible candidate gene. It must be noted that additional studies are required to confirm that the candidate genes truly play a role in ID. However, the results indicate that trio analysis is an efficient method to detect *de novo* mutations and novel candidate genes. These results also highlight the genetic heterogeneity in ID, as no two patients had *de novo* mutations in the same gene.

Exome sequencing has also been used to investigate causes of autosomal recessive ID (see Table 71.2). In one study, investigators sequenced the exomes of two parents with multiple affected children to look for heterozygous deleterious mutations within a 2-Mb linkage region (Caliskan et al., 2011). They identified a mutation in the gene *TECR* that was homozygous in all affected children. In another study, investigators set out to tackle autosomal recessive ID in 136 consanguineous families (Najmabadi et al., 2011). Using linkage data for their families that narrowed the genomic regions of interest, they captured the subset of exons within linkage regions for each family rather than sequencing the entire exome. They found mutations in 23 known ID genes in 26 families, providing a definitive diagnosis. In the remaining families, they identified 50 novel candidate genes, each with a homozygous mutation in a single family. Clearly, these candidate genes need to

be validated in additional samples, but the study provides a framework for evaluation of recessive forms of ID.

AUTISM SPECTRUM DISORDERS

Autism spectrum disorders (ASD), estimated to affect as many as 1/150 to 1/100 children (Chakrabarti and Fombonne, 2001, 2005), share common features of impaired social relationships, impaired language and communication, and repetitive behaviors or a narrow range of interests. Children with ASD often have comorbid conditions, including ID (approximately 70%) and epilepsy (approximately 25%), and most require lifelong social and educational support. Evidence for a strong genetic component comes from family and twin studies. In addition, many genetic syndromes caused by single gene mutations or chromosomal rearrangements are associated with ASD (Table 71.3). Therefore, extensive studies have been performed to identify the genes and genomic regions that have a large effect on genetic risk for ASD. We focus on the most recent findings from genome-wide approaches.

COPY NUMBER VARIATIONS IN AUTISM SPECTRUM DISORDER

Rare CNVs clearly play a role in the genetic etiology of ASD. One of the first CNVs to be associated with ASD was duplication of 15q11-q13, the same region associated with Prader-Willi and Angelman syndromes when deleted. Duplication of this region, which contains maternally and paternally imprinted genes, is associated with ASD when maternally inherited or derived, but not when paternally inherited (Cook et al., 1997) and is responsible for 1–3% of ASD (Hogart et al., 2010). More recently, genome-wide array technologies have been used extensively for CNV discovery in ASD. Since 2007 numerous studies have each identified multiple rare, often *de novo* variants in affected individuals that are either not present or present at a much lower frequency in unaffected individuals (Table 71.4). Together, these studies indicate that there is a strong association between *de novo* CNVs and ASD, especially in the case of simplex families where only one child is affected.

A number of recurrent CNVs are associated with an increased risk for ASD. One of the first regions to be strongly

TABLE 71.3. Examples of genetic syndromes in which autism spectrum disorder is a prominent feature

SYNDROME	CAUSATIVE GENE	INHERITANCE

associated with ASD was 16p11.2 (Kumar et al., 2008; Marshall et al., 2008; Weiss et al., 2008). The 16p11.2 region is approximately 550 kb and contains 25 annotated genes, although which gene or combination of genes contribute to the ASD phenotype is not yet known. Deletion or duplication of 16p11.2 can be found in up to 0.5% to 1% of children with ASD, but it is now clear that the same CNVs are also significant risk factors for ID (Bijlsma et al., 2009; Mefford et al., 2009; Shinawi et al., 2010), schizophrenia (McCarthy et al., 2009), epilepsy (Bedoyan et al., 2010; Mefford et al., 2011), and obesity (Jacquemont et al., 2011; Walters et al., 2010). Recurrent deletions of the 15q24 region cause a syndrome characterized by moderate to severe delays, including significant speech delays; many patients are also described as having ASD characteristics as well (Andrieux et al., 2009; El-Hattab et al., 2009; Klopocki et al., 2008; Mefford et al., 1993; Mefford et al., 2011; Sharp et al., 2007). As for ID, there are recurrent CNVs that seem to confer risk for ASD as well as other disorders, including 15q13.3 deletions (Ben-Shachar et al., 2009; Miller et al., 2008; Pagnamenta et al., 2009), 16p13.11 deletions and duplications (Ramalingam et al., 2011; Ullmann et al., 2007), and 17q12 deletions (Loirat et al., 2010; Moreno-De-Luca et al., 2010; Nagamani et al., 2010) (see the following).

Non-recurrent CNVs can be important for identifying specific genes that might be important for ASD risk. Multiple CNVs within the *NRXN1* gene have been reported in affected individuals (Ching et al., 2010; Glessner et al., 2009; Kim et al., 2008; Szatmari et al., 2007). Although deletions within the gene are also seen in some control studies, the frequency of *NRXN1* deletions is greater in cases compared to controls. This suggests that such deletions confer risk but are not completely penetrant. Deletions involving the *PTCHD1* gene highlight this gene's potential role in ASD (Noor et al., 2010; Pinto et al., 2010) as well.

TABLE 71.4. Key copy number variation studies in autism spectrum disorder

SINGLE NUCLEOTIDE VARIATIONS IN AUTISM SPECTRUM DISORDERS

Although there is ample evidence for a genetic contribution to ASD, identification of true “autism genes” has been slow. Certainly there are many genetic syndromes in which a significant proportion of affected individuals have features of ASD (see Table 71.3). Some of the most important players are *MECP2* (Rett syndrome), *FMR1* (Fragile X syndrome), *SHANK3* (Phelan-McDermid syndrome/22q13.3 deletion syndrome), *PTEN* (*PTEN* macrocephaly syndrome), and *TSC2* (tuberous sclerosis) among others. Clearly this supports the notion that a subset of genes and pathways are important for ASD risk.

Identifying genes that play a clear role in idiopathic or non-syndromic ASD have been more elusive, and the discovery of genetic variants that confer risk for ASD has been approached from multiple directions. Large chromosomal rearrangements in individual patients can provide clues to genomic regions that are important for risk and are often reported as case studies in the literature. For example, the *AUTS2* gene was described as a possible autism gene after it was found to be disrupted by an inversion breakpoint in monozygotic twins concordant for autism (Sultana et al., 2002). *SHANK3* emerged as an ASD risk gene by comparing overlapping deletions in patients with 22q13 deletions. More comprehensive analyses have been carried out since the introduction of genome-wide array technologies, and the role of rare CNVs is discussed in the following. Some candidate genes have been studied individually using standard sequencing techniques to look for rare variants in modest patient cohorts. Finally, MPS has recently been employed for genome-wide discovery of rare, *de novo* SNVs that may be causative in some patients.

Recently, exome sequencing has been employed to investigate the role of rare *de novo* variants in ASD (Table 71.5) (Chahrour et al., 2012; Iossifov et al., 2012; Neale et al., 2012; O’Roak et al., 2011, 2012; Sanders et al., 2012). All support a role for rare, protein-altering *de novo* mutations in the genetic etiology of ASD. However, they also highlight the significant genetic heterogeneity that underlies ASD risk. In one of the first

studies, exome sequencing was performed in 20 trios (O’Roak et al., 2011), and compelling *de novo* mutations in four of the 20 children were identified within genes that are known to be involved in brain development: *FOXPI* (Hamdan et al., 2010), *GRIN2B* (Endele et al., 2010), *SCN1A* (Claes et al., 2003), and *LAMC3* (Barak et al., 2011). Three large studies used exome sequencing in a total of 622 children with ASD (209 trios (O’Roak et al., 2012), 175 trios (Neale et al., 2012), 238 families (Sanders et al., 2012). There were eighteen genes in which two or more patients had a *de novo* non-synonymous change across the studies. Mutations in three of the genes were nonsense, splice, or frameshift. Another study performed exome sequencing in 343 simplex families and found 59 genes with *de novo*, likely gene-disrupting mutations (Iossifov et al., 2012) but none with a mutation in more than one patient. Based on their results, they estimate that there are 350 to 400 ASD susceptibility genes. Finally, one study has used exome sequencing to investigate a recessive model for autism in 16 families and identified several potential candidate genes (Chahrour et al., 2012).

CHILDHOOD ONSET SCHIZOPHRENIA

Childhood onset schizophrenia (COS) is a rare and severe form of schizophrenia with onset of symptoms before age 18. Because of similarities with other neuropsychiatric disorders and the progressive and evolving symptoms, COS can be difficult to diagnose early. Although there have been several studies aimed at identifying rare variants in adult-onset schizophrenia, fewer have been targeted specifically to COS. We briefly discuss the support for rare variants in schizophrenia generally, with a focus on studies that address COS.

RARE COPY NUMBER VARIATIONS IN CHILDHOOD ONSET SCHIZOPHRENIA

Early studies in COS highlighted the role of 22q11 deletions in affected individuals (Yan et al., 1998). Like many

microdeletions, the 22q11 deletion is associated with a wide range of cognitive abilities and other associated findings. It is one of the most common genetic factors associated with schizophrenia of adult onset as well as COS (Karayiorgou et al., 1995). All of these early studies were targeted and investigated the 22q11 region but not the rest of the genome.

The first genome-wide CNV studies in schizophrenia took place in 2008 and firmly established the role of both recurrent and non-recurrent CNVs in the genetic etiology of schizophrenia (International Schizophrenia Consortium, 2008; Stefansson et al., 2008; Walsh et al., 2008). Specifically, *de novo* mutations are more common in patients with sporadic schizophrenia. Furthermore, several recurrent CNVs are found at an increased frequency in patients with schizophrenia when compared with population controls, and all are associated with other neuropsychiatric conditions (see the following). Although the majority of studies have been performed in adults, at least two studies have looked specifically at COS. One study of 83 cases of COS found an excess of large (>150 kb) CNVs in affected children (Walsh et al., 2008). A deletion disrupting *NRXN1* was present in a pair of monozygotic twin children concordant for schizophrenia; similar deletions have been reported in adult-onset schizophrenia. Two children harbored recurrent duplications of 16p11.2. Another study of 96 patients with COS confirmed the importance of 22q11 deletions in this patient group and also identified a *NRXN1* deletion and two 16p11.2 duplications among other CNVs (Addington and Rapoport, 2009). Comparison of CNVs found in adult-onset disease compared with COS suggests that there are some shared risk factors, including 22q11 deletions, 16p11.2 duplications, and *NRXN1* deletions. Whether there are additional factors that influence age-of-onset or genetic variants that are specific to the childhood-onset form will require additional studies.

RARE SINGLE NUCLEOTIDE VARIATIONS IN CHILDHOOD ONSET SCHIZOPHRENIA

As for other psychiatric conditions, candidate genes have been studied individually in an attempt to identify rare variants associated with schizophrenia. In a study of several hundred candidate genes in 28 probands with COS, a maternally transmitted frameshift mutation in the X-linked gene *UPF3B* was identified in two brothers with COS, ASD, and ADHD (Addington et al., 2011). Mutations in the same gene are associated with ID. In a targeted analysis of the *SHANK3* gene, 2/185 affected individuals had a *de novo* mutation. In one family, three affected brothers shared the same mutations, likely as a result of germline mosaicism (Gauthier et al., 2010). As discussed, mutations in *SHANK3* are also important for autism risk.

Exome sequencing in sporadic cases of adult-onset schizophrenia suggests a role for *de novo* mutations (Xu et al., 2008). Notably, the 40 *de novo* mutations that were found in 27 patients were all in different genes, again supporting the notion that there is extensive genetic heterogeneity. Exome sequencing studies have not yet been published for COS, but it would not be surprising to find a similar role for severe *de novo* mutations as suggested by the finding of a *de novo* mutation in *SHANK3* in a patient with COS (Gauthier et al., 2010).

ATTENTION DEFICIT/HYPERACTIVITY DISORDER

Attention deficit hyperactivity disorder (ADHD) affects up to 5% of children and is characterized by motor hyperactivity, inattention, and impulsivity. The heritability of ADHD is approximately 0.8 (Hinney et al., 2011). Although GWAS have yielded inconsistent results, CNV studies have identified several genomic regions and pathways that may be important in the genetic etiology of ADHD. No exome sequencing studies have been performed in ADHD yet.

As for other childhood neuropsychiatric disorders, CNV studies in ADHD reveal an enrichment of rare CNVs in affected children. One study identified rare recurrent CNVs involving glutamate receptors in approximately 10% of cases across multiple cohorts (Elia et al., 2012). In another study, there was a clear excess of large, rare CNVs in children with ADHD compared to healthy controls (Williams et al., 2010). Duplications of 16p13.11—also seen in ID, schizophrenia, and ASD—were specifically enriched in this cohort (Table 71.6).

TOURETTE SYNDROME

Rare genetic variants have also been found in Tourette syndrome, a childhood-onset disorder characterized by multiple motor tics and one or more phonic tics. Historically, chromosome abnormalities in isolated patients or families have been used to identify potential genomic regions that are important for Tourette syndrome. To date, there has been a single genome-wide study of CNVs in 11 patients with Tourette syndrome. In that study, there was no enrichment of CNVs in cases versus controls, but several CNVs that have been implicated in other neuropsychiatric disorders were found in patients with Tourette syndrome, including a 1q21 deletion and two deletions involving *NRXN1*, lending further support for shared genetic susceptibility among multiple neuropsychiatric conditions. Single nucleotide variation studies in candidate genes have been relatively unrevealing,

TABLE 71.6. Copy number variation studies in attention deficit/hyperactivity disorder

STUDY	N	FINDINGS
Elia et al. (2012)	1013 ADHD 4,105 healthy children	Metabotropic glutamate receptor gene networks enriched (GRM family)
Williams et al. (2010)	366 ADHD 1,047 controls	Increased rate of large, rare CNVs in ADHD; excess of 16p13.11 dups
Elia et al. (2010)	335 ADHD 2,026 controls	Rare inherited CNVs enriched for genes also associated with ASD, schizophrenia, Tourette syndrome, including <i>A2BP1</i> , <i>AUTS2</i> , <i>CNTNAP2</i> , <i>IMMP2L</i> , <i>GRM5</i>

though several candidate genes remain promising. The *SLITRK1* gene is located near the breakpoint of a *de novo* inversion in a patient with Tourette syndrome and is involved in neurite outgrowth. Subsequent sequencing studies revealed three affected individuals with rare mutations, although follow-up studies have yielded varying results. The *CNTNAP2* gene was disrupted in three affected individuals from one family. This gene is an attractive candidate because it has been implicated in ASD and ID as well. Finally, in one family, two affected boys carry a maternally inherited *NLGN4X* deletion. *NLGN4X* is also involved in ASD and ID (State, 2011).

OTHER CHILDHOOD-ONSET PSYCHIATRIC DISORDERS

There has been one study of 90 individuals with intermittent explosive disorder (IED), which is characterized by episodes of aggression in which the individual acts impulsively, with a response that is grossly out of proportion with the associated stressors. Two patients were each found to have a rare CNV, suggesting that rare CNVs may play a role in the etiology of IED. One of the CNVs was a deletion of 1q21, which has also been seen in patients with ID, ASD, and schizophrenia (Vu et al., 2011). Bipolar disorder is a severe mood disorder characterized by alternating episodes of mania and depression. In some cases, age of onset is before age 18. There have been several studies to identify rare CNVs in patients with bipolar disorder (Grozeva et al., 2010; Malhotra et al., 2011; Zhang et al., 2009). One study included 107 patients with childhood onset. Six of 107 childhood onset patients had one or more *de novo* CNVs, and the rate of *de novo* CNVs was significantly higher in early onset compared with adult onset disease (Malhotra et al., 2011).

SHARED GENETIC SUSCEPTIBILITY

The discovery of rare genetic variants has been made possible by technological advances that allow efficient, genome-wide investigations in large numbers of patients and controls. These technologies have changed the direction of disease gene discovery, facilitating unbiased, hypothesis-free studies, compared with targeted and candidate gene studies of the past. One important outcome has been the simultaneous discovery of the same risk variant in different patient cohorts.

There are several examples of rare recurrent CNVs that appear to confer risk of several different psychiatric conditions (Mefford, 2009) (Table 71.7). Deletions and duplications of 16p11.2 were first described in patients with ASD and remain an important risk factor for this condition. However, it is now clear that the deletion is enriched in patients with developmental delay and ID. The duplication is important for schizophrenia and perhaps epilepsy. Deletions of 15q13.3 were first recognized in patients with ID, most of whom also had seizures. Additional studies of patients with epilepsy showed the deletion is enriched (and more frequent) in this patient population. Furthermore, it is also a risk factor for schizophrenia

TABLE 71.7. Copy number variations associated with risk for multiple conditions

CNV REGION	DISEASES ASSOCIATED WITH DELETION	DISORDERS ASSOCIATED WITH DUPLICATION
1q21.1	ID, SCZ, EP, ASD, IED	ID, ASD, CHD
3q29	ID, SCZ	ID

22q11	ID, SCZ	ID

ADHD, attention deficit/hyperactivity disorder; ASD, autism spectrum disorder; EP, epilepsy; ID, intellectual disability; IED, intermittent explosive disorder; SCZ, schizophrenia.

and autism. Another example comes from 1q21.1 deletions and duplication. Both are found in patients with ID or ASD, and deletions are enriched in patients with schizophrenia. Together, these results highlight the fact that the genetic architecture of each of these disorders is not distinct. Rather, there are probably many genes and pathways that, when disrupted, increase the risk of abnormal brain functioning. Whether the outcome is ASD, ID, schizophrenia, or a combination likely depends on genetic background and perhaps other epigenetic or environmental factors. Non-recurrent CNVs have also revealed genes and genomic regions that confer risk for various disorders. Deletions involving *NRXN1*, for example, have been reported in ASD and schizophrenia. Although deletions are occasionally seen in controls, the frequency is greater in cohorts of affected individuals. Similar conclusions about shared genetic risk can be drawn from rare SNVs. There are several genes that cause ID syndromes that can also cause ASD. For example, *FMR1* mutations, which are one of the most common causes of ID, are also found in boys with autism. The recent discovery of *de novo* mutations in *SCN1A*, *SCN2A*, and *GRIN2B* in ASD highlight a shared genetic susceptibility to ASD and epilepsy, as mutations in *SCN1A*, *SCN2A*, and *GRIN2A*, a close relative of *GRIN2B*, most often cause epilepsy syndromes that are also associated with ID.

CONCLUSIONS

Recent advances in genomic technologies have revolutionized the field of rare variant discovery. Numerous large investigations using these technologies have led to rapid advances in our understanding of genetic risk for various psychiatric conditions, and common themes have emerged. Each disorder that has been studied exhibits significant genetic heterogeneity. Therefore, despite the large number of patients that have been studied, only a small proportion of the genetic risk factors have been identified, and additional work is required. Most of

the variants that have a large effect on risk are rare variants, and each is found in only a very small percentage of affected individuals. The most frequent risk variants in each disorder are found in only approximately 1% of patients. Finally, one of the most intriguing themes to emerge is that some large-effect genetic risk factors are shared among multiple disorders.

The vast genetic heterogeneity for each of these disorders will complicate clinical diagnostics, and thoughtful consideration must be given to how to approach risk assessment and diagnostics in the clinic. However, the rapid pace of discovery in childhood psychiatric disorders, a group of conditions that has been largely intractable so far, lends hope for the future. Many risk genes and regions have been discovered, and a goal of future research should be to investigate the common pathways that appear to be important for normal brain development and function.

DISCLOSURE

TRACY L. BALE

Fetal antecedents such as maternal stress, infection, or dietary challenges have long been associated with an increased disease risk, capable of affecting multiple generations. The mechanisms through which such determinants contribute to disease development likely involve complex and dynamic relationships between the maternal environment, the endocrine placenta, and the epigenetic programming of the developing embryo itself. Although an appreciation for the importance of the epigenome in offspring disease predisposition has evolved, the incredible variability in critical factors such as gestational timing of insults, sex of the fetus, and maternal genetics make clear interpretations difficult. However, animal models have proved highly informative in providing the best knowledge yet as to just how dynamically responsive the epigenome is, and in determining important mechanisms that shape and reprogram the developing brain. This chapter discusses the epidemiological and clinical evidence and supportive animal models related to environmental influences on neurodevelopmental and neuropsychiatric disease risk.

Historically, the term epigenetics has referred to heritable traits that are not mediated by changes in DNA sequence. More recently, epigenetics has been used more broadly to refer to any change in gene function not associated with sequence variation (Jiang et al., 2008) and has been embraced by the neuroscience community as a means by which we can integrate a role for the environment to influence or “program” gene expression or patterns that may or may not be heritable (Borrelli et al., 2008; Sweatt, 2009). Epigenetic mechanisms typically involve biochemical modifications of the DNA or histones such as methylation or acetylation, as well as noncoding RNAs, including microRNAs. Increasing evidence notes that numerous types of chromatin modifications, referred to as chromatin remodeling, are widespread in the brain and undergo dynamic regulation in both the developing and adult nervous system (Tsankova et al., 2007).

FETAL ANTECEDENTS AND PROGRAMMING IN NEURODEVELOPMENTAL DISORDERS: CLINICAL AND EPIDEMIOLOGICAL STUDIES

Although evidence points to a strong genetic component in risk factors for neurodevelopmental diseases, in which the concordance rate for schizophrenia in monozygotic twins is between 50% and 60%, and 40% to 90% of the variance in autism risk is

attributed to genetic heritability, new studies have focused on the potential contributions of epigenetic factors (Brown, 2012). The interactions between the rapidly changing intrauterine environment and the genetic background of the developing fetus produce epigenetic programming changes at the level of transcription, ultimately shaping developmental trajectories. Birth cohort studies examining specific maternal exposures to stress, infection, and dietary challenges have provided the clearest evidence to date for the critical role such fetal antecedents play in disease risk, and the temporal specificity for exposure windows of susceptibility. These large registries allow prospective studies to be conducted, which greatly aids in the accuracy of exposure reporting and confirmation, and the collection of biological materials to be analyzed as potential biomarkers for genetic/epigenetic factors associated with susceptibility. In the following, evidence from clinical and epidemiological studies is described related to specific neurodevelopmental diseases and our current knowledge of fetal antecedents that increase risk for these disorders.

SCHIZOPHRENIA

Prenatal and early life events such as maternal stress and infection have been associated with an increased risk of schizophrenia (Brown, 2012). Studies from large birth cohorts in which clinical, neurocognitive, and neuroimaging measures have been obtained revealed strong associations between *in utero* exposure to stress, infections, hypoxia, starvation, and an increased risk for schizophrenia (Bale, 2011; Susser et al., 2008), including disturbances of executive function, working memory, verbal memory, and structural brain abnormalities among offspring with schizophrenia (Brown et al., 2009b). In support of a temporal specificity to the effects of fetal antecedents on long-term outcomes in neurodevelopmental disorders, a recent epidemiological study reported a significant association between maternal stress experienced during the first trimester of pregnancy with an increased risk of schizophrenia in males (Khashan et al., 2008). Prospective birth cohort studies have suggested that such stress exposures may act by altering brain developmental trajectories involving epigenetic modifications, the evidence for which in humans, however, is currently lacking.

Maternal infection and immune disturbances during pregnancy have a strong association with offspring schizophrenia risk. Influenza exposure during early or mid-gestation produced a three-fold increased risk for schizophrenia compared with controls (Brown, 2012). The presence of elevated IgG

antibody to *Toxoplasma gondii* in maternal serum taken during pregnancy was also associated with a twofold increased risk of schizophrenia (Brown, 2012; Mortensen et al., 2007). Maternal genital reproductive infections around the time of conception have also been reported to have a fivefold increase in schizophrenia risk. Clinical studies examining neural end points have found an association of prenatal infection with deficits in executive function and morphological changes in schizophrenia patients (Brown, 2012). More specifically, neuroimaging findings indicated that prenatal infection was related to enlargement of the cavum septum pellucidum and diminished intracranial volume in these cases (Brown et al., 2009a).

Similar to the contributions made by maternal stress or infection to offspring development and programming, maternal diet directly regulates fetal growth, epigenetic programming, and disease risk. Epidemiological studies have repeatedly found an increased risk of schizophrenia in offspring from mothers exposed to severe caloric restriction or famine. In addition to the volume of epidemiological reports demonstrating intergenerational consequences of maternal starvation, obesity, and metabolic syndrome during pregnancy, the first data pointing to molecular mechanisms are now beginning to emerge. Periods of famine affecting human populations for well-defined durations afford the potential to track effects of undernutrition during pregnancy on offspring outcome. Findings stemming from the Dutch Hunger Winter of 1944–1945 reveal consequences ranging from glucose intolerance, increased coronary heart disease, altered stress responsiveness, and schizophrenia for the adult offspring of pregnancies occurring during a period of reduced caloric availability and increased psychological stress (Brown and Susser, 2008; Ravelli et al., 1976). These outcomes have been associated with changes detected in circulating growth factors and alterations in DNA methylation patterns of several genes, including the imprinted gene, insulin-like growth factor-2 (IGF-2) (Bale et al., 2010). These findings were detected 60 years following the famine exposure, supporting the long-lasting programming effects of the epigenetic marks. Interestingly, data from the Dutch Hunger Winter and the nineteenth century Swedish famine revealed that severe caloric restriction during pregnancy has transgenerational consequences in which even the second generation of offspring had increased neonatal adiposity, and overall lower quality health as adults when their mothers were exposed to famine (Brown and Susser, 2008), suggesting that epigenetic marks in germ cells must have occurred during the initial insult exposure.

Although most epidemiological studies have focused on offspring outcomes following periods of famine or malnutrition during pregnancy, our changing landscape is shifting the focus to effects of maternal overnutrition. Certainly, transgenerational epigenetics may be contributing to the rapid amplification of obesity rates and human height observed in recent generations (Bale et al., 2010). In addition, predisposing subsequent generations to these traits through epigenetic inheritance may compound the rate at which phenotypes progress. Maternal obesity has also been associated with a two- to threefold increased risk for schizophrenia in the offspring from two separate birth cohorts (Khandaker et al., 2012).

AUTISM SPECTRUM DISORDERS

Many factors have been examined as potential fetal antecedents related to an increased risk for autism spectrum disorders (ASD), including stress and infectious and immune disturbances (Brown, 2012). Although genome-wide association studies (GWAS) and other genetic analyses studies have identified candidate ASD susceptibility genes, more recent work in identical and fraternal twin pairs with autism showed that genetics accounted for less of the disease risk than did the shared environment (Angelidou et al., 2012). Such analyses support the critical importance for consideration of the interaction between genetic susceptibility and potential environmental insults that may produce epigenetic changes in neurodevelopment. Studies using the Danish Medical Birth Register found an association between viral infection resulting in hospitalization in the first trimester of pregnancy and a threefold increase in ASD risk. In a prospective study by the Early Markers for Autism, in which the presence of 17 cytokines was assayed in maternal serum and related to offspring ASD diagnosis, the authors found that specific cytokines, including IL-4, IL-5, and IFN γ , were increased at mid-gestation in mothers of children diagnosed with ASD. Prospective studies have also reported associations between amniotic fluid levels of specific cytokines such as TNF α , IL-4, and IL-5 with an increased risk for ASD (as reviewed in Brown, 2012).

Maternal stress has also been associated with an increased risk for ASD, including stress exposure at 21 to 32 weeks of gestation, and postnatal stressors such as the death of a relative in the first six months of life (Angelidou et al., 2012). However, in a metaanalysis by Gardner et al. on combined studies published since 2007, only four factors appear to consistently increase the risk for ASD: advanced maternal age, advanced paternal age, being first born, and having a mother born outside North America, Europe, or Australia (Gardener et al., 2009). A recent follow-up metaanalysis study from this group has added interactions of factors including umbilical cord complications, fetal distress, birth trauma, and a low five-minute Apgar score with increased risk for ASD (Gardener et al., 2011). What is clear is that more information and controlled prospective studies are still needed for confirming links between maternal stress or infection with ASD risk (Guinchat et al., 2012).

AFFECTIVE DISORDERS

There is growing evidence supporting an association between fetal risk factors and affective disorder predisposition, likely involving early epigenetic shifts in developmental trajectories. Birth cohort studies have identified prenatal conditions, including maternal immune and stress responses, as significant risk factors for major depressive disorder (MDD) (Bale et al., 2010). For instance, second trimester maternal exposure to type A₂/Singapore influenza significantly increased the risk for unipolar and bipolar disorders in a cohort of Finnish and British adults. In addition, maternal exposure to famine during the second and third trimesters elevated offspring lifetime risk for MDD, supporting an important link between maternal nutrition and offspring neurodevelopment that may also relate to maternal stress resulting from insufficient food sources.

Although maternal infection, stress, and undernutrition differentially affect the developing fetus, there are likely shared underlying mechanisms contributing to an increased vulnerability to MDD, including effects on the developing stress neurocircuitry (Bale et al., 2010).

As the brain continues to mature and develop well into adolescence, appreciation of the influences of the postnatal environment on programming of disease risk is necessary. Studies of the long-term consequences of adverse early childhood experience have unequivocally revealed that adults exposed to child abuse and/or neglect are at a greater risk for the lifetime development of affective disorders. In clinical studies, there is clear evidence for long-term neurobiological, neuroendocrine, and immune alterations following exposure to early life adverse events during critical periods in brain development (Bale, 2011). In addition, plasma stress hormone levels in response to relatively mild stressors are markedly increased in patients who have experienced early life trauma, including sexual or physical abuse.

In humans and non-human primates, hypersecretion of the stress hormone corticotropin-releasing factor (CRF), as detected in the cerebrospinal fluid (CSF), has been found years after the initial period of stress exposure during early life. Similar results were found in clinical studies in which women with a history of child abuse and/or neglect exhibit hyperactivity of the hypothalamic–pituitary–adrenal (HPA) axis in the Trier Social Stress test and increased CSF CRF concentrations. In addition, these patients exhibited decreased CSF concentrations of oxytocin, a peptide shown to be important in social biology and bonding, increased proinflammatory cytokines such as IL-6, and reduced hippocampal volume as measured

by structural magnetic resonance imaging (Bale et al., 2010; Heim et al., 2009, 2010). Further supporting a gene x environment interaction for development of affective disorders is the growing evidence of a genetic predisposition that underlies a stress-sensitive phenotype, thereby increasing the likelihood for stress experience throughout life, and elevating the risk for disease presentation (Kendler, 1998).

What is clear from examination of the epidemiological literature is that although a relatively small number of fetal antecedents (e.g., stress, infection, dietary challenges) have been linked with the neuropsychiatric disorders discussed in the preceding, what distinguishes the outcomes is likely the timing of the exposure/insult combined with the genetic background and fetal sex of the individual. How these factors independently or combined can act to influence neurodevelopmental programming is best examined using animal models.

THE ANIMAL MODELS

The incredible complexity of neuropsychiatric diseases makes the generation of relevant and beneficial animal models difficult; but without these models, mechanistic studies are nearly impossible. Evaluation and diagnosis of a mental health disorder requires a clinical conversation with a patient so as to assess specific criteria. Obviously, this is not possible in an animal. Therefore, rather than producing models of diseases in their entirety, an alternate approach has been to focus on important aspects, or endophenotypes, of the disease that can be more clearly measured in animals (Table 72.1). Examples include

TABLE 72.1. Summary of animal models being examined in relation to early life exposure and long-term outcomes of endophenotypes relevant to neuropsychiatric disease

ANIMAL MODEL	HUMAN DISEASE	ENDOPHENOTYPE EXAMINED	CITATION
Maternal infection	Schizophrenia, OCD, PTSD, Tourette	Sensory motor deficits (PPI)	Bilbo (2010), Hsiao and Patterson (2012)
Maternal immune activation	Schizophrenia	Enlarged ventricles	Hsiao and Patterson (2012)
Uteroplacental inflammation	Schizophrenia, ASD	Purkinje cell loss	Hsiao and Patterson (2012), Howerton and Bale (2012)
Postnatal neglect	Anxiety	Anxiety-like behaviors, hippocampal GR, hypothalamic CRF	Meaney (2001), Korosi (2010), Hackman (2010)
Postnatal stress	Depression	Stress reactivity and coping, depression-like behaviors	Franklin (2010) Bale (2010)
Prenatal stress	Schizophrenia, ASD	Male specific stress sensitivity, cognitive deficits	Kapoor (2008), Mueller (2008), Morgan (2011)
IUGR; low protein	Depression	Anhedonia	Vucetic (2010)
Caloric restriction	Affective disorders	Stress reactivity and coping, hippocampal GR expression	Bale (2010), Lesage (2001), Lingas (1999)
Maternal obesity	ASD, Anxiety	Anxiety-like behaviors, social anxiety, raphe TPH2 expression	Sullivan (2010), Vucetic (2010), Li (2010)

stress responsivity (behavioral or physiological), cognitive performance, spatial learning, and social behaviors. Many of these outcomes have been pharmacologically validated, with human pharmaceuticals having known efficacies in mental health disorders. These studies provide a wealth of opportunities to manipulate the animals' environment while controlling all other variables so as to identify important mechanisms involved in epigenetic programming and brain development.

In examining the prenatal or intrauterine environment, animal studies have examined factors such as maternal stress exposure, infection, and dietary changes (high fat, or low protein) and their impact on offspring outcomes during specific developmental windows and as adults. Postnatal environments have also been studied for promoting changes in maternal care that are associated with long-term effects on offspring brain and behavior. Transgenerational effects have been examined in these models to determine potential epigenetic programming that involves the germ cells, potentially altering future generations' disease susceptibility. An additional benefit provided by animal models is the ability to examine the temporal specificity for effects of fetal antecedents. Because fetal organ and tissue development occurs over the course of gestation, it follows that the impact of a given insult would depend on the stage at which it occurred. Thus, by more closely examining these specific periods of development, greater insight has been obtained as to points of increased vulnerability, as well as the potential for improved interventions and biomarker identification in predicting neurodevelopmental disorder risk. Animal models hold the greatest promise to accomplish this for their ability to control and study necessary variables such as genetic background and life experience, while manipulating the environment during specific windows of development.

PROGRAMMING EFFECTS OF EARLY STRESS EXPOSURE

PRENATAL STRESS

Stress pathway dysregulation is the most pervasive symptom in neuropsychiatric disease, and both clinical and basic research has identified factors important in the developmental programming and maturation of this system, as well as the sensitive periods during which perturbations may be disruptive. Animal models examining maternal stress have provided mechanistic insight into the long-term programming of important endophenotypes. As in humans, outcomes from maternal stress studies in animals have varied depending upon the stressors utilized, the outcomes examined, and timing of the stress event during pregnancy (Bale, 2011). Overall, in mice, rats, guinea pigs, and nonhuman primates, prenatal stress increases the sensitivity of the offspring HPA stress axis, anxiety-like and depressive-like behaviors, and cognitive deficits; all endophenotypes associated with neuropsychiatric disease.

Although prenatal stress has been broadly associated with offspring disease, the developing nervous system is unlikely to show uniform vulnerability to perturbations over the course of gestation. To compare maternal stress experience across early, mid, or late pregnancy on programming of offspring stress

regulation, a chronic stress model in mice determined that early gestation (days 1 to 7 of the 20- to 21-day gestation in mice) resulted in male offspring with an increased stress-sensitive phenotype as adults (Mueller and Bale, 2008). These males had elevated amygdalar CRF, and reduced hippocampal glucocorticoid receptors (GR). Epigenetic analyses determined that DNA methylation changes of these genes correlated with their expression. Interestingly, similar outcomes have been reported following gestational glucocorticoid exposure on offspring GR expression and promoter methylation, suggesting potential common mechanisms and points of vulnerability that may relate to direct or indirect actions of glucocorticoids during brain development (Bale, 2011).

A prenatal stress model in the guinea pig has similarly explored the timing specificity of prenatal stress using short periods of daily flashing light as a maternal stress beginning on embryonic day E50 or E60 of the 70-day guinea pig gestation. Although stress beginning at E50 resulted in increased anxiety-like behaviors, elevated basal corticosterone levels, and lower hippocampal GR in adults, stress beginning at E60 failed to produce these outcomes (Kapoor et al., 2008). Overall, these results support epidemiological findings as to the importance of temporal specificity for maternal stress programming of offspring.

POSTNATAL STRESS

Rodent models examining the early postnatal window of brain development have produced a great deal of evidence for the effects of both enhanced and fragmented maternal care producing long-term effects on the developing brain. Meaney et al. have contributed a wealth of information to the field as to the epigenetic programming that occurs in early life related to the quality of maternal care (Hackman et al., 2010; Meaney, 2001). This group characterized a rat model in which dams had either high or low levels of early postnatal maternal care—defined as high or low licking and grooming. In this model, the postnatal interactions of the dam with her litter determined the behaviors of the offspring as adults, in which high licking and grooming offspring showed reduced levels of anxiety-like behaviors and diminished HPA stress axis activity. The epigenetics involved in these outcomes, at least in part, appeared related to the DNA methylation status of the GR in the hippocampus of these offspring. High licking and grooming mothers produced enhanced tactile stimulation of their pups, resulting in increased expression of specific transcription factors during brain development that ultimately dictate expression levels of GR. This is one example, then, of a gene that is epigenetically programmed during early development lasting into adulthood and having a potential impact on shaping offspring stress responsivity.

In contrast to models of stress resilience, chronic postnatal stress can promote cognitive *decline* via functional and structural programming of specific brain regions, including the hippocampus. These studies suggest that the magnitude of stress exposure may determine its long-lasting effects, such that modest postnatal stress may promote resilience, whereas severe or chronic stress may set in motion mechanisms that contribute to stress-related neurodevelopmental disease (Bale et al., 2010). For instance, in a model in which dams are provided

very limited nesting and bedding material as a stressor in the postpartum environment, epigenetic changes were identified within the adult offspring hippocampus where the ability of a transcriptional repressor to bind to the silencing region of the stress gene, CRF, was found, thus altering the ability of these offspring to appropriately respond to and cope during stress experience as adults (Korosi et al., 2010).

Animal models have also examined transgenerational outcomes demonstrating germ cell programming from stress exposure in both the prenatal and postnatal environments. Prenatally, studies in mice have shown that males exposed to stress *in utero* and presenting with increased stress sensitivity themselves as adults, can pass on this phenotype to their male offspring (Morgan and Bale, 2011). In examination of the brain miRNA environment, it was found that there were significant differences in the expression of a number of these noncoding RNAs in these second-generation males, supporting an epigenetic target of maternal stress that was present into the second generation not requiring subsequent re-exposure to the insult. Similarly, in a mouse early postnatal stress model, offspring continued to present with a depressive-like phenotype through three generations, with comparable changes detected in DNA methylation in the germline of these mice (Franklin et al., 2010). These studies showing interactions of the environment with the genome at the level of placing long-lasting epigenetic marks in the chromatin that remain through cell divisions and across generations, support the susceptibility of the germline to external influences that could increase the disease susceptibility in subsequent generations.

MATERNAL INFECTION AND IMMUNE ACTIVATION

Numerous animal models of maternal infection show similar relationships with that reported in epidemiological studies in which maternal immune activation during pregnancy produced offspring endophenotypes associated with neurodevelopmental disorders, including ASD and schizophrenia (Meyer et al., 2011). Such studies have utilized several models, including maternal influenza viral infection, injection of the pathogen mimics Poly I:C and lipopolysaccharide (LPS), and the proinflammatory cytokine IL-6 (Howerton and Bale, 2012). The most consistent phenotype produced in these models is a deficit in offspring pre-pulse inhibition (PPI) in response to an acoustic startle, a change that is reversed by the administration of the antipsychotic drugs haloperidol or clozapine. Sensorimotor gating deficiencies, phenotypes measured by PPI, are commonly associated with schizophrenia, and have also been demonstrated in numerous other psychiatric or affective disorders such as obsessive compulsive disorder, Tourette syndrome, and posttraumatic stress disorder, and thus are highly relevant endophenotypes in which potential epigenetic mechanisms can be explored. Again, highlighting the importance of gestational timing for the impact of fetal insults in producing long-term outcomes, a single administration of the proinflammatory cytokine, IL-6, at mid-gestation in mice was sufficient to produce significant deficits in both PPI and latent inhibition. Maternal immune activation in rodents

using a low dose of LPS during mid-gestation also produced offspring with deficits in PPI, and these offspring also exhibited enlarged ventricles, a hallmark of schizophrenia (Hsiao and Patterson, 2012).

The mechanism and potential epigenetic involvement in maternal immune activation programming of the offspring developing brain is not clear. Certainly, maternal cytokines have direct access to the placenta, the intermediary tissue that serves to protect the developing fetus, and have also been detected in the amniotic fluid following maternal immune challenge (Howerton and Bale, 2012). Therefore, there are likely direct as well as indirect downstream targets of these maternally produced cytokines that are involved in programming changes in the fetal brain. Of note, uteroplacental inflammation is sufficient to produce an increase in expression of apoptotic markers, including caspase-3 and -4 in Purkinje cells of the fetal ovine cerebellum, similar to the Purkinje cell loss reported in ASD and schizophrenia brains (Hsiao and Patterson, 2012). These results suggest that a contributing mechanism for maternal infection to alter brain development involves immune effectors at the level of the placenta. Interestingly, studies in mice and rats have clearly demonstrated that pregnant dams treated with viral “mimics” have reported features of schizophrenia in their offspring, supporting that a replicating virus is not required to transmit these programming outcomes, and that the array of pathogens that may promote inflammatory processes is great.

MATERNAL DIET: LOW PROTEIN AND HIGH FAT

Molecular and phenotypic evidence for programming effects of altered maternal nutrition including protein restriction, high fat diet, and methyl donor supplementation on brain development has been collected from extensive studies in animal models. In general, consequences of maternal dietary manipulations on first generation offspring reflect those observed in humans, although the extent of phenotypes, mechanisms, and sex-specific outcomes vary depending on the diet, timing of exposure, and model organism examined (Bale et al., 2010).

INTRAUTERINE GROWTH RESTRICTION AND LOW PROTEIN MODELS

Rodent models have demonstrated an important link between the maternal nutritional availability and offspring brain development, especially for models of maternal low protein that typically induce an intrauterine growth restriction (IUGR) phenotype (Dunn et al., 2011). In mice, a protein deficient diet throughout pregnancy and lactation produced profound changes in offspring reward-related behaviors as adults in which IUGR mice showed a reduced preference for a palatable sucrose solution and hyperactivity in response to an acute cocaine injection, such reduced reward sensitivity or anhedonia is an endophenotype of affective disorders, including depression and anxiety. These behavioral changes were associated with programming differences in reward circuitry

including increased expression and reduced DNA methylation of the promoter regions of key dopaminergic genes in the ventral tegmental area, prefrontal cortex, and nucleus accumbens (Vucetic et al., 2010). Mechanistically, one of the ways in which protein deficiency may produce changes in the offspring brain is via an intersection with immune activation. For instance, in a rat model of maternal low protein, increased levels of the proinflammatory cytokines TNF α and IL-6 were found in the placenta, again suggesting that common pathways may be involved in programming offspring disease risk.

It is also clear that pregnancy undernutrition is a stressor, and likely elevates maternal stress responsivity. In rats, maternal 50% food restriction during late pregnancy increased maternal plasma corticosterone levels and fetal adrenal weights. Offspring subsequently showed changes in hippocampal GRs and HPA axis sensitivity similar to that reported in maternal stress models (Lesage et al., 2001). Similar results were found in a guinea pig model of maternal nutrient restriction of 48 hours of food deprivation in which both maternal and fetal cortisol levels were elevated during late gestation, and GRs were reduced in the offspring hypothalamus and hippocampus as adults (Lingas et al., 1999).

MATERNAL HIGH-FAT DIET AND OBESITY MODELS

Because the organization of neural circuits controlling energy balance takes shape during perinatal life, considerable attention has focused on the developing hypothalamus, the source of neuroendocrine control, including that of stress regulation. Interestingly, the adipocyte hormone leptin, which is dramatically increased in the obese state, plays a vital role in directing development of hypothalamic projections in and around the arcuate nucleus. Moreover, secretion of leptin both within the fetus and from the placenta during development changes in response to the nutritional environment. Leptin signaling is thus poised to influence the developing brain regarding maternal over- or undernutrition via distinct actions on two functionally divergent neuronal populations, the anorexigenic pro-opiomelanocortin (POMC) and orexigenic neuropeptide Y (NPY) neurons (Bale et al., 2010). Target projections of these neurons include the paraventricular nucleus and the lateral hypothalamus, hypothalamic regions that exert widespread regulatory control over homeostatic functions throughout life. Such studies have perhaps identified specific modes of neurodevelopmental programming whereby the wiring of the hypothalamus is determined through endocrine signals. In addition, mice fed a high-fat diet throughout pregnancy produce offspring with altered DNA methylation patterns in dopaminergic and opioid genes and behaviors, suggesting that an obese maternal environment programs offspring with reward pathway dysregulation that may ultimately influence mood and affect (Li et al., 2010).

As mentioned, there is convincing evidence for a likely intersection between maternal dietary challenges and immune activation. In both rodents and nonhuman primates, studies have demonstrated increased inflammatory processes in important brain regions in offspring born to mothers on a

high-fat or obesogenic diets. Rat offspring from a dam fed a high-saturated fat diet during pregnancy showed significant levels of activated microglia in their hippocampus at birth that remained high throughout life, consistent with an increased basal neuroinflammatory tone (Bilbo and Tsang, 2010). These offspring also displayed increased anxiety-like behaviors and reduced performance ability in a spatial learning and memory task, supporting a likely contribution of local immune factors such as proinflammatory cytokines in disrupting normal brain function and stress processing. Further, in the nonhuman primate, offspring from macaque mothers fed a high fat diet for four years before pregnancy showed substantial increases in proinflammatory cytokines and activated microglia in their hypothalamus during the third trimester (Grayson et al., 2010). Female offspring in these studies also demonstrated high levels of social anxiety and fear of novelty as infants (Sullivan et al., 2010). Results from these studies support a potential link between maternal nutritional intake throughout pregnancy and increased neuroinflammation in the developing brain and long-term changes in behaviors relevant to neurodevelopmental disease.

Epigenetic mechanisms, which exert lasting effects on gene expression and can be heritable, are a particularly intriguing target when examining links between the perinatal nutritional environment and offspring metabolic phenotype. For example, foods high in choline cause marked changes in DNA methylation, which, in turn, alter long-term gene expression. Studies have demonstrated that choline deficiency during pregnancy produced alterations in histone methylation and subsequent changes in gene expression in mice (Bale et al., 2010). Pregnant dams fed choline-deficient diets during late gestation produced offspring with diminished progenitor cell proliferation and increased fetal hippocampus apoptosis, altered hippocampal angiogenesis, insensitivity to long-term potentiation as adults and decreased visual-spatial and auditory memory. These changes in fetal brain development were associated with epigenetic alterations in DNA and histone methylation in the fetal hippocampus. Similarly, studies using changes in mouse coat color as a marker of dietary and nutrient influence on epigenetic regulation of the *agouti* locus demonstrated how relatively minor changes in DNA methylation can produce a profound phenotypic impact (Waterland, 2003). Such studies support the ultimate mechanistic impact for minor dietary and nutritional fluctuations during key points in development.

FETAL SEX AS A FACTOR IN EPIGENETIC PROGRAMMING

Epidemiological studies linking fetal antecedents with long-term disease risk have established gender as an important determinant in disease severity and onset. As an example, pregnant mothers exposed during their second trimester to the stress of the 1940 invasion of The Netherlands had male, but not female, offspring with an increased risk of schizophrenia (van Os and Selten, 1998). Further, many neurodevelopmental disorders have a strong sex bias, including ASD with an overall sex ratio of 4.3:1 for boys-to-girls (as reviewed in

Newschaffer et al., 2007). However, when further separated for cognitive impairment, this bias was even further increased for ASD without mental retardation to 5.5:1, suggesting that distinct underlying mechanisms or predisposing factors may be involved. As exposure to maternal stress before 32 weeks' gestation has been suggested as a potential contributing factor to ASD (Beverdorf et al., 2005), understanding the role sex plays in the specificity of response to stress during development may provide unique insight as to disease etiology. A recent report detected a significant effect of maternal depression during pregnancy on offspring postnatal anxiety development, particularly in males (Gerardin et al., 2010). These studies support both a sex- and temporal-specificity in the association between maternal stress and offspring disease. Although there are many factors that likely contribute to sex differences in disease predisposition, sex-specific responses to fetal antecedents occurring during sensitive windows of development may promote long-term programming effects that underlie such disease biases. Along these lines, structural brain volume analyses using functional magnetic resonance imaging (fMRI) in male and female patients with schizophrenia have confirmed a disruption of the normal sexual dimorphism of the brain, including the dimorphic ratio of orbitofrontal cortex to amygdala where male schizophrenic patients showed a phenotypically more female pattern in these brain regions (Bale et al., 2010).

The brain develops in the face of combined and opposing forces of resiliency and vulnerability. The central factors important in resilience, ongoing neurogenesis, migration, myelination, differentiation, and synaptogenesis are the same processes subject to derailment, which can promote lasting consequences. The complex interplay of genetics, early experience, and later environment underlies the weak but consistent heritability of numerous neurodevelopmental disorders. The developing brain is organized by developmental hormone exposure, with males experiencing elevated testosterone levels during normal testes development. Aromatization of this testosterone to estradiol in the brain drives masculinization, an active process affecting cell differentiation and connectivity in the brain. Estrogenic involvement in cell death and cell birth in the developing nervous system is a critical component in programming the sexually dimorphic brain (McCarthy et al., 2009). The variety of mechanisms evoked by estradiol during development provides numerous avenues for disruption of the active process of masculinization. Programming of important regulatory brain regions, such as the neuroendocrine hypothalamus, via steroid hormone effects on cell migration patterns during early development may also contribute to sex differences in disease susceptibility (Bale et al., 2010).

In rodent models, studies have taken advantage of the ability to manipulate the early postnatal critical window to examine the organizational effects on long-term stress responsivity, resulting in an established sex difference in stress responsivity in adult mammals. Similar to outcomes reported with prenatal stress exposure, hippocampal GR expression was altered in female offspring masculinized at birth by a single injection of testosterone, supporting the importance of the male testosterone surge in normal wiring of these pathways (Bale, 2011). In addition, the early postnatal period is a sensitive window

during which hormonal exposure produces organizational effects on maturation of the serotonin system, potentially leading to long-term changes in adult stress sensitivity. In addition to the early critical period of programming, the rise in testosterone beginning in puberty exerts modulatory actions on neurotransmitter systems critical in regulation of stress physiology and coping. Such systems affected included serotonergic and γ -aminobutyric acid (GABA)-ergic (Bitran et al., 1993). Therefore, the coordinated impact of masculinization at both time periods may interact with components of sex chromosomes to orchestrate a complete "normal" male phenotype. Neuropsychiatric disease predisposition may then involve a mismatch between brain organizational programming and activational hormones.

Similar to models of maternal stress, there is also evidence to support that offspring programming responses to maternal immune activation are also sex dependent. For example, male offspring of pregnant rats challenged with LPS late in gestation showed significant deficits in PPI, whereas females were unaffected by this insult (Howerton and Bale, 2012). Similarly, male but not female mice exposed during late gestation to the viral mimic Poly I:C displayed behavioral and cognitive inflexibility, key negative symptoms in schizophrenia. These sex-dependent programming effects were associated with significant reductions in glutamate content in the prefrontal cortex in the males exposed to the prenatal immune activation (Meyer et al., 2011).

Little is currently understood regarding how offspring sex may influence the epigenetic response to a changing maternal environment. It is likely that sex-specific responses to fetal antecedents during sensitive windows of development contribute to these differences. Studies in animal models of prenatal stress have begun providing interesting clues as to the timing and mechanisms involved in how perturbations in the maternal milieu may have sex specificity in their effects on the developing brain (Bale et al., 2010). The disruption of sex-dependent processes is a common theme in the prenatal stress literature. Sex differences in neurodevelopment are the result of both genetic sex and circulating gonadal hormones. One of the first papers modeling prenatal stress in rats found that chronic restraint during the final week of gestation disrupted male sex behavior (Ward, 1972). Late gestational restraint stress has also been shown to disrupt the organizational perinatal testosterone surge, reduce adult testis size, shorten anogenital distance, and block the differentiation of sexually dimorphic brain nuclei in males (Bale, 2011). Similarly, male mice exposed to maternal stress during early gestation have reduced testis size and testosterone levels and a shortened anogenital distance as adults, supporting a disruption in their normal masculinization. Such outcomes demonstrate potential sex-specific mechanisms for changes in the programming of the sexually dimorphic brain despite a shared intrauterine environment.

There are many epigenetic mechanisms by which estrogen promotes and drives sex differences in the developing brain. During the critical window of brain sexually dimorphic brain programming, estradiol can broadly act to alter DNA methylation patterns, including that of its own estrogen receptor alpha (ER α), effectively shaping the landscape to be more or less

responsive to the hormonal status of the animal (McCarthy et al., 2009). One mechanism by which estrogen is thought to modulate methylation is through its effects on DNMT gene expression and activity levels. These effects are brain region specific, providing yet another level of control for sex differences to progress and ultimately affect systems outcomes such as stress responsiveness. Estradiol can also directly alter histone modifications, including actions on histone deacetylases (HDACs) (McCarthy et al., 2009). A single postnatal administration of an HDAC inhibitor in males during the critical window disrupted programming of the sexually dimorphic BNST, a brain region important in stress neurocircuitry. In addition, the broad epigenetic programming effect of estrogen has been shown for dramatic shifts in the miRNA environment in the developing brain. In the early postnatal mouse brain, males and females have significant differences in expression patterns of the 250 most abundant miRNAs. These sex differences were dependent on the conversion of testosterone to estradiol in males, as a single administration of an aromatase inhibitor on postnatal day 1 completely shifted the normal male pattern to that of females (Morgan and Bale, 2011). These studies provide substantial evidence for epigenetic mechanisms for steroid hormones to impact neurodevelopment, producing dramatic and important sex differences. However, these mechanisms are also vulnerable to perturbations in the environment, shifting “normal” developmental patterns and trajectories. As described, maternal stress and infection have both been associated with dysmasculinizing phenotypes, suggesting that a disruption at

some level in male sexual differentiation or gonadal development occurs that alters testosterone production during the organizational period.

INTRICACIES OF THE PLACENTAL CONTRIBUTION TO FETAL PROGRAMMING

The developing placenta is an intriguing candidate tissue for mechanistic examination of epigenetic programming, as it is a rapidly developing and sex-specific endocrine tissue that continues to respond to the dynamic maternal milieu throughout pregnancy. The placenta serves as the critical messenger between the maternal and embryonic compartments, and therefore is poised to be influenced by perturbations occurring in pregnancy by a number of mechanisms, including alterations in: (1) nutrient and oxygen transport, (2) inflammatory responses, and (3) epigenetic programming (Bale et al., 2010) (Fig. 72.1). Tight control of placental and embryonic epigenetic machinery is critical during gestation when a wave of genome demethylation before *de novo* re-methylation by DNA methyltransferases, establishment of imprints, and sex determination occurs, identifying novel targets as highly vulnerable to maternal disturbances that could result in embryonic reprogramming. For instance, inflammatory cytokines can directly affect levels and activity of DNA methyltransferases (DNMT), as well as regulate placental receptors and transporters for

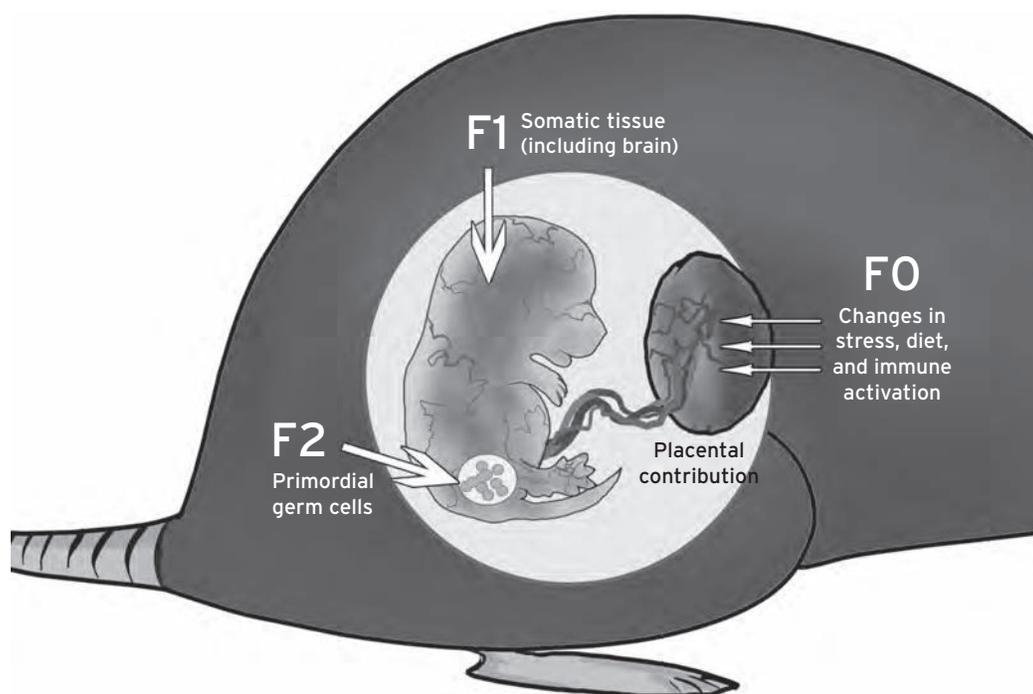

Figure 72.1 Intersection of prenatal insult and developmental timing to program tissue targets and affect subsequent generations. Information regarding maternal stress, infection, or diet perturbations, in the form of changes in hormonal milieu, is transmitted from the maternal compartment to the fetal compartment via the placenta. The dynamic process and trajectory of fetal development provides a temporal specificity for responses to fetal antecedents. Acute programming of somatic tissues can lead to changes in long-term health outcomes in the first generation. In addition, the primordial germ cells, which contribute genetic and epigenetic information to the second generation, are also present and can undergo reprogramming during embryonic development. Thus, a truly “transgenerational epigenetic” mark must be present into a third generation. In addition, embryo sex plays an important role in determining how an insult may become part of the epigenome and passed on to future generations.

folate, an important methyl donor shown to regulate levels of methylation of non-imprinted genes during pregnancy, thus shifting more broadly the epigenetic landscape (Bale, 2011).

Evidence from animal models of maternal stress supports an important regulatory role of the placenta in mediating effects between the maternal and fetal compartments. In early prenatal stress studies, a sex-specific effect of stress on placental epigenetic machinery was shown in which maternal stress increased expression of DNMT1 and the methyl binding protein, MeCP2, in males (Bale, 2011). Previous studies in mice have reported that regulation of placental methylation patterns is predictive of similar embryonic changes critical in neurodevelopment. Recent studies examining early life stress found similar changes for MeCP2 expression and methylation in the brains of first- and second-generation stressed mice (Bale, 2011). Further, maternal stress in mice has reported significant increases in the expression of genes important in growth and development including PPAR α , IGFBP-1, GLUT4, and HIF3 α in male but not female placentas (Bale et al., 2010). Mechanistically, the link between maternal stress and changes in placental gene expression may involve direct or indirect actions of stress hormones. As an example, stress-induced glucocorticoids increase expression of PPAR α , and PPAR α in turn drives expression of IGFBP-1, suggesting one mechanism whereby maternal stress could directly affect placental gene expression patterns directly relevant to embryo development. In addition, reductions in growth factors have been linked to affective and neurodevelopmental disorders, and IGFBP-1 is known to down-regulate genes involved in embryonic growth. Thus, as one example these studies suggest that an elevation in placental IGFBP-1 with a consequent decrease in available growth factors during critical developmental periods could impart a sex-specific effect on male fetal programming. Alterations in oxygen and nutrient availability have also been associated with inflammation, and there is an established association between placental inflammatory events and an increased risk for affective disorders, schizophrenia, and autism (Bale et al., 2010). How these placental outcomes are sex dependent remains unknown, but may be related to a protective or buffering mechanism of genes on the X chromosome. Because X inactivation occurs to a much lesser extent in the placenta, increased gene dosage in female placentas could underlie an altered response to the changing maternal environment.

The ability for maternal stress hormones (cortisol or corticosterone) to gain access to and affect fetal brain development is highly dependent on placental levels of 11 β -hydroxysteroid dehydrogenase-2 (11 β -HSD2), the placental barrier enzyme that converts glucocorticoids to their inactive metabolite. At the interface of the maternal:fetal circulation is the syncytiotrophoblastic cells that express high levels of 11 β -HSD2, and function to exclude the majority of maternal active glucocorticoids before they reach the fetal compartment. Typically, in early-mid gestation, fetal blood has greater than 10-fold lower cortisol levels than maternal blood (O'Donnell et al., 2009). Environmental perturbations that would serve to decrease 11 β -HSD2 expression could then expose the fetus to higher levels of active glucocorticoids. Such evidence has been reported in animal models in which pharmacological

blockade of 11 β -HSD2 was administered during pregnancy and resulted in significant increases in glucocorticoid receptors in the amygdala of the offspring as adults (Holmes et al., 2006). Genetic disruption of placental/fetal 11 β -HSD2 to reduce its expression was also found to produce offspring with higher levels of anxiety-like behaviors. Perturbations in maternal diet are also known to affect placental 11 β -HSD2 where a low protein diet during pregnancy significantly decreased its activity, supporting again a link between nutritionally deficiencies and stress axis changes (O'Donnell et al., 2009).

Fetal antecedents such as high fat diet or obesity and maternal stress have also been associated with increases in placental inflammation (O'Donnell et al., 2009; Frias et al., 2011). Cytokine production in the placenta can increase markers of immune activation in the developing fetus or disrupt overall placental function, producing long-term programming changes in the offspring. In macaques, maternal high-fat diet increased placental inflammatory cytokines and expression of Toll-like receptor-4 (Frias et al., 2011). Similarly, high-fat diets in rodents during pregnancy have also shown significant increases in placental inflammatory cytokines, supporting a change in appropriate placental function in response to an unhealthy environment. Timing of these effects is also important in predicting outcomes. For instance, maternal immune activation during early gestation can result in a failure for implantation to occur, whereas mid-gestation inflammation in the placenta has been linked to schizophrenia and ASD-like phenotypes (Hsiao and Patterson, 2012).

Critical epigenetic processes occur within the placenta as part of the regulation for normal development and function, and disruptions in programmatic changes in the chromatin have been linked to increased disease risk for the offspring (Hsiao and Patterson, 2012). Chromatin remodeling complexes and DNA methyltransferases (DNMTs) are necessary for epigenetic reprogramming that occurs in pre-implantation development. This highly regulated process produces competent embryos and the trophoblastic cells of the placenta. The same epigenetic marks found in fetal tissue including DNA methylation, miRNAs, and histone modifications have also been reported in placental tissue. Studies have established unique roles for DNMT isoforms during pre-implantation in the placenta to maintain uniform methylation imprints in all embryonic and extraembryonic cells, including the placenta (Ackerman et al., 2012). Recent studies have identified miRNAs that are specific to the placenta, where their expression pattern appears to dynamically change across pregnancy in humans and rodents. As these miRNAs are also released from the placenta and are detectable in the maternal serum encased in microvesicles, there is potential to classify them as biomarkers of placental function. The necessity of miRNA expression in placental development has been established, in which mice deficient in the Argonaute-2 gene, a protein component of the RNA-induced silencing complex (RISC), show abnormal placenta function resulting in embryonic lethality (Ackerman et al., 2012). The placental miRNA environment also appears to be susceptible to perturbations resulting from such insults as hypoxia, immune activation, and dietary challenges, supporting a likely role for miRNAs in programmatic changes that are poised to alter fetal development.

CONCLUSIONS

In examination of the epigenetic mechanisms that may contribute to neurodevelopmental disease risk, the necessity for and value in studies using valid animal models in which variables such as environmental conditions, temporal specificity, and offspring sex can be evaluated. The transmission of epigenetic marks to future generations through reprogramming of the germ cells adds to the complexity in establishing causal links between disease presentation and fetal antecedents in clinical and epidemiological studies. In looking at offspring phenotypic changes, it is clear that although some phenotypes terminate with the first generation, others will be transmitted across multiple generations (Dunn et al., 2011). The degree to which there is true transgenerational “epigenetic” involvement in a given end point is determined by the ability for that mark to be erased and re-established outside of a re-exposure or continuation of the insult. Further, the sex-specificity of transgenerational epigenetic programming requires examination at both the level of transmission of an effect as well as the inheritance of it. In other words, can both mom and dad pass on the trait? And do both male and female offspring inherit it? Maternal exposure

to aversive environments such as maternal stress, infection, or obesity results in a variety of phenotypes that have different transmission characteristics as they pass through the generations. Information about maternal experience, in the form of changes in hormonal milieu, can be transmitted via the placenta to the fetal compartment producing a direct action on the developing embryo (Dunn et al., 2011) (see Fig. 72.1).

In addition to ascertaining the transmission and generational passage of epigenetic marks, understanding the cell type specificity and involvement is also helpful in determining in what tissue an effect might occur as windows of developmental vulnerability to environmental challenges may be tissue specific (Fig. 72.2). Somatic tissues may be acutely programmed, leading to changes in health outcomes in the first generation. However, if prenatal insults do not directly affect the germline, the phenotype will terminate with this generation. Phenotypes that persist through the second generation but not a third may relate to the programming of the primordial germ cells during the initial maternal insult, and acquired transient epigenetic marks only capable of passing through a single generation. Thus, transmission of an epigenetic trait does not demonstrate a fully integrated, transgenerational

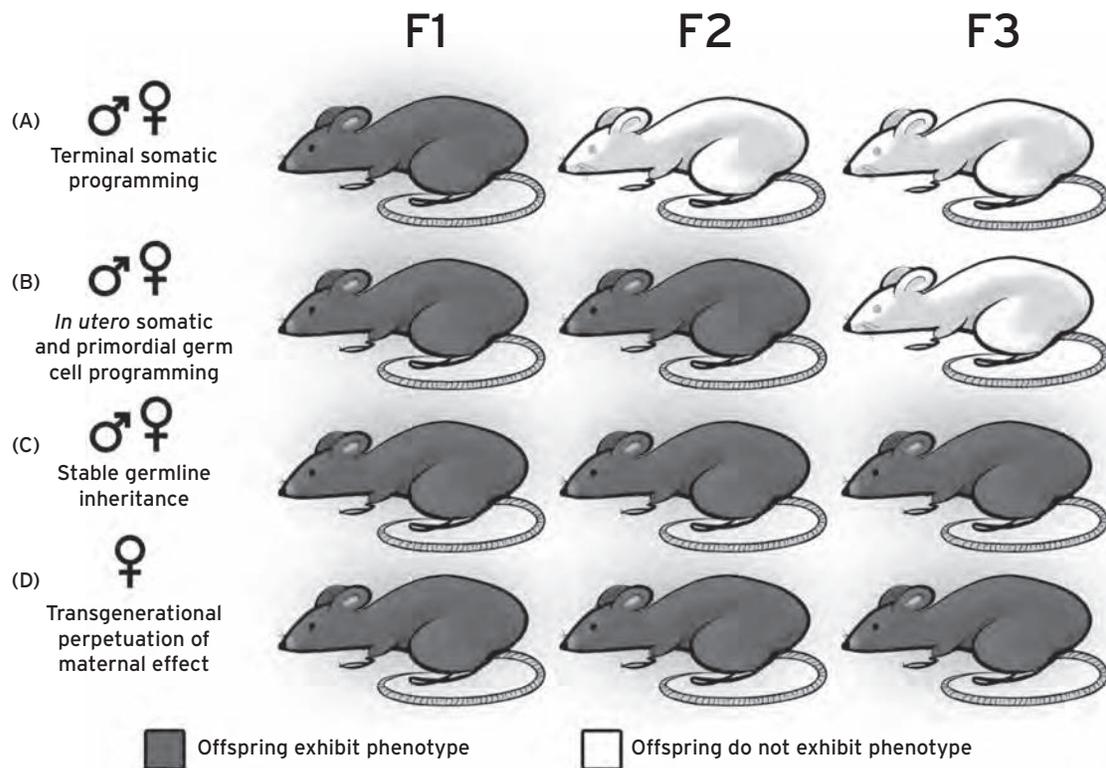

Figure 72.2 Modes of transgenerational epigenetic transmission. Several mechanisms for transgenerational epigenetic transmission are possible, as exemplified here in dark gray. Dark gray mice represent a changed phenotype, whereas white mice represent the “normal” end point, indicating that the phenotype has not been transmitted to that generation. The sex symbols at left indicate the maternal or paternal lineage capable of transmitting phenotypes in the indicated manner. (A) In utero somatic programming may acutely affect tissue and brain development in the fetus, initiating a developmental trajectory that results in an adult phenotype that is not transmitted into the next generation. (B) In addition to in utero somatic programming, changes in the maternal environment can acutely program primordial germ cells, resulting in transmission of the phenotype into the second generation. In this scenario, germ cells must be directly exposed to a maternal insult. (C) In utero exposure is sufficient to stably alter the germline of offspring, resulting in many generations of transmission without the need for re-exposure to the original maternal insult. (D) Transgenerational phenotypes may occur through a maternal effect wherein programming during gestation or through exposure to altered maternal behavior results in an adult phenotype in female offspring. The presence of this phenotype during pregnancy in the mother can in turn acutely program the next generation, perpetuating the transgenerational trait.

germline-based mechanism until it reaches the third generation. However, if stable inheritance is only observed through the female line it may be caused by the presence of a maternal behavioral or uterine effect. Examination of transgenerational transmission through the paternal line avoids many of these confounding variables.

Our understanding of the mechanisms contributing to transgenerational epigenetic programming by fetal antecedents such as maternal stress and diet is likely to dramatically increase in the next decade. Prospective epidemiological studies are underway that will utilize banked tissue samples from birth cohorts to identify potential biomarkers predictive of disease. Such insight will no doubt yield great advances in disease etiology and provide novel targets and therapies in disease prevention and treatment. Studies examining effects across the maternal, placental, and embryonic compartments will be able to identify temporal and sex-specific markers that may provide our greatest insight into both direct and indirect gene targets. Necessary in this pursuit is the dissection of the complex role sex plays on both sides of the proverbial epigenetic coin for the transmission as well as the inheritance of given traits.

73 | ANIMAL MODELS IN PSYCHIATRIC DISORDERS OF CHILDHOOD ONSET

RICHARD PAYLOR, ALEXIA M. THOMAS, SURABI VEERARAGAVAN,
AND SHANNON M. HAMILTON

Research conducted to elucidate the mechanisms underlying psychiatric disorders occurs with greater flexibility of manipulation using animal models. This is particularly true with childhood disorders, in which human samples available to researchers are not only limited, but there are also ethical considerations regarding the ability of children to provide informed consent. Cellular and *in vitro* assays and computer-based models offer alternative strategies to elucidate mechanisms underlying cellular processes. However, it must be considered that many neurological disorders are characterized by complex alterations in behavior that are likely the culmination of multiple pathways and networks spanning the brain. Therefore, it is important to bear in mind that studies of these behavioral components may be best modeled at the whole organismal level.

How are animal models designed or chosen to represent complex human psychiatric disorders? For those disorders in which the etiology is known, models can be more easily constructed; for example, by genetic perturbation or chemical/environmental insult based on the known etiology. Unfortunately, for many disorders little is known regarding the underlying pathology, and other methods must be used to choose suitable models for study. In these cases a model is often chosen based on its ability to mimic the human condition phenotypically. For psychiatric disorders this relies heavily on characterization of rodent behavior. At present there are many tools available to investigate rodent behaviors that span multiple behavioral domains, as indicated in Table 73.1. However, it must be kept in mind that behaviors in rodent models are likely not completely analogous to human behavior.

Regardless of how a model is created, each one must meet certain criteria to be considered relevant for the study of a particular disorder. Currently, the accepted standard in ascertaining the appropriateness of a model is how well it conforms to three criteria: face validity, construct validity, and predictive validity.

A model with face validity is one in which the characteristics observed in that model parallel those made in humans with the disorder. These characteristics may be at the molecular, cellular, or behavioral level. Construct validity requires that a model recapitulate known etiological factors of the disease (e.g., genetic or environmental). Genetic studies, including gene association and linkage studies, have implicated genes for particular disorders that can then be targeted for investigation

using transgenic animal models. Predictive validity refers to the expectation that one will be able to make predictions about the human condition based on the animal model. For example, pharmacological treatments effectively implemented in human patients would be expected to demonstrate similar effectiveness in a proposed animal model. In order to increase confidence in evaluating the potential effectiveness of novel therapies in human patients, it is important to have already established predictive validity in the model.

Although models that fit all three validity criteria are favored over those that meet only one or two, critical insights into behavioral pathways may still be made for those models not meeting full validation status. This is important considering that many psychiatric conditions have no known cause.

This chapter highlights the major animal models currently employed in the research of childhood-onset psychiatric disorders.

AUTISM SPECTRUM DISORDERS

MODELING AUTISM SPECTRUM DISORDERS IN ANIMALS

Modeling autism spectrum disorders (ASDs) in animals is challenging on several counts. (1) Autism spectrum disorder is defined by human behaviors. These include a number of diagnostic criteria, particularly in the domains of social interaction and social communication behavior, which are uniquely human. Additionally, behavioral traits exhibited across the ASD spectrum are highly variable both in terms of the presence (number and type) of traits individuals exhibit and the magnitude of each trait's expression. (2) The majority of instances of ASD remain idiopathic. Known genetic causes of ASD are highly complex with no single insult likely contributing to more than approximately 2% of all ASD cases and most contributing to less than 0.005%. Even for instances in which a genetic insult can be identified, the underlying pathology remains undiscovered. Thus, there are currently no biomarkers available for validating any animal model of ASD.

Despite these difficulties, significant progress has been made in identifying behaviors and pathologies relevant to ASD that are assayable in animals, particularly in rodent models. Because the majority of these models are rodent, that is this section's focus. Many behavioral assays have been proposed

TABLE 73.1. Common behavior tests used to characterize rodent models of childhood onset psychiatric disorders

BEHAVIOR TEST	DESCRIPTION
ANXIETY/FEAR	
Active/Passive Avoidance	Measures the avoidance of an area where a foot shock was given. Passive avoidance required the mouse to not enter the area where the foot shock was presented. Active avoidance requires the mouse to exit the area where the foot shock was presented upon a cue
Contextual Fear Conditioning	Measures the amount of freezing when placed in an environment where a previous negative stimulus (foot shock) was given
Elevated Plus Maze	Measures time spent in the open arm versus protected arm of a cross-shaped arena
Elevated Zero Maze	Measures time spent in the open area versus protected area of a circular arena
Light Dark Emergence	Measures latency to emerge from the dark chamber to the light chamber. Also measure total time spent in light and dark chambers, and activity levels in these chambers
Open Field	Measures time spent in the center of the open field arena versus the perimeter or corners of the arena
Reward/Aversion	Measures the latency to obtain a reward in the presence of an aversive stimulus (ex. predator urine, brightly lit novel arena)
REPETITIVE/STEREOTYPICAL BEHAVIORS	
Marble Burying	Measures the number of marbles buried as a result of compulsive digging or shifting in bedding
Non-nutritive Chewing	Measures amount of chewing of non-nutritive clay or substances
Repetitive Grooming	Measures number of grooming sessions and total time spent grooming in a 24-hour period. Also measures time spent grooming relative to other adaptive behaviors (eating, sleeping)
DEPRESSION	
Learned Helplessness	Measures latency to escape a foot shock after repetitive training with foot shock in an inescapable chamber
Porsolt Forced Swim	Measures the time spent in vigorous swimming relative to the time spent floating in a tall cylinder filled with water
Tail Suspension	Measures the time spent struggling relative to the time spent immobile when suspended by the tail
LEARNING AND MEMORY	
Barnes Maze	Measures the ability to learn the location of an escape hole in a circular maze with 18 evenly spaced holes using spatial environmental cues
Morris Water Maze	Measures the ability to learn the location of a hidden platform using extra-maze spatial environmental cues
Radial Arm	Measures the number of entries into one of eight arms that are baited with food or water using spatial environmental cues; may tap into cognitive preservation
T-Maze/Y-Maze	Measures the correct initial entry into an alternating arm of the maze baited with food or water using spatial environmental cues; may tap into cognitive preservation
SOCIAL PARADIGMS	
Nest Building	Evaluates size and organization of nest building; may also assess procedural cognitive function
Pairing in Novel Environment	Measures amount of social approach of two mice paired in a novel environment
Resident Intruder	Measures amount of social approach when an intruder mouse is introduced into the home cage of the test mouse following social isolation
Social Approach-Partitioned	Measures amount of time spent near the partition dividing the test mouse from either a stranger or known mouse
Social Approach-Three Chamber	Measures amount of time spent in an empty chamber versus a chamber containing a stranger mouse. Second trial measures the time spent in the chamber with a known mouse versus a stranger mouse versus an empty chamber
Social Recognition	Measures the amount of social interaction between the test mouse and a second mouse on the first and subsequent exposures
Ultrasonic Vocalization-Adults	Measures the number and duration of ultrasonic vocalizations of male mice exposed to female mice in estrous OR male mice during a resident intruder test
Ultrasonic Vocalization- Neonates	Measures the number and duration of ultrasonic vocalizations of pups during brief isolation from the dam and/or littermates

(continued)

TABLE 73.1. (Continued)

BEHAVIOR TEST	DESCRIPTION
OTHER	
Delayed Reinforcement	Measures the ability to wait for a preferred reinforcer (ex. water) over the immediately available less-preferred reinforce (ex. quinine). The time for the preferred reinforcer increases with each trial.
Reaction-Time Task	Measures the number of nose poke entries to receive a reward during a cued time period
Home Cage Activity	Measures the amount of total, horizontal, and vertical activity in a home cage environment to test for habituation
Latent Inhibition	Measures the impaired performance during an active avoidance task when test training includes exposure to the cued stimulus but without any reinforcement contingencies
Open Field Activity	Measures the amount of total, horizontal, and vertical activity in a novel environment; other activities including stereotypic or repetitive patterns of movement can also be assessed
Pre-pulse Inhibition/ Sensory Motor Gating	Measures the inhibition of a reflexive acoustic startle response to be inhibited when weaker stimuli are presented before the startle stimulus
Acoustic Startle	Measures the startle response to a loud auditory stimulus
Hot Plate	Measures the latency to respond to a heated plate as an index of thermal sensitivity
Von Frey Hairs	Measures a withdrawal response from mechanical stimulation to determine a tactile detection threshold
Running Wheels	Measures the amount and duration of activity in a 24-hour period. Manipulation of light and dark cycles can allow for measuring circadian rhythm based on activity patterns over several months

(Adapted from Robertson H.R., Feng G. (2011) Annual research review: transgenic mouse models of childhood-onset psychiatric disorders. *J. Child Psychol. Psychiatry*, 52(4):442–475.)

and utilized for characterizing ASD models, particularly assays in the social, repetitive, and other domains listed in Fig. 73.1. Based on assessment of ASD phenotypes in both humans and mice with disruptions in ASD genes, defined groups of changes have been identified leading researchers to stress that five levels of analysis should be considered when investigating or reviewing mouse ASD models: (1) molecular assays, (2) nervous system morphology, (3) electrophysiological assays, (4) neurological assays, and (5) higher-order behavioral assays (Buxbaum et al., 2012).

Current mouse models for ASD can be divided into three general groups of (1) genetic models—based on genes believed to contribute to ASD, (2) environmental models—based on environmental or pharmacological insults that have been linked to ASD, and (3) behavioral models—based on engineered or naturally occurring animal models whose behaviors appear to parallel core features present in human ASD. Although the study of behavioral models will undoubtedly lead to a better understanding of biological mechanisms underlying specific phenotypes, this discussion focuses on construct validity-based models.

CANDIDATE-GENE-BASED MODELS FOR AUTISM SPECTRUM DISORDERS

A number of synaptic genes have been implicated in ASD (Betancur, 2011). For instance, some of the earliest gene candidate models for ASD, based on identification of single gene disruptions in humans, include models in which the postsynaptic neuroligin (NLGN) and presynaptic neurexin (NRXN) families of cell adhesion proteins have been disrupted, including NLGN1, NLGN3, NLGN4X, and NRXN1 (Betancur

et al., 2009). The most well-studied NLGN model is a NLGN3 knockin mouse replicating a human point mutation. Variable behaviors were identified by different groups. Autism spectrum disorder-like phenotypes of impaired social interactions and altered synaptic transmission (enhanced inhibitory transmission) were observed by one group, whereas a second group failed to observe any social deficits, but did observe decreased pup USVs (Betancur et al., 2009; Robertson and Feng, 2011). Neither group observed deficits in repetitive behaviors. NLGN3 and NLGN4 KO mice showed impairments in domains of social and communication behaviors, but not repetitive behaviors, whereas NLGN1 and NRXN1 KO mice showed elevated repetitive grooming behavior. They also, respectively, showed synaptic alterations of impaired hippocampal LTP and hippocampal excitatory transmission (Robertson and Feng, 2011).

The shank family of proteins, particularly SHANK3, which operate in the postsynaptic density as intracellular binding partners of NLGNs, have also been implicated in ASD, as well as schizophrenia. Although SHANK3 KO mice have shown mild autism-like phenotypes, SHANK2 KO mice exhibited ionotropic glutamate receptor up-regulation, fewer dendritic spines, decreased basal synaptic transmission, and altered excitatory currents. Behaviorally they exhibited ASD-like abnormalities in social behaviors, vocalization, and increased repetitive behaviors. Of clinical relevance, the authors identified that social and vocalization changes were caused by alterations in synaptic glutamate receptor expression, suggesting that ASD therapies might benefit from a better understanding of underlying synaptopathic phenotypes (Schmeisser et al., 2012). Additionally, the gene *Shank3* is included in the deletion region identified in 22q13.3 deletion syndrome (Phelan-McDermid syndrome) and is thought to be major causative factor; thus, SHANK KO

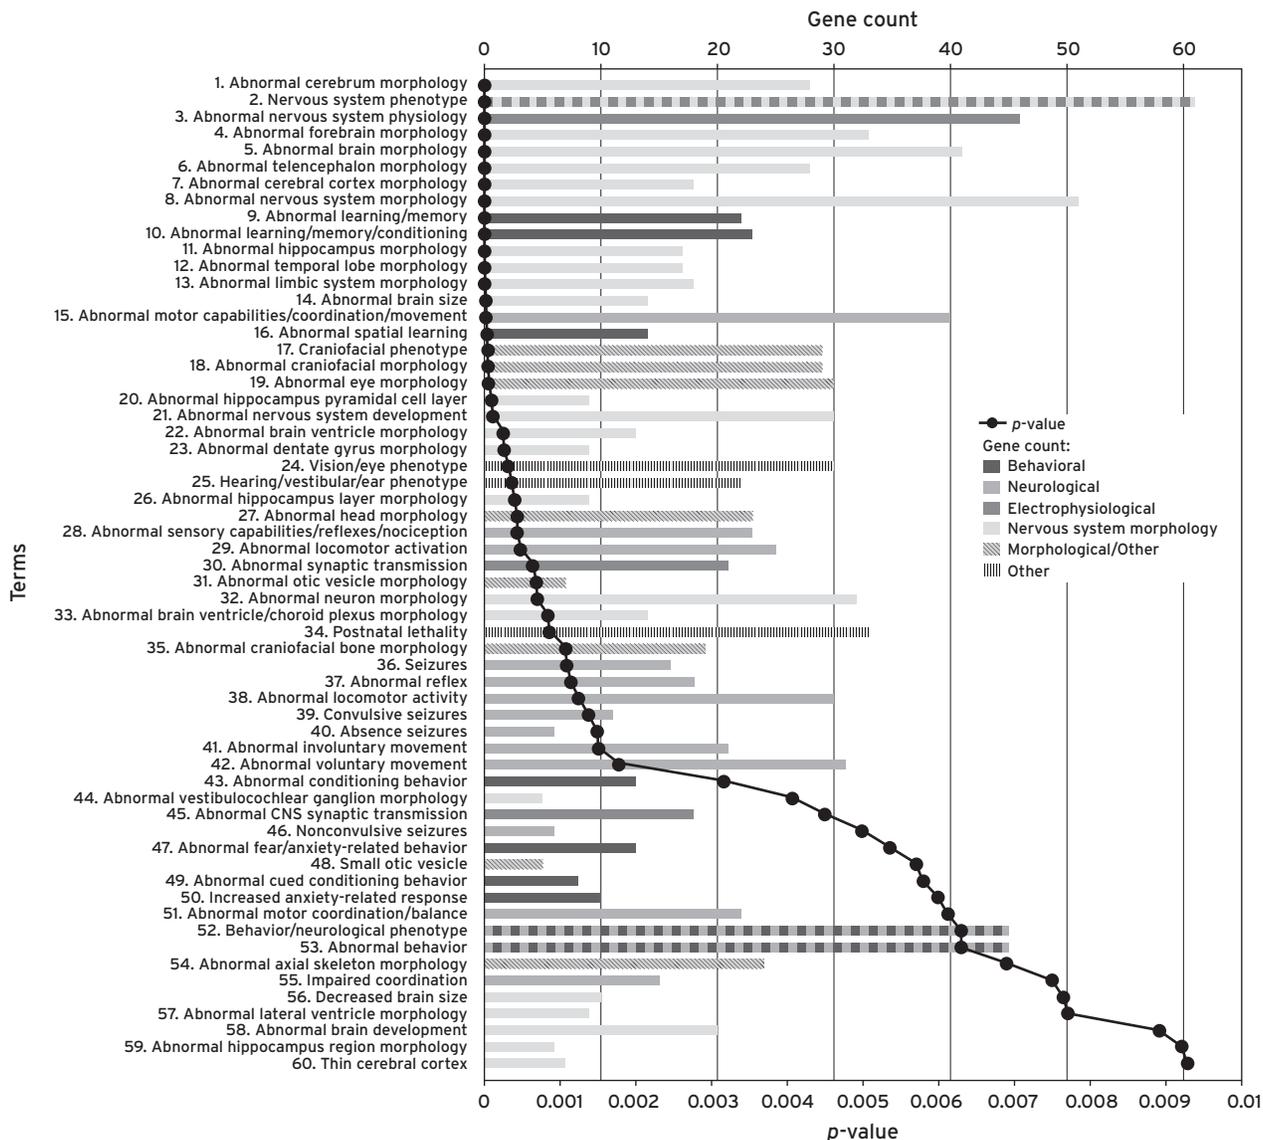

Figure 73.1 Mouse phenotype categories associated with ASD genes. ASD genes (N = 112) were analyzed for enrichment in mouse phenotypes using ToppGene with a Bonferroni corrected p value cutoff of 0.01. Categories are arranged from most significant and downwards (purple line), and for each category, the number of genes in the ASD112 list for which there were murine models with the associated category are indicated by the length of the horizontal bars (gene count). To highlight differing phenotypic categories, bars are color-coded as indicated in the inset to the figure. Categories relating to nervous system morphology phenotype domains are colored light blue, whereas other morphological categories are colored dark blue, electrophysiological categories are colored pink, neurological categories are colored peach, and higher-order behavioral categories are colored green. Categories corresponding to more than one phenotyping domain are presented as alternating colors, and categories that do not relate to the phenotyping scheme are colored yellow. (Adapted from Buxbaum J.D., Betancur C., Bozdagi O., et al. (2012) Optimizing the phenotyping of rodent ASD models: enrichment analysis of mouse and human neurobiological phenotypes associated with high-risk autism genes identifies morphological, electrophysiological, neurological, and behavioral features. *Mol. Autism*, 3(1):1. (See color insert).

models may provide useful insights into this neurodevelopmental disorder.

TUBEROUS SCLEROSIS COMPLEX

Approximately 1% of children with ASD have tuberous sclerosis complex (TSC). Although full knockout of the *Tsc1* gene in mice leads to limited viability, heterozygous loss of *Tsc1* or *Tsc2* in mice results in TSC-like behaviors, including several related to ASD, specifically impaired learning and memory, social behaviors, and pup vocalizations, as well as disrupted

synaptic plasticity (Khwaja and Sahin, 2011). However, despite the relevant behavioral abnormalities, the hallmark anatomic abnormalities of TSC are not present in these mouse models. Through *in vitro* as well as mouse model-based studies, the mammalian target of rapamycin (mTOR) pathway has been strongly implicated in both TSC and PTEN-related disorders. *PTEN* mutations have been identified in individuals with ASD (Betancur, 2011). In the *Pten* condition null mouse model of ASD, reciprocal social interaction deficits and impaired PPI have been reported (Kwon et al., 2006). This model also exhibits brain abnormalities similar to those observed in humans with PTEN disruptions such as macrocephaly, spontaneous

seizures, and electroencephalogram abnormalities. TSC1, TSC2, and Pten KO mouse models were successfully improved on a number of measures including seizure, cognition, neuronal hypertrophy, and hippocampal synaptic plasticity by targeting this pathway with pharmacological agents such as rapamycin (Betancur et al., 2009).

SYNDROMIC DISORDER MODELS

Fragile X syndrome is one of the most significant known genetic causes of ASD because approximately 30% of persons with FXS also satisfy the requirements for an ASD diagnosis. Numerous animal models of FXS exist with various behavioral phenotypes (described previously), but few of these reproducibly recapitulate ASD-relevant traits. For instance, the *Fmr1* gene was knocked out on six different mouse genetic backgrounds (hybrid strains) and only knockout (KO) mice on a C57/B6 x DBA/2J background showed consistent ASD-relevant traits of decreased social interactions, altered ultrasonic communication, and stereotypic/repetitive behaviors (Spencer et al., 2011). Thus, all animal models for FXS may not necessarily translate as ideal models for studying ASD. It is possible that, as most ASD-linked genetic insults exhibit incomplete penetrance because of human genetic variability, the same may hold true for animal models.

RETT SYNDROME

Loss-of-function mutations in the gene encoding methyl-CpG-binding protein 2 (MECP2) cause Rett syndrome (RTT), a neurological disorder defined by a period of apparently normal development followed by the manifestation of various behavioral and physiological symptoms including hand stereotypies, loss of verbal skills, motor impairments, poor sociability, and respiratory problems. *Mecp2* mutations can also lead to other neurodevelopmental disorders including cognitive disorders, childhood-onset schizophrenia, and a subset of persons with Rett syndrome also meet the diagnostic criteria for ASD. Thus consequences of loss of MECP2 from animal models yield potential insights into a variety of neurodevelopmental disorders. Numerous mouse models of RTT, including tissue and time-specific models, have demonstrated the molecular and phenotypic consequences of loss of *Mecp2*. These phenotypes include abnormal gait, limb stereotypies (reminiscent of hand-clasping observed in humans with RTT), seizures, cardiorespiratory irregularities, altered social interactions, anxiety, learning and memory deficits, growth failure, and early death (Khwaja and Sahin, 2011). Autism-like phenotypes, including repetitive behaviors, were specifically observed in a mouse model in which *Mecp2* expression was uniquely disrupted in only GABAergic neurons (Chao et al., 2010). Additionally, mice with a full loss of *Mecp2* and mice expressing a truncated version of *Mecp2* exhibit fewer numbers of synaptic connections, synaptic plasticity deficits, and spine morphology defects (Robertson and Feng, 2011). It is encouraging that separate postnatal applications, reactivation of *Mecp2* gene expression, systemic treatment with an active peptide fragment of insulin-like growth factor 1, and treatment with ampakine CX546 (although more

limited), have been demonstrated to rescue abnormal phenotypes in *Mecp2*-deficient mouse models (Betancur et al., 2009; Khwaja and Sahin, 2011).

15q11-13 DUPLICATION/DELETION SYNDROME

Perturbations of chromosomal region 15q11-13 have been implicated in several neurodevelopmental disorders depending on the genes and allele (maternal or paternal) affected, including Angelman syndrome, Prader-Willi syndrome, and ASD. This region includes genes such as the imprinted ubiquitin ligase *Ube3A* and GABA_A receptor subunit genes. Mice modeling the loss of these genes individually exhibit a wide variety of behavioral deficits. For instance, data from several labs indicate that *Gabrb3* KO mice have impaired social interaction and nesting, repetitive circling behaviors, impaired learning and memory, increased tactile sensitivity, hyperactivity, and increased seizure susceptibility (Robertson and Feng, 2011). A paternal 15q11-13 duplication mouse model of ASD, duplicating a 6.3-Mb analogous murine chromosomal region, replicates the full spectrum of ASD core symptoms resulting in altered communication (ultrasonic vocalization measures elevated pups and decreased in adults), reduced social interest, and a deficit in behavioral flexibility (poor reversal learning in the Morris water maze and Barnes test).

WILLIAMS-BEUREN SYNDROME

Williams-Beuren syndrome (WBS) is a genetic deletion disorder characterized by prominent physical and cognitive attributes including hypersociability. Although children with WBS pursue social interactions, they often have difficulty maintaining friendships. Williams-Beuren syndrome mouse models, generated through deletion of chromosome 7q11.23 regions defining the disorder, exhibit phenotypes that remarkably parallel the human phenotypes, including physical deficits, craniofacial dysmorphism, body and brain growth retardation, and disrupted motor coordination, as well as social/cognitive impairments, hypersociability in social approach, direct social interaction and social choice, and mild intellectual disability (Li and Roy, 2009). A second study that disrupted only a single gene in the mouse WBS locus, *Gtf2i*, also observed increased social interactions and a lack of habituation to a social partner (Sakurai et al., 2010). When considered together, findings of hypersociability in WBS mouse models combined with decreased social behaviors observed in models of ASD causal genes correlatively suggest mouse models of human social disorders may indeed be informative at the mechanistic level and may provide a unique opportunity for comparisons attempting to identify molecular substrates underlying the directionally divergent behaviors.

Many single-gene candidate and rare syndromic models exist exhibiting various combinations of ASD-related behavior and/or pathology (see Betancur, 2011 for extensive review of genes and syndromes implicated in ASD). Several additional genetic mouse models of ASD that show promising phenotypes include mice with induced expression deficits of the

genes Reelin, an extracellular matrix protein, Dishevelled-1, involved in the WNT signaling pathway, Engrailed-2, a neurodevelopmentally important transcription factor, and contactin associated protein-like 2, a neuroligin family cell adhesion molecule.

ENVIRONMENTAL MODELS FOR AUTISM SPECTRUM DISORDER

Maternal infection during the first trimester is increasingly becoming recognized as a risk factor for ASD. Rodent models of maternal infection have been generated through respiratory infection via influenza virus or administration of maternal immune activating (MIA) substances such as polyinosine:cytosine (poly(I:C)) and lipopolysaccharide (LPS) (Patterson, 2012). Offspring from these models exhibit ASD-related phenotypes such as impaired social and communication behaviors and increased stereotyped behaviors in addition to non-core symptom behaviors. Cellular deficits present in MIA models include histopathological changes, altered dopaminergic neurochemistry, Purkinje cell disruption, and synaptic communication between hippocampus and prefrontal cortex, and in LPS models include altered hippocampal cell density and dendritic arbors, as well as a variety of synaptic input, response, and plasticity impairments (Patterson, 2012).

Valproic acid (VPA) intake during pregnancy increases ASD susceptibility in offspring, thus administration of VPA to pregnant rodents, most commonly rats, serves as another prominent environmental model for ASD. In rat models numerous behavioral abnormalities are observed in offspring, including ASD-like behaviors such as reduced social interaction, increased repetitive behaviors, and altered sensitivity to sensory stimuli, in addition to relevant physiological changes in microcircuit connectivity, immune abnormalities, and synaptic alterations in the lateral amygdaloid nucleus (Patterson, 2012).

AUTISM SPECTRUM DISORDER MOUSE MODELS IN SUMMARY

There are numerous additional mouse models relevant to ASD that already exist and are still being engineered because of the tremendous genetic variability underlying the disorder. Although not every model, or even all of the aspects of a few models, can be thoroughly captured in this discussion, an expert review of mouse and human phenotypes in ASD provides some broad insights into what we have learned from mouse models of ASD. Buxbaum and colleagues performed an unbiased assessment to identify what phenotypes were enriched in mouse models of 112 ASD causal genes (see Fig. 73.1). Interestingly, they found that social domain deficits (as assayed) were minimally observed, suggesting that broad neurological examinations in mice are important for best understanding the gene functions. Additionally, electrophysiological alterations were present, absent, and directionally divergent across models, suggesting that a hypothesis of a simple imbalance in excitation and inhibition is too broad based on currently compiled data. Certainly, the study of the etiology

of ASD is still in its infancy and as the number of proposed susceptibilities grows along with their animal model counterparts, research studies and the comparisons and conclusions drawn across them will benefit greatly from some level of standardization across genetic backgrounds and assays.

As approximately 80% of ASD cases claim no discernible cause, face validity-based models may still provide novel targets to assess for in human ASD, but cumulatively should be considered with caution as insults unrelated to human ASD may phenocopy ASD-related phenotypes in mice. Ultimately, as additional genes or environmental insults are implicated in ASD, construct validity-based models will continue to allow for increased understanding of specific gene and neural circuitry contributions to physiology and behavior.

INTELLECTUAL DISABILITY

Intellectual disability (ID), previously known as mental retardation, is one of the most common central nervous system impairments, affecting 1% to 3% of the general population. Intellectual disability is characterized by failure to develop normal intellectual functioning, limitations in adaptive behavior including communication and social skills, and most important, the cognitive impairments occur before 18 years of age. The diagnosis of ID is based on cognition, language and social skills, and modeling the cognitive phenotypes in an animal, understanding the manifestation of the phenotypes and interpretation of the behavioral outcomes become very challenging (Ropers, 2008). The causes of ID are heterogeneous, and both genetic and environmental factors have been shown to play important roles. Therefore, based on the causal agents the animal models of ID can be classified into two broad categories: (1) genetic models and (2) environmental models.

The genetic causes of ID include chromosomal abnormalities (e.g., Down syndrome), microdeletions (e.g., Williams-Beuren, DiGeorge, Prader-Willi, Angelman), and coding abnormalities in single genes (e.g., Fragile X syndrome) (Bessa et al., 2012). This section highlights some of the most important animal models of ID.

DOWN SYNDROME

Down syndrome (DS), caused by human trisomy 21, is the most common genetic cause of intellectual disability, affecting 1 in 750 newborns (Parker et al., 2010). Patients with DS present a wide range of clinical features, including craniofacial abnormalities, cardiac defects, hypotonia, gastrointestinal defects, increased incidence of childhood leukemia, and dementia at later stages of life. One of the hallmarks of DS is intellectual disability, which affects 100% of the individuals with IQs ranging from 30 to 70. Some of the cognitive deficits include impairment in long-term memory, spatial memory, and problems in acquiring new skills. The current hypothesis for the pathogenesis of DS is that the phenotypes are caused by extra copies of dosage-sensitive genes present on chromosome 21 (Haydar and Reeves, 2012; Rueda et al., 2012).

MOUSE MODELS OF DOWN SYNDROME

A number of different mouse models of TRS21 have been created based on synteny between human chromosome 21 (HSA21) and mouse chromosomes 10 (Mmu10), 16 (MMu16), and 17 (Mmu17). Overall, the DS mouse models fall under two broad categories: (1) chromosomal trisomy that includes mice trisomic for chromosomal regions syntenic to HSA21 and (2) transgenic mice overexpressing select dosage-sensitive genes present on HSA21 (Vacano et al., 2012).

CHROMOSOMAL TRISOMY

The first mouse model of DS termed Ts16 was created by spontaneous robertsonian translocation resulting in animals trisomic for Mmu16. But these embryos died *in utero*, making it unsuitable for studying various aspects of DS. However, biochemical studies conducted on cell lines derived from Ts16 have been used to study some of the biological processes, including apoptosis (Vacano et al., 2012). Another major disadvantage with this mouse model is that Mmu16 is syntenic with some regions on HSA3, 8, and 16; hence, these animals are trisomic for a number of genes not present on HSA21, suggesting that this might not be the ideal model of DS. The second model of TRS21 is the Ts65Dn mouse model, a partial trisomy of Mmu16 encompassing a portion of HSA21. These mice are trisomic for about 96 genes syntenic to HSA21 and also trisomic for about 60 centromeric genes on Mmu17. These mice exhibit a number of features seen in patients with DS including craniofacial abnormalities such as hypoplasia of the proximal facies, brachycephaly, altered skull and mandibles, hydrocephaly, tremors and seizures, and degeneration of basal cholinergic forebrain, which has been shown to contribute to dementia seen in patients with DS. They also exhibit congenital heart defects, myeloproliferative disorders, decreased bone density, and show altered incidence of certain cancers (Rueda et al., 2012; Vacano et al., 2012). Some of the behavioral abnormalities include hyperactivity and learning and memory defects (Das and Reeves, 2011). This model seems to exhibit good face validity in spite of not exhibiting perfect construct validity. The Ts65Dn mouse model has been used to investigate therapeutic potential of a number of drug targets, including memantine, which has been shown to improve learning and memory in mutant mice (Rueda et al., 2012).

Another example of a partial trisomic model is the Ts1Cje mouse model, which is a partial trisomy of Mmu16 for a region that contains about 74 genes syntenic to HSA21. These mutants show enlarged brain ventricles and decreased neurogenesis. Learning and memory defects in these mutants are less severe compared with the Ts65Dn mutants. The Ts1Rhr mouse model is trisomic for the DS critical region encompassing about 33 genes and has been created by chromosome engineering. These animals exhibited a number of behavioral and neurophysiological phenotypes that are characteristic of DS but some of the phenotypes were found to be less severe compared with Ts65Dn mouse model (Roubertoux and Carlier, 2010). To model the trisomy of HSA21 syntenic to Mmu17, the Ts1Yah mouse model was created, which is trisomic for 12 genes in the Mmu17

region. These animals exhibit learning and memory defects in the Y arm maze and novel object recognition, but show improved performance in the Morris water maze, suggesting the variation and complexity of DS phenotypes (Rueda et al., 2012). Also, mouse models that are trisomic for the complete HSA21 syntenic regions on Mmu16 (Dp (16)1Yep/+), Mmu17 (Dp (17)1Yep/+), and Mmu10 (Dp (10)1Yep/+) were created. However, the mouse model that exhibits perfect construct validity is the Dp(10)1Yep/+; Dp(16)1Yep/+; Dp(17)1Yep/+ mouse model, which is trisomic for the entire HSA21 syntenic region on Mmu10, 16, and 17. The mutants exhibit several DS phenotypes, suggesting that this model has good face validity as well (Vacano et al., 2012). The Tc1 or the human transchromosomal mouse model has the entire human HSA21 stably introduced into the mouse genome. The Tc1 model has been shown to exhibit several phenotypes observed in individuals with DS.

OVER-EXPRESSION OF DOSAGE-SENSITIVE GENES

The second category of mouse model comprises dosage-sensitive genes that have been implicated in causing DS phenotypes (Lana-Elola et al., 2011). A few examples of dosage sensitive genes on HSA21 implicated in various DS phenotypes are as follows: (1) Learning and memory: amyloid precursor protein (APP), dual-specificity tyrosine-(Y)-phosphorylation regulated kinase 1A (DYRK1A), synaptojanin 1 (SYNJ1); (2) motor coordination: DYRK1A, APP; (3) cardiac defects: collagen VI alpha-1 (COL6A1), Down syndrome cell adhesion molecule (DSCAM); (4) increased incidence of cancer: v-ets erythroblastosis virus E26 oncogene homolog 2 (ETS2); (5) craniofacial abnormalities: ETS2. Transgenic over-expression and knockout models of these genes have provided a valuable tool in understanding the development of DS phenotypes. However, it is important to consider the genetic background of the mouse models because the phenotypes show variability across different strains of mice.

Overall, the chromosomal trisomic models have provided a valuable tool to recapitulate human DS phenotypes and led to the identification of a number of dosage-sensitive genes that play important roles in contributing to DS. These models have also enabled us to develop novel therapeutic strategies for treatment of DS phenotypes.

DIGEORGE SYNDROME

DiGeorge syndrome (DGS) results from a deletion of chromosome 22q11.2 that is characterized by neonatal hypocalcaemia, susceptibility to infection, hypoplasia of parathyroid glands, cardiac malformation, short stature, mild to moderate learning difficulties, cleft lip, deafness, low set ears, and slant eyes. A variety of psychiatric problems have also been reported, including schizophrenia and depression (Bessa et al., 2012). *Tbx1* knockout mice displayed a wide range of developmental anomalies recapitulating some of the DGS phenotypes in humans, including hypoplasia of the thymus and parathyroid glands, cardiac outflow tract abnormalities, abnormal facial structures, and cleft palate. Another gene implicated is the CRKL and *Crkl*

knockout mice have shown a number of DGS phenotypes, including in cranial and cardiac anomalies (Guris et al., 2001). Another example is the *Dfl* knockout mouse, which exhibits learning and memory and sensorimotor gating abnormalities (Paylor et al., 2006). These mouse models have enabled us to better understand the mechanism underlying DGS.

FRAGILE X SYNDROME

Fragile X syndrome (FXS) is the most common form of X-linked intellectual disability and accounts for about 10% to 20% of all inherited IDs (Chiurazzi et al., 2008). Fragile X syndrome presents with a wide spectrum of physical abnormalities, including prominent protruding ears, elongated face, macroorchidism, and behavioral abnormalities, including hyperactivity, obsessive-compulsive behavior, aggression, self-injurious behavior, alterations in sensorimotor gating, cognitive impairments, and abnormal social behavior. Several magnetic resonance imaging (MRI) studies have reported neuroanatomical abnormalities and generalized seizures in patients with FXS (Hagerman et al., 2012).

MOUSE MODELS OF FRAGILE X SYNDROME

FMR1KO MOUSE MODEL

To understand the function of FMRP and the disease mechanism in FXS, a *Fmr1* knockout (*Fmr1KO*) mouse model was created in 1994 by the Dutch-Belgium Fragile X consortium (Bakker et al., 1994), and this model has been widely used in studying FXS. The *Fmr1KO* mice (both males and females) are viable and fertile and did not show any gross morphological abnormalities. Microscopic examination of the brain in the *Fmr1KO* revealed dendritic spine abnormalities in different brain regions, which recapitulates the spine abnormalities observed in patients with FXS (Rubeis et al., 2012). Electrophysiological studies revealed enhanced long-term depression (LTD) mediated by the metabotropic glutamate receptor 5 (mGluR5) and the M1 muscarinic acetylcholine receptor (mAChR) in the *Fmr1KO* mice (Dolen et al., 2010). One of the most consistent phenotypes seen in *Fmr1KO* mice is macroorchidism, which recapitulates the macroorchidism phenotype seen in patients with FXS. Behavioral abnormalities in *Fmr1KO* mice include increased locomotor activity and impairment, acoustic startle response, and sensorimotor gating deficits. Mutant mice exhibited a decreased startle response and an enhanced PPI response to sound stimulus when measured using whole body flinch protocol. However, this phenotype is opposite of what has been reported in patients with FXS, who exhibit enhanced startle response and decreased PPI when measured using an eye-blink conditioning protocol. They also show abnormal social behavior, alterations in social and non-social anxiety, and mild learning and memory impairments (Baker et al., 2010; Krueger et al., 2011; Spencer et al., 2011).

POINT MUTATION MODEL

The second mouse model, the *Fmr1I304N* mice, carries a single missense mutation (I304N), resulting in a substitution

of isoleucine (Ile) to asparagine (Asn) in the *Fmr1* gene, has been reported in a severely affected FXS patient with a normal repeat length and an unmethylated CPG island who presented with an IQ below 20 and severe macroorchidism. Behavioral analysis in the *Fmr1I304N* mutant mice photocopied the null mutation, including increased activity, decreased acoustic startle response, and increased susceptibility to AGS (Zang et al., 2009). Thus, the I304N point mutation model provides a valuable model to understand FXS behaviors and to test and validate treatments for FXS.

YAC TRANSGENIC MICE

An FMR1 YAC transgenic mouse model containing a 450 kb region of the human Xq27.3 region with the entire *FMR1* gene was created to investigate the function of FMRP and to assess the therapeutic potential of introducing FMRP in the *Fmr1KO* mice. Introducing FMRP in the KO mice rescued a number of phenotypes including macroorchidism, activity and anxiety measures, prepulse inhibition, social behavior, and audiogenic seizures. However, transgenic expression of FMRP overcorrected some of the behaviors, including activity and anxiety in the WT animals expressing the YAC transgene (Willemsen et al., 2011). There are a number of mouse models that carry CGG repeat expansion similar to the human disorders, including the CGG repeat knockin (KI) mouse model, with a portion of the mouse *Fmr1* gene along with the repeat tract replaced with a human *FMR1* permutation with (CGG) 98 repeats. The KI mice showed increased activity and less anxiety in the open field assay, impaired learning and memory in the passive avoidance assay, and defects in social interaction (Qin et al., 2011). The neurohistological and behavioral phenotypes observed suggests that the KI mice provide a useful tool to study the mechanism of instability and pathogenesis of FXTAS.

OTHER MODELS

Apart from mouse models of FXS, a drosophila model exists that recapitulates some of the salient features seen in FXS. Anatomically the null mutants are normal; however, they do exhibit enlarged testes as seen in humans and mouse models with a loss of FMRP. Behaviorally, loss of dFMR1 expression can lead to flight/motor defects, erratic activity with bouts of hyperactivity, abnormal circadian cycle, and courtship behavior defects. Orthologues of all three *FMR1*-related genes have been identified in zebrafish, and thus morpholino antisense oligonucleotide repression of *fmr1* mRNA translation in zebrafish embryos was utilized to study FXS and were phenotypically normal, making it not a suitable model to study FXS (Bhogal and Jongens, 2010).

THERAPEUTIC IMPLICATIONS

Over the last decade the *Fmr1* KO mouse model has been used in the identification of molecular pathways thought to play a role in the pathogenesis of FXS. As a result, specific molecules have been identified as potential therapeutic targets, not only because of their probable involvement in FXS, but also because

of the availability of tools to manipulate their expression, including receptor antagonists and molecular inhibitors. Some of the molecular targets include metabotropic glutamate receptor (mGluR 5) antagonists, GABA agonists, NMDA receptor antagonists, muscarinic receptor antagonists, and PAK inhibitors, to name a few. A number of these molecules are currently being tested in preclinical and clinical trials, suggesting the validity of these model systems in therapeutic applications (Dolen et al., 2010; Hagerman et al., 2012; Rooms and Kooy, 2011).

X-LINKED LISSENCEPHALY

Another example of an X-linked ID is lissencephaly that occurs because of mutations in *Dcx*, which encodes doublecortin, a microtubule associated protein playing an important role in growth of neuronal processes. Although the *Dcx* knockout mice show normal neocortical lamination and neocortical neurogenesis, they show abnormalities in hippocampal lamination. The *Dcx* mutants also exhibit impairments in contextual and cued fear conditioning (Bessa et al., 2012).

Both FXS and X-linked lissencephaly represent syndromic models of ID in which the cognitive impairments are associated with clinical and biological features. The non-syndromic models represent the second category, in which cognitive impairment is the only manifestation of the disease. The non-syndromic models are valuable tools in identifying genes and pathways involved in cognitive processes. One of the genes involved in non-syndromic ID is *Gdi1*, which encodes a rabGDP-dissociation inhibitor and has been shown to be important for neuronal maturation. Although the *Gdi1* knockout mice show normal behavior outcomes in most assays, they exhibit impairments in short-term memory and abnormal social behavior (Bessa et al., 2012). The *Gdi1* mouse model acts as an important tool in understanding the mechanism underlying cognitive processes.

INBORN ERRORS OF METABOLISM

Metabolic disorders are caused by mutations in genes encoding enzymes, resulting in reduced enzyme activity, leading to toxic buildup of metabolites in the system. Intellectual disability is commonly seen in metabolic disorders along with other behavioral problems, including ataxia, seizures, and motor problems. The most common metabolic disorder associated with ID is phenylketonuria (PKU), with an incidence of 1:10,000 in the general population.

MOUSE MODELS OF PHENYLKETONURIA

Phenylketonuria is a metabolic disorder caused by mutations in phenylalanine hydroxylase gene (PAH) that is essential for metabolism of phenylalanine (Phe) in the system, which converts phenylalanine to tyrosine. Phenylketonuria results in the toxic accumulation of phenylalanine in the body. Phenylketonuria presents with a number of clinical features, including intellectual disability, abnormal gait, eczema, epilepsy, abnormalities in executive function, learning and

memory defects, and autism. One of the best-known treatments for PKU is dietary restriction of phenylalanine. Initially, mouse and rat models of PKU were created by artificially increasing Phe concentration by Phe supplements or enzyme inhibitors. But a true genetic model of PKU was created by ENU mutagenesis of the BTBR mice. The BTBR-Pah^{enu2} mice carries a point mutation in the PAH gene and has best construct validity. Some of the phenotypes in the Pah^{enu2} mice includes light pigmentation, increased Phe concentration in the blood, and reduced levels of Tyr, all of which are seen in human patients. The mouse model also recapitulates some of the human behavioral phenotypes, including short-term memory defects, and impairments in procedural memory and motor defects. Thus, Pah^{enu2} mice provide a very valuable tool to improve our understanding of the genetics and neurobiology of PKU in humans (Martynyuk et al., 2010).

ENVIRONMENTAL MODELS OF INTELLECTUAL DISABILITY

A number of environmental factors cause ID, including prenatal exposure of the fetus to toxic substances, radiation, infection, and malnutrition, suggesting the heterogeneity of this disorder. Treatment of pregnant rats with methyazoxymethanol (MAM) represents a good animal model of environmental cause of ID. Offsprings of MAM-treated rats showed a number of cognitive defects and hyperactivity. Animal models of lead exposure have also been shown to cause cognitive impairments. Also animal models of congenital toxoplasmosis, congenital rubella syndrome, and fetal alcohol syndrome are being tested as models of ID (Scorza and Cavalheiro, 2011).

ATTENTION DEFICIT/HYPERACTIVITY DISORDER

Attention deficit hyperactivity disorder (ADHD) is a highly heritable and heterogeneous disorder that is characterized by three behavioral phenotypes: hyperactivity, impulsiveness, and impaired sustained attention. It likely results from complex gene-gene and/or gene-environment interactions, although an exact etiology for ADHD remains highly elusive. A number of animal models have been proposed, each falling within one of three general categories of insult to the biological system: genetic, chemical, and environment. Cumulatively, findings from these multiple models will hopefully provide insight to the pathophysiology for this heterogeneous disorder. This section is aimed at highlighting some of the models used for ADHD-related research. More in-depth coverage of these and other models is discussed in several reviews (Arime et al., 2011; Russell, 2007; Russell, 2011; Sontag et al., 2010; van der Kooij and Glennon, 2007).

GENETIC MODELS OF ATTENTION DEFICIT/HYPERACTIVITY DISORDER

Probably one of the most well-studied and characterized models is the spontaneously hypertensive rat (SHR). This model was created through the selective inbreeding of Wistar-Kyoto

rats with high blood pressure, which produced a rat model that not only develops hypertension over time, but also exhibits each of the three core ADHD symptoms: hyperactivity, impulsivity, and poor sustained attention. The SHR also has been found to exhibit dysfunctions within the dopaminergic system, consistent with findings that individuals with ADHD demonstrate dopamine-related abnormalities. More specifically, SHR exhibits impaired dopamine release and reduced expression of the dopamine transporter (DAT) gene. Furthermore, SHR demonstrate enhanced norepinephrine release, thereby implicating the noradrenergic system. It is important to mention that hypertension in untreated ADHD patients has not been reported. Therefore an attempt was to separate the hypertensive phenotype from the more ADHD-related phenotypes with the creation of a WKHA rat. However, even though WKHA rats are hyperactive and hypersensitive to stress, they lack predictive validity because methylphenidate (a clinically used psychostimulant) causes a further increase rather than a decrease in locomotion.

Mice lacking functional neurokinin-1 (NK1) receptors through knockout strategies for the tachykinin-1 receptor gene display hyperactivity that is ameliorated by both D-amphetamine (a clinically used psychostimulant) and methylphenidate. Inattentive and impulsive phenotypes have also been described, supporting the face validity for this model. These mice also exhibit dysfunction in the regulation of dopaminergic, noradrenergic, and serotonergic transmission.

DAT knockout (DAT-KO) mice reportedly exhibit hyperactivity, impulsiveness, and increased inattention. Both D-amphetamine and methylphenidate alleviate hyperactivity. Although extracellular dopamine is elevated, dopamine release appears to be decreased. Some have questioned the relevance as a model for ADHD since DAT-knockdown mice (expressing 10% normal levels of DAT) display stereotypies in addition to hyperactivity and impulsivity, which is not consistent with ADHD but instead is suggestive as a model for Tourette syndrome.

Children with high levels of thyroid-stimulating hormone (TSH) and resistance to thyroid hormone exhibit symptoms of ADHD. Mice expressing a mutated human thyroid receptor demonstrate all three ADHD-related phenotypes. Methylphenidate can reduce the hyperactivity, and abnormalities in dopamine turnover have been found in this model.

The coloboma mutant mouse contains mutations in the genes for the synaptosomal-associated protein-25 (SNAP-25) and phospholipase C β -1 (PLC β -1), both of which are important for synaptic function. Polymorphisms of SNAP-25, a protein that assists in the fusion of synaptic vesicles to the plasma membrane during neurotransmitter release, have been found to be associated with ADHD. Coloboma mice display hyperactivity and impulsivity, consistent with ADHD. Even though δ -amphetamine reduced ADHD-related symptoms in coloboma mice, methylphenidate was unable to do the same, thereby questioning the predictive validity for this model.

Other genetically based models include the Naples high excitability (NHE) rat, poor performers in the five-choice serial reaction time (5-CSRT) task, and mutant mice for Grin1, a gene encoding a subunit of the NMDA receptor. Grin1-mutant

mice are hyperactive, NHE rats exhibit hyperactivity and inattentiveness, whereas animals selected for deficiencies in sustained attention as poor performers during the 5-CSRT task display inattentiveness and impulsivity, but no hyperactivity. Interestingly, dysfunction in dopamine function is associated with poor performers in the 5-CSRT task. Further studies are required to determine the relevance of these models to ADHD.

CHEMICAL MODELS OF ATTENTION DEFICIT/HYPERACTIVITY DISORDER

Neonatal exposure to 6-hydroxydopamine (6-OHDA) in rats has been used as a model for ADHD. They display hyperactivity and impaired spatial learning, which improves with methylphenidate or D-amphetamine treatment; however, they exhibit no impulsiveness. Decreases in dopamine and DAT have been reported as well as increases in serotonin and serotonin transporter binding. Hyperactivity can be ameliorated with inhibitors of norepinephrine and serotonin transporters, supporting a role for these systems in the observed hyperactivity phenotype.

Prenatal or early postnatal exposure to a variety of chemical compounds has been proposed to increase the risk for developing ADHD, including exposure to nicotine, ethanol, and polychlorinated biphenyls. Prenatal or early postnatal exposure to nicotine or ethanol induces hyperactivity in rodents. Associated dopaminergic changes also have been identified: ethanol exposure leads to decreases in dopamine and DAT expression and nicotine exposure can decrease levels of dihydroxyphenylacetic acid (DOPAC) and alter dopamine turnover.

ENVIRONMENTAL MODELS OF ATTENTION DEFICIT/HYPERACTIVITY DISORDER

There are some indications that hypoxia during birth may increase the risk of ADHD. Hypoxia induced in neonatal rats leads to hyperactivity. Furthermore, D₁ receptor levels are reportedly increased in this model, along with alterations in dopamine, serotonin, and norepinephrine levels; however, DAT expression appears to be unaltered. Further studies are required to confirm its validity as a model for ADHD.

The diversity of animal models proposed illustrates the diversity in potential causes for ADHD. Although it remains to be clarified how relevant each of these models is to the human manifestation of ADHD, these models have helped to begin elucidating the mechanisms underlying behavioral phenomena relevant to ADHD. These animal studies have highlighted the potential importance of not only the dopaminergic system, but also that of the noradrenergic and serotonergic systems. Behavioral phenotypes giving rise to ADHD may likely culminate as a result of complex interactions between multiple monoaminergic neurotransmitter systems.

TOURETTE SYNDROME

Tourette syndrome (TS) is a condition characterized by uncontrollable audible and/or motor tics. Even though studies have suggested that genetics plays a critical role in the cause of TS,

no specific genes have been confirmed as risk factors (State, 2010). Despite the lack of known susceptibility genes for TS, the generation of several animal models has been useful in elucidating potential mechanisms underlying TS.

Animal models with face validity exhibit behaviors analogous to the motor tics observed in human patients, including motor stereotypies, sequential super-stereotypy, circling, repetitive grooming, and self-injurious behaviors. Alternatively, other models have been constructed based on the known pathophysiology of TS (Felling and Singer, 2011). Abnormalities within the dopaminergic system have been identified in individuals with TS (Muehlmann and Lewis, 2012). Even though levels of dopamine or its primary metabolites appear normal, other dopaminergic system abnormalities have been found, including increased dopamine transporters in the caudate and putamen, elevated putamen dopamine release, increased D_2 receptor sensitivity, and decreased caudate volumes that seem to correlate with symptom severity. Therefore, animal models have been created based on the hypothesis that abnormal regulation of synaptic dopamine and signaling within basal ganglia circuits may play a role in the pathogenesis of TS.

PSYCHOSTIMULANT MODEL

Psychostimulants that exhibit dopaminergic-enhancing properties also may result in people experiencing tics. Therefore, these drugs are used in rodent models to investigate behavioral phenomena such as motor stereotypies as well as the brain structures believed to underlie these behaviors, including basal ganglia circuitry.

DOPAMINE TRANSPORTER KNOCKDOWN MOUSE

A mouse model containing a knockdown mutation of the dopamine transporter gene (DAT-KD mouse) effectively expresses 10% normal DAT levels and results in a 170% rise in extracellular dopamine within the striatum. DAT-KD mice exhibit hyperactivity, perseverative walking patterns, and stereotypic grooming sequences that are resistant to interruption. On the contrary, this model fails to demonstrate tic-like motor stereotypies and therefore models more closely perseverative-type behaviors.

D1 RECEPTOR CHOLERA TOXIN TRANSGENIC MODEL

D1CT-7 transgenic mice express an intracellular form of cholera toxin that is under the control of the D_1 promoter in a subset of neurons containing D_1 receptors that are active in sensorimotor, orbitofrontal, corticostriatal, and limbic circuits. These mice display compulsive behaviors, including repetitive climbing, digging, leaping, and grooming. Furthermore, they exhibit TS-relevant phenotypes such as juvenile-onset tics that are effectively reduced following administration of clonidine, a treatment used to suppress tics in humans. Although these behaviors demonstrate face validity for the model, mutants

also express an increased susceptibility to seizures, a phenotype uncommon for those with TS (Felling and Singer, 2011; Wang et al., 2009).

MONKEY FOCAL STRIATAL DISINHIBITION

One hypothesis asserts that tics are produced by abnormal focal disinhibition of striatal neurons. Disinhibition of the putamen in monkeys using $GABA_A$ antagonists results in motor tics, thereby supporting the involvement of the striatum in tic production.

AUTOIMMUNE MODELS

Another hypothesis proposes that TS may in part result from dysfunction of the immune system. Some studies have injected sera or IgG from TS patients into rodent striatum, but this approach has been met with conflicting results. Some report elevations in stereotypic-like behaviors, whereas others report no effects. Another model is based on findings that some children with TS experience a worsening of their symptoms following streptococcal infections or those with no prior history suddenly present with symptoms following similar infections. Immunization of mice with Group A β -hemolytic streptococcal (GABHS) can induce motor-related disturbances that correlate with IgG deposits in deep cerebellar nuclei. This model, however, is geared to elucidate the mechanisms by which GABHS may alter neuronal function, and is therefore not specifically targeted toward understanding TS.

OTHER MODELS

Other psychiatric disorders of childhood onset may include schizophrenia, obsessive/compulsive disorder, anxiety, and mood disorder. The reader is encouraged to visit other units in this book covering these conditions.

CONCLUSIONS

Despite the complexity of psychiatric disorders, much has been learned from the animal models currently available. Even though it is unlikely that a “perfect” model will ever be created embodying every aspect of a disorder, as more information is gathered regarding underlying pathologies, current models can be improved upon, bringing us closer to understanding these disorders. In fact the first genetic rat models for autism and other neurodevelopmental disorders were generated in 2011. Although their validity as models have yet to be established, these lines hold the promise of providing additional novel insights that complement the basic research already being carried out in mouse lines.

The multitude of models available to researchers for a given disorder illustrates not only the complexity in creating a model for a complex psychiatric disorder, but also the seeming difficulty in creating a single model supports the contention that many of these disorders are likely multifactorial. For instance, ASD prevalence rates are likely caused

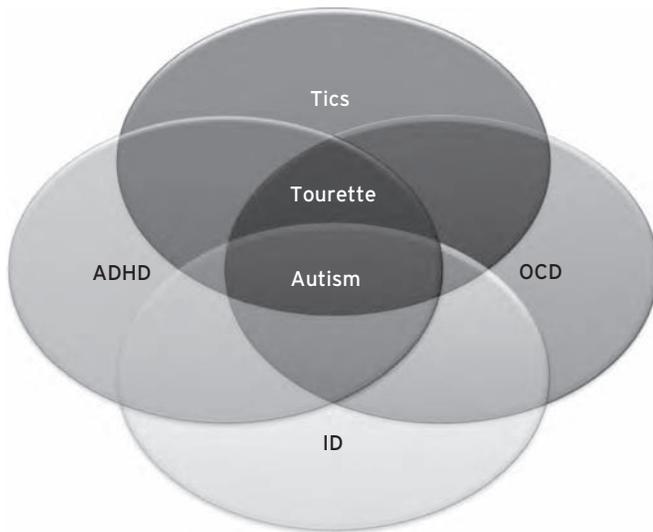

Figure 73.2 Example of how behaviors from multiple psychiatric disorders may overlap and form complex relationships. ADHD, attention deficit/hyperactivity disorder; ID, intellectual disability; OCD, obsessive-compulsive disorder.

by a combination of modes of inheritance (i.e., owing to different causes or ASD subtypes that remain to be defined), epigenetic effects, or a combination of genetic and environmental factors. Thus far, approximately 20% of ASD has been linked to genetic causes (Betancur, 2011). As the immense heterogeneity of ASD symptoms, severity, onset, and genetic etiology unfolds, animal models, as described in the preceding may offer a means for unraveling the underlying pathophysiology of ASD and developing functional or novel therapeutics.

Interestingly, many of the observed symptoms are shared across multiple psychiatric disorders. For example some form of anxiety can occur with many of the mentioned disorders. An example of how characteristics may overlap between disorders is illustrated in Fig. 73.2. This overlap may suggest that either shared pathways underlie multiple disorders or there are various pathways underlying a given behavior that can be disrupted in multiple ways.

As these animal models improve, they will continue to provide insight into candidate genes for disorders and the neurological pathways underlying the observed phenotypes, as well as help to identify therapeutic targets for future development. Evidence for the reversibility of phenotypes in several animal models at birth or even in adults provides hope that despite the occurrence of these disorders during a critical developmental time period, systems underlying these conditions may be highly plastic, thereby allowing multiple opportunities for therapeutic intervention.

74 | NEUROPATHOLOGY AND SYNAPTIC ALTERATIONS IN NEURODEVELOPMENTAL DISORDERS

MARA DIERSSEN AND SALVADOR MARTÍNEZ

The term neurodevelopmental disorder has been classically restricted to intellectual disability (ID) (Table 74.1). However, epidemiological studies increasingly demonstrate that most psychiatric disorders begin during childhood or adolescence (Kessler et al., 2007). Moreover, even though the notion of critical periods is still accepted, our concept of development in temporal terms has dramatically changed in the last years, and neurodevelopment now is considered to encompass the period from fetal life into adolescent brain maturation and synaptic pruning. This change in our conceptualization of neurodevelopment has led to an increased interest in understanding the role of neurodevelopmental processes, not only in ID, but also in mental illnesses such as schizophrenia and autism spectrum disorders (Kendler et al., 2005; McGrath et al., 2003). Mental disorders that become symptomatic in childhood or adolescence are affected by early environmental conditions that may interact with genetic risk factors. This increases the potential to identify genes leading to deviations from normal development, at prodromal stages in which intervention might be particularly useful.

Significantly, neurodevelopmental disorders have been found to share a number of similarities in terms of common genetic risks, co-occurrence of neurodevelopmental symptom domains, cognitive processing deficits, early onset, and chronic course. Schizophrenia, autism, and intellectual disabilities, for example, are spectrums of diseases with broad sets of causes that have overlapping phenotypes and genetics, which is suggestive of common deficits. Other disorders of childhood and adolescence, such as attention deficit/hyperactivity disorder (ADHD), eating disorders, or the separation anxiety disorders (Krueger and South, 2009), may not overlap in terms of risks and manifestations.

Structural brain development in healthy children follows complex, regionally heterochronous trajectories (Giedd et al., 1999). In gray matter development, whether measured by cortical volume or thickness, there is a phase of early increase, followed by a late childhood/adolescent phase of adjustment, before the cortex settles into adult dimensions. White matter has a more sustained pattern of expansion, persisting through adolescence. Given the complexities of these trajectories and their exquisite genetic control, it is not surprising that small disturbances can result in disturbances in cognition, affect, and behavior. For example, a disorder may be characterized by a delay in the pattern of typical development, or may be associated with differences in the temporal occurrence of the

neural changes. Another possibility is a more profound deviance in the basic shape of the typical developmental trajectory. Obviously, these anomalies are not mutually exclusive. (A trajectory could incorporate elements of delay but also be altered in speed.) Anomalies in developmental trajectories are linked with ADHD or schizophrenia (Arango et al., 2008; Hoftman and Lewis, 2011), but also autism (Courchesne et al., 2007) and neurodegenerative disorders (Grilli et al., 2003).

This chapter gives a general view of the fetal and postnatal development that can be disrupted in an age-sensitive manner. It also discusses some of the common cellular and molecular targets that may explain similarities and differences in the phenotypes and comorbidity.

THE PRENATAL DEVELOPMENT OF THE REGIONAL DIVERSITY OF THE BRAIN

NEURAL TUBE FORMATION

The structural and functional complexity of the brain derives from precise orchestration of molecular and cellular mechanisms regulating the main developmental processes of neural progenitors: proliferation, differentiation, and synaptogenesis, in a temporospatial pattern defined into the matrix of embryonic development and perinatal life. The vertebrate central nervous system originates from the embryonic dorsal ectoderm. Differentiation of the neural plate epithelium from the ectoderm constitutes the first phase of complex processes called gastrulation and neurulation, which culminates in the formation of the neural tube.

Neurulation is a fundamental event of embryogenesis that culminates in the formation of the neural tube, which is the precursor of the brain and spinal cord. The bending of the neural plate involves the elevation of the neural folds establishing a trough-like space called the neural groove (20 days of gestation), which becomes the lumen of the primitive neural tube after closure of the neural groove (between 22 and 28 days of gestation). With the closure of anterior and posterior neuropores, the first phase of neural tube formation is completed, and internal cavities of the neural tube are no longer in connection with amniotic fluid. In addition, the neural folds generate the specialized cells of the neural crest. Then the most anterior portion of the neural tube balloons into three primary vesicles: the forebrain (prosencephalon), midbrain (mesencephalon), and hindbrain (rhombencephalon; Fig. 74.1). By

the time the posterior end of the neural tube closes, secondary bulges—the optic vesicles—have extended laterally from each side of the developing forebrain. Then the prosencephalon becomes subdivided into the anterior secondary prosencephalon (telencephalon and hypothalamus) and the more caudal diencephalon.

Anomalies of neurulation normally generate severe malformations in the embryos and are classified as dysraphias. Several genetic anomalies have been detected underlying these malformations, including mutations in *VANGL1* and *VANGL2* (OMIM 610132 and 600533, respectively) as well as *SCRIB* (OMIM 607733) and *SHH* (OMIM 600725). When the process of fusion of neural folds does not occur at any level of the neural groove craniorachischisis results. When the closure skipped areas localize at different levels, anencephaly, exencephaly, or meningomyelocele (from rostral to caudal) results.

After the posterior neuropore closes (28 days of gestation), the second phase of caudal neural tube formation begins. This process requires the formation of the caudal cell mass. Neural progenitors differentiate around vesicles in contact with caudal neural tube, and then these vesicles coalesce and fuse with the central canal (30 to 50 days of gestation); and finally there is a regressive process in the tail (50 to 100 days of gestation). Abnormal development of the caudal neural tube formation generates defects of closure and malformation in the lumbo-sacrococcygeal levels of the spinal cord: myelocystocele, diastematomyelia, and myelomeningocele. Myelomeningocele

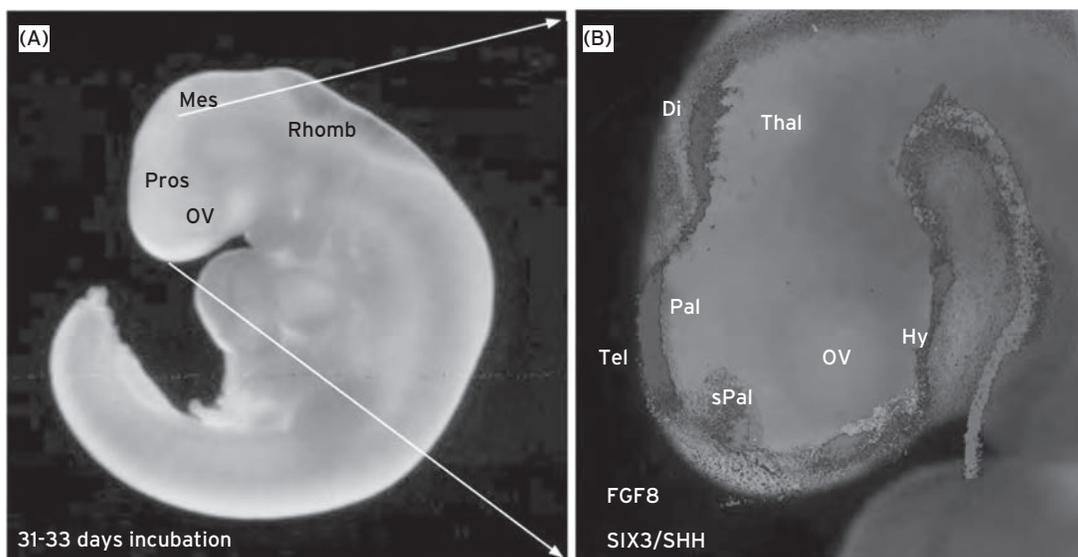

Figure 74.1 Human embryo at postneurulation stage. (A) Lateral view of a human embryo of 31–32 days of incubation. The main brain regions were detected: Prosencephalon (Pros), mesencephalon (Mes), rhombencephalon (Rhomb) and optic vesicle (OV). (B) Magnification of the anterior brain area where different gene expression patterns have been represented by different gray shades. The expression patterns were translated from mouse embryos sections at equivalent stage of neural tube development (E11.5). Di, diencephalon; Hy, hypothalamus; OV, optic vesicle; Pal, pallium; sPal, subpallium; Tel, telencephalon; Thal, thalamus. (Data from *Developing Mouse Brain in the Allen Brain Atlas* website: <http://www.brain-map.org/>.)

is a frequent malformation commonly associated with multiple human syndromes of genetic origin, including Joubert syndrome, DiGeorge syndrome, Waardenburg syndrome, and orofacioidigital syndrome, some of which have psychiatric manifestations, as well as toxic agents associated with another tube defect, folate sensitivity.

NEURAL TUBE REGIONALIZATION

The discovery that putative regulatory genes (mainly coding for transcription factors) are expressed in regionally restricted patterns in the developing forebrain has provided new tools for defining histogenetic domains and their boundaries at higher resolution (see Fig. 74.1; Puelles and Rubenstein, 2003). This molecular regionalization has unveiled the morphological significance of numerous gene expression patterns in the neural tube, suggesting the existence of molecular subdivisions of the main AP and DV zones, representing histogenetically specified domains of neural precursors. Genetic alterations associated with brain regionalization anomalies frequently occur with important structural alterations in brain morphogenesis that

finally appear as congenital malformations such as holoprosencephaly (OMIM 236100; caused by combinations of mutations in genes as *SIX3*; Fig. 74.1), *ZIC2*, and *GLI2*, which are transcription factors coding for positional information in the prosencephalon at early stages of neural tube development. But smaller genetic alterations underlying copy number variants could produce subtle variations in regionalization that modify regional morphogenesis and synaptogenesis of the affected region, which may represent a predisposition to develop intellectual disabilities and/or psychiatric disorders (revised in Malhotra and Sebat, 2012).

The longitudinal study of this molecular/structural causal association in the neural tube of experimental models has shown how the expression of particular genes is directly related to neural morphogenetic and cytogenetic development. For instance *Gbx2* expression in mouse embryos is associated with the generation of thalamic neurons, which develop into the thalamocortical projection (Fig. 74.2) (Miyashita-Lin et al., 1999), whereas *Lhx8* and *Tbr1* expression are associated with the development of basal forebrain cholinergic neurons (Pomero et al., 2011). Thus, elaborated cellular interactions

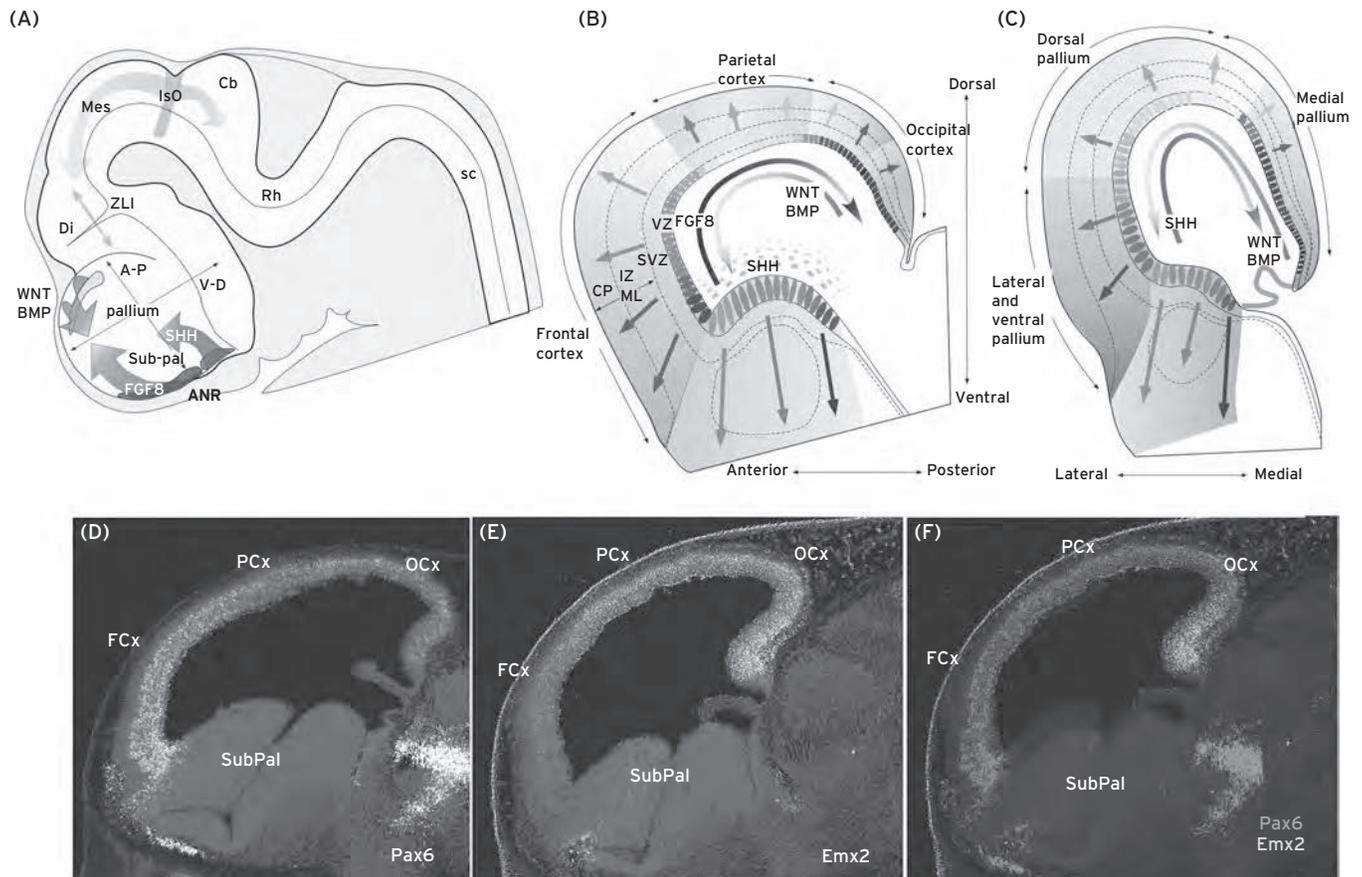

Figure 74.2 Morphogenetic signals and telencephalic regionalization. (A) Schematic representation of neural tube (lateral view) where the main brain regions have been identified and morphogenetic signals regulating telencephalic regionalization have been represented by colors and arrows. Wnt and Bmp are dorsalizing signals, Fgf8 is a rostralizing signal, and Shh is a ventralizing signal, acting upon dorsal (pallial) telencephalon to specify cortical functional areas in the epithelium. (B,C) Schematic representation of a section in anteroposterior (B) and coronal (C) planes of the dorsal telencephalon (pallium and subpallium) that were color coded in neuroepithelial cells. Colored arrows in the ventricle and the dashed area (B) represent morphogenetic gradients that were translated through the neural wall by radial migration of neural cells into the different cortical regions (radial arrows and color gradient domains). (D–F) Sagittal sections showing the gradient expression pattern of two transcription factors: Pax6 regulated by rostral and ventralizing signals (D), and Emx2 regulated by dorsalizing signals (E). F, A combinatory Photoshop reconstruction of both gradient patterns. (See color insert).

regulate the establishment of the common complex structural pattern of the developing brain in vertebrates. Distinct neural and glial identities are acquired by neuroepithelial cells according to their relative positions in the neural tube wall, through a progressive restriction of their histogenetic potential, under the influence of local environmental signals. Evidence for controlling morphogenetic processes at specific locations of the developing neural crest and neural tube has suggested the concept of morphogenetic organizers. Such centers regulate by their own signaling the choices of identity and regional polarity of neural precursors in neighboring neuroepithelial regions and may even function as target-derived presynaptic organizers to specify the type of synaptic terminals (Terauchi et al., 2010).

Three regions in the neural plate and tube have been identified as putative secondary organizers (Fig. 74.2A). Two of these organizers control prosencephalic regionalization: the anterior neural ridge (ANR) at the anterior end of the neural plate, and the zona limitans intrathalamicae (ZLI) in the middle of the diencephalon. In addition, the isthmic organizer (IsO) at the mid-hindbrain boundary controls mesencephalic and rostral rhombencephalic (including cerebellar) regionalization. To focus the present chapter on mental function related structures, we describe only the mechanisms of anterior prosencephalic regionalization and concentrate on the function of the anterior neural ridge (ANR).

ANTERIOR NEURAL RIDGE

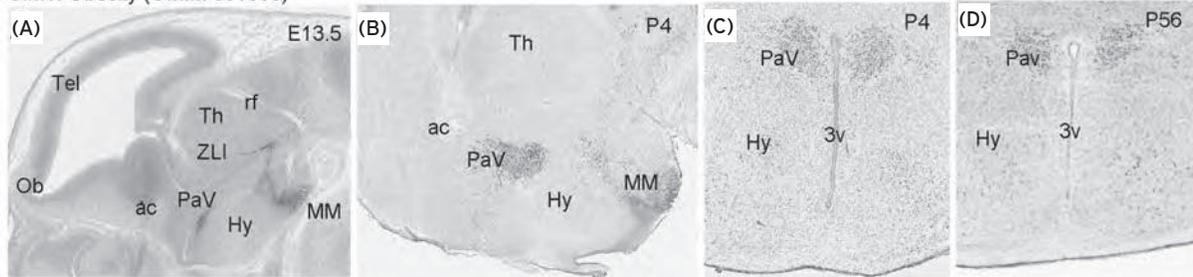

The most anterior secondary organizer, the ANR, is a morphologically indistinct median sector at the junction between the neural plate and non-neural ectoderm. The ANR controls prosencephalic regionalization and proliferation and it was demonstrated that some genes expressed in this region control others that are necessary for telencephalic and hypothalamic specification (Fig. 74.2A). In particular, the *Fgf8* gene is expressed very early in ANR cells, and has been shown to be crucial for specification of the anterior areas of the forebrain and telencephalon. *Fgf8* hypomorphic mutations in both mouse and zebrafish result in a small telencephalon and midline anomalies. Prosencephalic regionalization by FGF8 signal operates at least in part through inhibition of *Otx2* and *Emx2* expression, in cooperation with BMP4, WNT, and SHH signaling molecules. Modifications in this interactive molecular network originate important anomalies in brain and skull development. For instance, decreasing FGF activity caused by mutations in FGF receptors (FGFR1 and FGFR2) produces severe brain alterations and different forms of craniosynostosis (including Apert syndrome; OMIM 101200) (revised in Chi et al., 2003; Rice, 2005; Storm et al., 2006). Less severe alterations in this FGF signaling have been described in hypogonadotropic hypogonadism (OMIM 146110), Jackson-Weiss syndrome (OMIM 123150), Kallmann syndrome 2 (OMIM 147950), Pfeiffer syndrome (OMIM 101600), and Trigonocephaly 1 (OMIM 190440). These syndromic forms of FGF signaling anomalies show limb and cephalic patterning alterations (because of FGF expression in ectodermal apical ridge of the limb bud and branchial arches), together different degrees of sensorial—hearing and smelling—deficits (because of the requirement of

FGF signaling in cephalic placode development). Moreover, different degrees of developmental retardation and ID (with or without telencephalic structural phenotype) are also present that can be attributed to anomalies in cortical regionalization derived from expansion deficits of the cortical surface (Rash et al., 2011). Morphogenetic influences derived from secondary organizers regulate progenitor proliferation in the developing cortex. For instance, ID can be associated with anomalies in the regulation of centrosomic distribution and mitotic spindle orientation of neuroepithelial precursors, disrupting spatial and temporal rates of neuronal progenitor proliferation and differentiation, and causing a reduction of normal cortical surface and cerebral volume. Alterations of these processes course with primary microcephaly—MCPH1 gene (MIM 251200)—or secondary microcephaly associated to neural migration alterations: LIS1 (OMIM 601545) and NDEL1 (OMIM 607538) (Guerrini and Marini, 2006; Hippenmeyer et al., 2010).

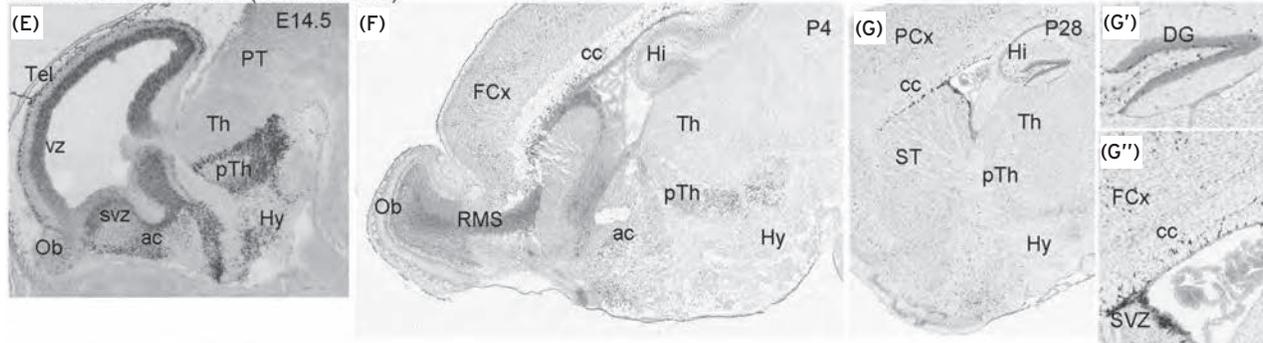

Another gene coding morphogenetic information is sonic hedgehog (SHH), which is expressed in the subpallium slightly later than *Fgf8* expression in the ANR. Abundant data suggest that SHH signaling is both necessary and sufficient for the specification of the ventral pattern throughout the nervous system. After abundant experimental demonstrations in animal models, it is widely accepted that normal patterning in the telencephalon depends on the “ventral” repression of GLI3 function by SHH and, and conversely on the “dorsal” repression of SHH signaling by GLI3. Different types of *GLI3* mutations in humans produce craniofacial and brain anomalies together with other patterning anomalies. The SHH signal in the subpallium has also been shown to be involved in the regulatory activity of NKX2.1, a homeodomain gene required for the development of the telencephalic subpallium as well as the hypothalamus, the latter being ventral part of the forebrain (see Fig. 74.1). The *DLX2* gene codes for a transcription factor expressed in the subpallium, prethalamus, and thalamus, and regulates the expression of *ARX* (Colasante et al., 2008) in prosencephalic progenitors (Fig. 74.3E–G). It is an essential gene in the proliferation and migration of neural progenitors. Mutations of *ARX* frequently have been involved in X-linked ID (OMIM 300419) and epilepsy. The hypothalamus is the main brain center regulating homeostasis by controlling autonomous nervous and hormonal systems, where molecular patterns define neurons with specific functional properties; for instance, SIM1 is a transcription factor expressed in the hypothalamus, in the paraventricular hypothalamic nucleus (Fig. 74.3A–D). SIM1 haploinsufficiency is associated with hyperphagia and obesity. In addition, in close relation to this ventral signal coded by *SHH*, a longitudinal column of epithelial progenitors is specified along the whole neural tube to produce oligodendroglial progenitors, revealed by the expression of PLP/dm20, PDGFalpha, and OLIG1/2. Although very little is known about the underlying physiopathological mechanisms, extensive knowledge has been accumulated about myelin developmental anomalies in relation to mental disorders and ID (Dong and Greenough, 2004; Takahashi et al., 2011).

All these recent findings on the molecular regionalization of the neuroepithelium support the protomap model

for neocortical areal specification, in which neocortical progenitor cells become patterned by extracellular signals into molecular domains that in turn generate area-specific neurons. The protomap is thought to be underpinned by spatial differences in progenitor cell identity that is reflected by regional specific genes at the transcriptional level (Fukuchi-Shimogori and Grove, 2001; Grove and Fukuchi-Shimogori, 2003). Furthermore, cross-regulation among the rostral (FGF-signal dependent), dorsal (BMP- and WNT-signal dependent), and ventral (SHH-signal dependent) secondary inductive centers plays an essential role in patterning the early telencephalon. Modulation of this cross-regulation has the potential to regulate the relative size of structures whose morphogenesis is

controlled by a given patterning center (Hamasaki et al., 2004). For instance, a reduction in FGF8 signaling reduces the ratio of the frontal motor versus sensory regions of the neocortex. Therefore, controlling the relative strength and range of a given patterning signal may provide a fundamental mechanism to modify the relative sizes of brain subdivisions during evolution and in disease states. Nevertheless, very little is known about the underlying processes that generate local reduction or lack of progenitors in specific cortical regions, as is the case of schizencephaly, in which mutations of *EMX2*, *SIX3*, and *SHH* have been reported (Aronica et al., 2012).

Once the developmental processes have operated, both spontaneous and sensory-driven neural activity are essential

for instructively guiding the process of synapse development. These effects of neuronal activity are transduced in part through regulation of a set of activity-dependent transcription factors that coordinate a program of gene expression required for the formation and maturation of synapses (West and Greenberg, 2011). A number of human neurodevelopmental disorders have been linked to anomalies in the expression of these activity-regulated genes, such as Fragile X syndrome, Angelman syndrome, and ASD, in which it seems that excitatory and inhibitory synaptic equilibrium in the cortical regions is distorted. Indeed, the transcription of these activity-dependent genes regulates the fine-tuning of the adequate distribution of ion channels in specific neuronal populations. This is the case of *GYRK2* (*KCNJ6*), a gene regulating GABAergic (inhibitory synaptic function) in the substantia nigra, thalamus, and hippocampus. It has been related to familial Parkinson disease and Down syndrome functional alterations (Fig. 74.3H–J).

A mechanistic model can be proposed to understand brain regionalization in which morphogenetic signals from different organizer regions interact in regulative networks to establish initial territories of specified progenitor cells, establishing the molecular domains in which specific functional areas will develop (see Fig. 74.2). Then, the same or different signals, acting at different temporospatial scales, may stabilize the final molecular codes in these regions and regulate the production of specific cell types. Then, young neural cell follows specific migratory patterns of radial and/or tangential movements to generate the cellular diversity of neural structures. This cellular diversity is required for the establishment of neuronal connectivity networks and intercellular trophic support (e.g., neuron–glia interactions). Eventually, ambient influences, acting through posttranscriptional mechanisms, can modify the structural and functional properties of such neural systems, both in positive (adaptive) or negative (toxic) directions (see following sections).

NEURAL MIGRATION IN THE CORTEX AND SYNAPTOGENESIS DURING EMBRYONIC STAGES

The neurons and glial progenitors generated from the ventricular and subventricular layers of the pallium migrated to populate specific radial strata in the mantle layer (Fig. 74.4F,G). This migration is known as radial migration because it follows the radial axis in the brain wall, and migrating young neurons are guided to the pial (external) surface by radial glia fibers (Fig. 74.4A). In the pallium the first migration from the ventricular progenitors form a cellular layer known as the cortical plate (50 to 54 gestation days in humans), which represents the primordium of the cortex (embryonic days 12.5 to 15.5 in mouse development). Then at three months of gestation in human embryos the cells of layers IV, V, and VI are generated and migrate into the cortical plate (Fig. 74.4D), which correspond to E15.5 to 18.5 in mouse development. Structural maturation beyond this time is complex and varies in the different regions of the pallium, following a general lateromedial gradient; that is, starting from the lateral pallium (allocortex)

at 70 to 80 days and progressing dorsally. Although the superficial neurons (layers II and III) are still generating, the neurons in the cortical plate become grouped into the six layers, corresponding to those of the adult cortex between six and seven gestational months (Fig. 74.4E; perinatal development in the mouse cortex). Intercalated with or after radial migration, other directions also can be followed by migratory neural cells, which do not follow radial glia axis and are known as tangential migration (Fig. 74.4F,G; revised in Molnar and Clowry, 2012).

We previously described that cellular migrations are essential processes necessary to develop cellular diversity in brain areas and require precisely coordinated movements in time and space. Cell–cell and cell–substrate interactions underlie the guidance mechanisms of these migrations during brain development, by signal–receptor interaction coded by ephrins and their receptors (revised in Rodger et al., 2012), SLIT proteins, ROBO receptors (see Fig. 74.4A,B), neuregulin1, and ErbB4 receptors, as well as FGF8 and FGF receptors (FgfR; Pombero et al., 2011). Finally, positioning of cells in the specific layers of growing cortical areas is dependent on the Reelin (RELN) signaling cascade generated from Cajal–Retzius cells, which are produced very early in development in layer I (revised in Frotscher, 2010). Actually, the RELN signal is received in migrating cells by apolipoprotein E (Apo-ER2) or very low-density lipoprotein (VLDLR) receptors and transduced by tyrosine phosphorylation of the Disabled-1 (DAB1) protein. Disruption of the *RELN* gene in humans results in severe brain abnormalities, including lissencephaly and cerebellar hypoplasia, and patients show ataxia, ID, and seizures. It is interesting to note that important tangential migration of neurons coming from the subpallial ganglionic eminences generate early cortical GABAergic interneurons, starting to invade the pallium at six weeks of gestation and generating deep layer interneurons (predominant from six to 15 gestation weeks), whereas during the second half of gestation, the cortical subventricular and subgranular zones (progenitor proliferating layers especially prominent in primates and humans) originate locally the most numerous superficial interneurons, which are completed by interneurons in layer I that originate in the cortical surface by the subpial granular layer (revised in Bystron et al., 2008).

Developmental defects in neuronal positioning and synaptic connectivity are commonly found in neurological and psychiatric diseases, and they are believed to underlie many cognitive and affective disorders (Barkovich et al., 2005; Harrison and Weinberger, 2005; Tabares-Seisdedos et al., 2006). Several mouse mutants are currently available that model at least some aspects of human developmental brain disorders that might be related to similar structural alterations. With the identification of the genes mutated in these animals and the study of the cellular basis of their phenotypes, we have taken significant strides toward an understanding of the mechanisms controlling proper brain development and the consequences of their dysfunction. In particular, mouse mutants deficient in the *Reelin* and *Lis1* expressions have provided valuable insights into the mechanisms of cortical development. Absence of *Reelin* expression in the spontaneous mutant mouse reeler leads to extensive defects in neuronal position and dendrite development. In humans, loss

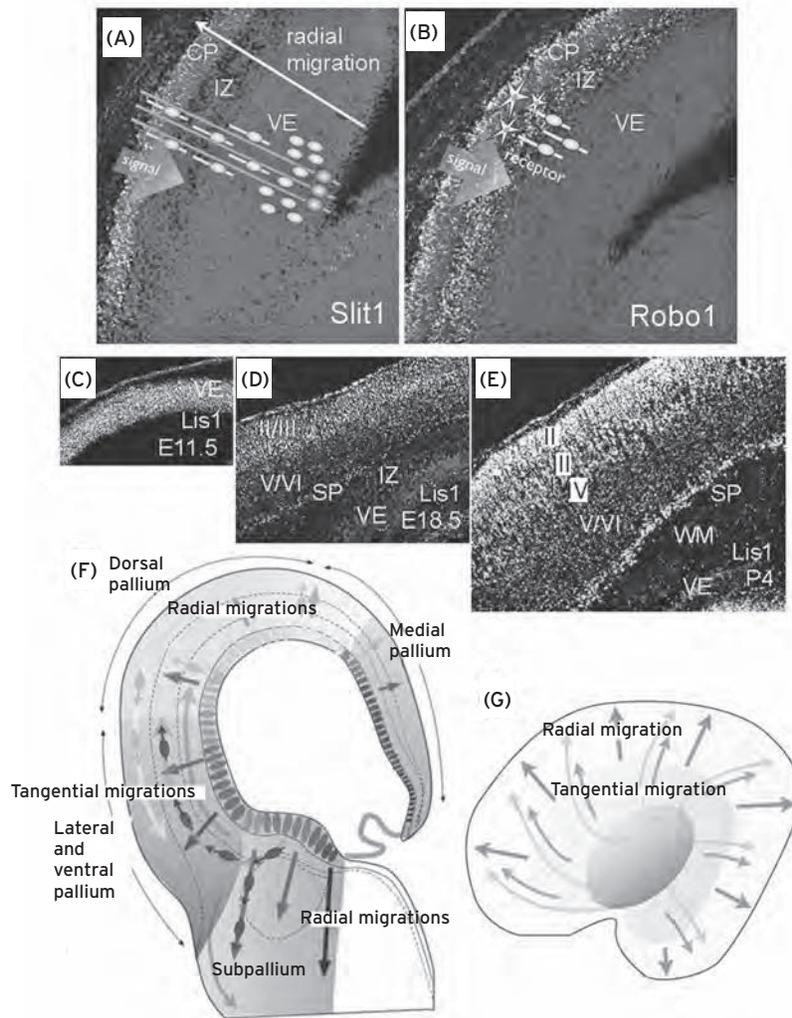

Figure 74.4 Neuronal migration in the pallium: cortical development. (A,B) Signal: *Slit1* expression in E15.5 mouse embryo in the cortical plate. Neural progenitors proliferate in the ventricular epithelium (VE) and subventricular zone (yellow ovoid cells), radial glia cells are schematized in gray with long radial processes crossing the neural wall from ventricular to pail surface. Migrating neurons were distributed in between radial glia processes in the intermediate zone (IZ; yellow ovoid soma with processes) toward the cortical plate (CP). In an equivalent section the receptor of *Slit1*, *Robo1* is expressed in migrating cells of the IZ. (C–E) Expression of *Lis1* gene in developing and postnatal mouse cortex. (F) Schematic representation of a coronal section where different lateromedial (ventrodorsal) pallial domains are represented by colored fields. Radial migration is represented by radial arrows and tangential migrations are represented by concentric distributed arrows. Migrating cells were represented by ovoid soma and arrows. (G) Planar representation of the telencephalic vesicle where radial migrations are represented by orange arrows; pallio-pallial tangential migration is represented by grey arrows; subpallio-pallial tangential migration, coming from the subpallium (central orange ovoid). (See color insert).

of *RELN* (OMIM 600514) results in a type of lissencephaly with severe cortical and cerebellar malformation (Norman-Roberts type lissencephaly; revised by D’Arcangelo, 2006). Genetic and biochemical studies using mouse mutants suggest that the *Lis1* protein may participate in the Reelin signaling pathway, controlling cortical development by its interaction with the dynein system and, therefore, neuronal motility.

A recent classification proposed for developmental cortical malformations in humans by Barkovich and co-workers have listed the human genetic mutations identified as malformations owing to abnormal neuronal migration (Barkovich et al., 2005). Most of the genes identified in human’s cortical malformations also have been proved as functionally relevant to neuronal migration in mice; suggesting that in these situations the mouse models are of great value for analyzing the physiopathological mechanisms of these human diseases (Webber

et al., 2009). Indeed, it is of special relevance that alterations in the Reelin-dependent genetic cascade activate complex molecular interactions regulating cell migration and microtubule transport. Mutation in some of the molecules involved in this interactive cascade produced important alterations in cell migration and, subsequently, in cortical structure, characterized phenotypically by different degrees of cortical dysplasia, such as the double-cortex syndrome within lissencephaly spectrum (Cardoso et al., 2003), whereas mutations in some other molecules (e.g., *DSC1*) or moderate genetic alteration of lissencephaly critical region genes produce functional alterations without important structural malformation that may manifest as schizophrenic or bipolar disease symptoms. A recent metaanalysis showed that more than 290 genes have been involved in mental retardation associated with syndromes and metabolic or neurological disorders (Chelly et al.,

2006). Although it was estimated that most of the genes remain to be discovered, a table of known monogenic causes of mental retardation shows that neuronal migration and synaptic function-related genes predominated over other functions. Therefore, we can speculate about the importance of neuronal connectivity (synaptogenesis) with or without evident migratory alterations during human development as a substrate of mental retardation and/or predisposition to develop a mental disease. Copy number variants in developmental genes controlling principal neurodevelopmental processes, such as brain regionalization, neural cell migration/differentiation, and synaptogenesis have been postulated underlying the neurobiological roots of mental disorder predisposition (Insel, 2010; Malhotra and Sebat, 2012).

POSTNATAL NEURAL DEVELOPMENT

As discussed, the major developmental processes in the human telencephalon following closure of the neural tube are neuronal proliferation, astrocytic proliferation, neuronal migration, neurite (i.e., axonal and dendritic) growth, neuronal apoptosis, axon myelination, synaptogenesis, and neurite pruning. All of these processes begin during gestation, but the development of the brain circuitry requires the coordination of a complex set of postnatal neurodevelopmental events, such as neurite proliferation, axonal myelination, neurite pruning, and synaptogenesis, which exert their major effects during postgestational development (Giedd and Rapoport, 2010). Thus, the early postnatal period is crucial for brain development. The newborn brain at two to four weeks of age is approximately 36% the size of an adult brain and grows to about 80% of adult size by two years of age (Knickmeyer et al., 2008). Possibly, this dramatic brain growth is not primarily caused by postnatal cortical neurogenesis and neuronal migration (Bhardwaj et al., 2006; Shankle et al., 1999), but by the expansion of glia and myelination. At two to four weeks of age, the primary cortical areas, including motor, somatosensory, visual, and auditory cortices are well defined, but instead, association cortices at this age can be less clearly identified. Thus, the development of gray matter connections, especially in sensorimotor and visual cortices and the onset of myelination, drives the striking development of the brain during the perinatal and early postnatal period.

ENVIRONMENTAL INFLUENCES ON BRAIN DEVELOPMENT

During development, neural networks are shaped by experience-dependent processes that selectively strengthen and prune connections, creating and restructuring synaptic maps, or even changing dendritic architecture locally. The final neuronal circuits, primary mediators of the brain's diverse functional capacities, and their connectivity, rely on experience-dependent sculpting (Maffei and Turrigiano, 2008; Tau and Peterson, 2010). This environmental sensitivity is especially important during the so-called critical periods; sensitive temporal windows of elevated plasticity allowing the structural consolidation

of neuronal circuits and their connectivity. It was long believed that the potential for organization or reorganization existed only during these critical periods in early development, so that over time neural connections become more stable, forming widely distributed, interconnected networks involving balanced excitation and inhibition and structural stabilizers such as myelin. However, the successful treatments for adults with stroke or amblyopia suggest that the potential for circuit reorganization persists well into adulthood; thus, the final neuronal circuits are neither present at birth nor are they invariant through life (Michel, 2012). Besides, it has been proposed that each functional modality (from basic visual processing to language and social skills) has a different postnatal "critical" period.

Thus, the early postnatal and infancy periods are times of opportunity, but also of great vulnerability for the developing brain. Early disruption of proper sensory or social experiences results in mis-wired circuits that will respond suboptimally to normal experiences in the future. These deviations of the typical trajectories of maturation of neural circuits can also be caused by genetic alterations intrinsically impairing the response of the system to the environment, or to the combined effects of adverse experience on genetically abnormal brain maturation, leading to pathogenesis through both genetic and epigenetic mechanisms.

In this scenario, epigenetic mechanisms reveal as a critical determinant in disease predisposition and outcome. The term epigenetics has referred to heritable traits that are not mediated by changes in DNA sequence, and more broadly to any change in gene function not associated with sequence variation and promoted by the environment to influence or "program" gene expression or patterns that may or may not be heritable (Nicol-Benoit et al., 2012). Although often restricted to chromatin modifications specifying the sets of genes to be expressed or repressed, epigenetic mechanisms also include other gene expression controllers, such as noncoding RNAs, including microRNAs. Increasing evidence shows epigenetic processes are widespread in the brain and undergo dynamic regulation in both the developing and postmitotic neurons. Epigenetic gene control is in fact an intrinsic mechanism for normal tissue development. The epigenetic marking of chromatin provides a ubiquitous means for cells to shape and maintain their identity, and to react to environmental stimuli via specific remodeling. In mature, differentiated neurons in the central nervous system, epigenetic codes are critical for basic cellular processes such as synaptic plasticity, and play critical roles in encoding experience and environmental stimuli into stable, behaviorally meaningful changes in gene expression (Day and Sweatt, 2011; Graff and Mansuy, 2008).

In humans, because maturation processes in the brain continue well into adolescence, the influence of the epigenetic programming on disease risk and pathogenesis is critical. For example, early life environmental threats, such as stress (McEwen et al., 2012), influence the long-term outcome of neurodevelopmental disorders. Mutations in epigenetic components are associated with multisystem disease syndromes in human beings, all of which involve the nervous system; thus, the alteration of the epigenetic machinery may be a common process in many neurological diseases. In fact, anomalies in the

epigenome have been demonstrated to be critical factors in a number of cognitive and behavioral disorders (Lockett et al., 2010). The epigenetic mechanisms that contribute to these deficits include the deregulation of essential components of the epigenetic machinery, alterations in the expression of genes important for cognition and behavior by epigenetic mechanisms, instability at trinucleotide repeats, and the breakdown of major epigenetic processes such as imprinting and X-chromosome inactivation. Some illustrative examples include Rett syndrome (caused by mutations in the methylated DNA binding protein MecP2), Rubinstein-Taybi syndrome (caused by mutations in the histone acetyltransferase CBP), and Coffin-Lowry syndrome (caused by mutations in histone phosphorylase; see Urduingio et al., 2009 for a review).

NEURAL PLASTICITY AS A COMMON MECHANISM IN NEURODEVELOPMENTAL DISORDERS

Neural plasticity can be defined as the ability of a neuron or network to functionally or structurally alter in response to changes in input or activity. During the postnatal period, but also in infancy and adolescence, neural plasticity is one important mechanism in circuit development and refinement. Often, an outcome of neuronal plasticity is a structural plasticity manifested as a change of neuronal morphology (Urbanska et al., 2012). The number and branching pattern of dendrites are strictly correlated with the function of a particular neuron and the geometry of the connections it receives. The development of proper dendritic tree morphology depends on the interplay between genetic programming and extracellular signals. Spinogenesis is also an important target for structural plasticity. Spines are tiny actin-rich dendritic protrusions that harbor excitatory synapses. If plasticity mechanisms operate abnormally—either through long-lasting epigenetic modifications or disruption of functional mechanisms—neuronal networks improperly develop in response to activity-dependent experience. In psychiatric disorders and ID syndromes, plasticity malfunction leads to aberrant morphology and/or number of excitatory dendritic spines, a sign that is considered pathognomonic of ID, suggesting important changes in structural plasticity. Of course, the birth, death, and cellular characteristics of neurons, as well as the formation and reformation of their axons, dendrites, and synapses are also possible contributing factors.

In fact, most neurodevelopmental disorders can be considered synaptic plasticity disorders, in which different genomic causes result in abnormal synaptic development. Accumulation of this abnormal synaptic development, over time, leads to a characteristic and consistent behavioral and/or cognitive phenotype (Zoghbi, 2003).

SYNAPTOGENIC PROTEINS IN MENTAL ILLNESS

As described, neurons are connected by synapses in complex networks that regulate specific physiological and behavioral outcomes in adulthood. For this reason, circuit development is considered a fundamental unit for regulating specific physiological and behavioral outcomes in adulthood. Synapses are

the basic units of neural connectivity and communication in the brain in which synaptic transmission relies on the coordinated function of highly specialized structures on both sides of the cleft, involving membranous organelles, cytoskeleton, and vast protein networks. Postsynaptic neurotransmitter receptors, with associated scaffolding and signaling molecules, should be precisely aligned on the dendrite opposite chemically matched presynaptic vesicles with regulated release and recycling machinery in the axon. If we consider that a typical neuron may contain 1,000 to 10,000 synapses, and each synapse contains more than 1,000 protein components (Bayes et al., 2011) and that the complex neuronal networks derived from this connectivity will regulate behavioral outcomes in a dynamic manner, it becomes clear that synaptogenesis is a highly sensitive process.

Multiprotein complexes in the synapsis are organized into molecular networks that detect and respond to patterns of neural activity. These synaptic organizing proteins mediate plasticity and dynamic synaptic changes during postnatal brain maturation and contribute to synaptic specificity, pairing specific presynaptic and postsynaptic cells, and controlling where and when synapses are formed (Siddiqui and Craig, 2011) and destroyed. Many synaptogenic genes are at high risk for predisposing to neurodevelopmental disorders (Valnegri et al., 2012; van Bokhoven, 2011). Synaptic gene alterations include copy number variants, protein-truncating frame shifts, and function-altering missense variants, some *de novo*, contributing to the disease through pre- and/or postsynaptic alterations. Although in the last two decades a number of synaptic genes have been discovered whose mutations cause ID and a number of neuropsychiatric disorders, we are still far from identifying the impact of these mutations on brain development and neuronal function. One prominent example is the so-called synaptic organizing proteins, which include synaptic adhesion complexes and secreted factors (Betancur et al., 2009). The synaptogenic adhesion complexes are composed of transmembrane presynaptic and postsynaptic partners that bind in trans across the cleft, as in presynaptic neuroligin (NRXN) and postsynaptic neuroligin, for example (Bottos et al., 2011). Such cleft-spanning synaptic organizing complexes often have bidirectional activity, inducing presynaptic and postsynaptic differentiation, and mediating cell adhesion and alignment of the pre- and postsynaptic specializations. Since the initial linkage of mutations in neuroligins 3 and 4 to autism, evidence has rapidly accumulated for the contribution of neuroligin and neuroligin variants to disorders such as schizophrenia and ID. NRXN bind multiple structurally diverse partners across the cleft. Neuroligin-1 is the major glutamatergic neuroligin and binds only β -neurexins. Neuroligin-2 functions specifically at GABAergic synapses and appears to bind all neurexins. Of particular interest is the replicated finding of SHANKS deficits, which directly implicates glutamatergic synapse dysfunction in both autism and Asperger syndrome (Buxbaum, 2009). This finding is supported by the replicated findings with NRXN1 and NLGN3/4, which can also play a role in excitatory synapse formation, maintenance, and plasticity. NRXN1 deletions have been associated with autistic spectrum disorders, and confer risk for schizophrenia, suggesting an etiological overlap between both disorders.

Recent studies have identified leucine-rich repeat transmembrane neuronal proteins LRRRTMs to be trans-synaptic partners for neurexins (Linhoff et al., 2009). LRRRTM1 and LRRRTM2 are glutamatergic postsynaptic proteins and bind α and β neurexins and compete with neuroligin-1 for an overlapping face of β -neurexin (-S4). Given their broadly overlapping expression patterns, neuroligin-1, LRRRTM1, and LRRRTM2 are likely to coexist at many glutamatergic postsynaptic sites (Wright and Washbourne, 2011). Other proteins have also been well documented for their role in experience-dependent plasticity such as ephrins and EphRs or the Wnt family and could thus be good candidates for neurodevelopmental disorders (Attwood et al., 2012). Other synaptogenic proteins have not been systematically studied but associations were also found for LRRRTM1 and GluR δ 1 with schizophrenia and SynCAM1, SHANK3, and CNTNAP2 with autism.

SPINE PATHOLOGY

A close look onto the surfaces of the dendritic processes of neurons allows the observation of small protrusions called dendritic spines, small protrusions (<2 μ m) that contain postsynaptic densities (PSD), which are major sites of excitatory synapse. Typically, adult dendritic spines are composed of a bulbous head with a thin neck. In younger neurons, dendritic shafts are covered by thin, long protrusions called dendritic filopodia, which are thought to be precursors of spines. Filopodia typically lack "heads," whereas mature spines have a distinct head and neck, giving rise to different morphologies named mushroom-like, stubby, thin, and branched. At the cellular level, the primary function of dendritic spines is to compartmentalize local synaptic signaling pathways and restrict the diffusion of postsynaptic molecules, insulating signaling molecules to a specific PSD. Dendritic spines and filopodia show rapid actin-based motility in the time scale of seconds (Yuste, 2011). This confers highly dynamic properties to the spines, which morphology can change very rapidly upon different types of stimulation by remodeling the architecture of their actin cytoskeleton (Penzes and Rafalovich, 2012).

During brain development, the initial dendritic arborization and outgrowth of dendritic spines precede synapse formation, and the number and morphology of the spines change dramatically as synaptic contacts mature. This happens as a response to environmental inputs, activity, and experience that strengthen the immature synaptic connections. On the contrary, inactive synapses become weaker and are eventually eliminated (use it or lose it). Thus, elimination of spines and change of their morphology also seem to be essential to establish neuronal circuits in early life.

Abnormal protrusion morphology in different brain areas seems to be a hallmark of many syndromic or non-syndromic mental disorders (van Spronsen and Hoogenraad, 2010; von Bohlen Und Halbach, 2010). The first link between neurodevelopmental disorders (e.g., ID) and aberrant spines was reported by Purpura (1974) and showed a significant increase of abnormally long, thin spines on dendrites of cortical neurons in children with ID. Later, many ID syndromes have been reported presenting alterations in spine morphology

and synapse number and have been linked to mutations in synaptic proteins involved directly or indirectly in the stabilization of the spine structure, including different signaling pathways, epigenetic regulators, and local mRNA translation at the synapse (Dierssen and Ramakers, 2006). For example, as stated, mutations in synaptic scaffolding protein SHANK3 and adhesion molecules neuroligin-3 and -4 have been linked to autism spectrum disorder but further evidence also suggests that other neurodevelopmental disorders involve defects in the regulation of actin cytoskeleton (Dierssen and Ramakers, 2006; Goellner and Aberle, 2012; von Bohlen Und Halbach, 2010). For example, the schizophrenia risk factor DISC1 regulates dendritic spine morphology via Rac1 and mutations in the cofilin kinase PAK3 (p21-activated kinase) gene lead to X-linked mental retardation. Moreover, decreased levels of PAK3 relate to synaptic dysfunction in Alzheimer's disease and possibly FXS, and PAK3 inhibition in mice causes cofilin pathology and memory impairment, consistent with a potential causal role of PAK defects in cognitive deficits in Alzheimer's disease. The inability to preserve the spine structure causes profound alterations in neural circuit formation and can thus alter information processing, learning, and memory, and produce behavioral impairment (Lott and Dierssen, 2010). However, whether this phenotype is a cause or derives from the mental disturbance and whether we can use this feature as a translational end point to investigate the therapeutic effects of pharmacological interventions are still open questions.

Besides altered spinogenesis, altered spine pruning can also account for mis-wired circuit formation. In 1982, Feinberg (Feinberg, 1982, 1990) proposed that schizophrenia is a disease of aberrant synaptic pruning, based on findings of progressive postnatal "synaptic pruning" and aberrant synaptic elimination in early adolescence. This hypothesis was further expanded by the proposal that hyperpruning of collateral axons in the prefrontal cortex and defective pruning of certain brain structures leads to the aberrant connectivity of schizophrenia. This was further demonstrated by Golgi-impregnation studies revealing a region- and disease-specific decrease in dendritic spine density in dorso-lateral prefrontal cortex layer III pyramidal cells in subjects with schizophrenia (Glantz and Lewis, 2000). Aberrant synaptic conductance and/or efficacy in schizophrenics are also observed in the subcortical gray matter, where striatal spines were reduced in size by approximately 30%. Another good example of pruning alterations is Fragile X syndrome (FXS). In a FXS mouse model, the *Fmr1* knockout mice, the persistent increase in spine density in dentate gyrus in the absence of a defined pruning period argues for a role of FMRP in processes controlling developmental pruning. However, the disruption of the regulation of forming, stabilizing, or removing dendritic spines is a common phenotype in many neurodevelopmental disorders. Changes in the cytoskeletal structure are important for the protrusion morphology and play a role in many forms of ID that have been related to LIMK1, oligophrenin-1, PAK3, and ARHGAP6. Small GTPases, such as Rho, Rac, and Cdc42, are proteins known for their effects on the actin cytoskeleton and microtubule organization.

Different mental retardation-associated genes have been identified that encode modulators of the Rho GTPases. Disturbances in these genes can lead to mental retardation and—on the morphological level—to alterations in dendritic spines (von Bohlen Und Halbach, 2010). A good example is Down syndrome (for a comprehensive review see Dierssen et al., 2009). Postmortem studies show that patients with Down syndrome start their lives with an apparently normal neuronal architecture that progressively degenerates, showing reduced dendrites and degenerative changes in older age. Significantly, abnormalities of synaptic density and length, fewer contact zones, a reduction of dendritic spines, and shorter basilar dendrites are observed in Down syndrome brains. Several candidate genes within the Down syndrome critical region are involved in synaptic plasticity with particular impact on dendritic function and spine motility and plasticity. Among those, *DSCR1*, *DYRK1A*, or *ITSN1* may be candidates to explain the dendritic spine functional and structural alterations. Interestingly, Intersectin controls local formation and branching of actin filaments and Dyrk1A phosphorylates actin-binding proteins, and may also have a role in shaping the interaction of the spine membrane with the actin cytoskeleton (see Dierssen et al., 2009, 2012).

EXCITATORY/INHIBITORY IMBALANCE

In the mammalian cortex roughly 80% of neurons are excitatory (pyramidal cells) and 20% are inhibitory interneurons (Rubenstein and Merzenich, 2003). Pyramidal cells specialize in transmitting information between different cortical areas and from cortical areas to other regions of the brain, whereas interneurons primarily contribute to local neural assemblies, where they provide inhibitory input and shape synchronized oscillations. Complex brain circuitries comprise hierarchical networks of these excitatory and inhibitory neurons (for a review see Birke and Draguhn, 2010). Establishing and maintaining the appropriate ratio of excitatory versus inhibitory synapses is a critical factor that enables circuit threshold definition and balances output responsiveness. In fact, excitation and inhibition are balanced globally in cortical networks but their ratio may vary dramatically with brain region, development, or aging, and ratios do not necessarily reflect the excitation–inhibition synaptic balance per individual neuron. Balance between feedback or feedforward inhibition and recurrent excitation can give rise to balanced network amplification (Carvalho and Buonomano, 2009; Murphy and Miller, 2009) or stability (Marino et al., 2005). In sensory cortices, such a balance serves to increase temporal precision and reduce the randomness of cortical operation (Cruikshank et al., 2007; Pouille et al., 2009).

Excitatory and inhibitory synapses show divergent features. Excitatory synapses target on mature mushroom-shaped spines containing a prominent postsynaptic density (PSD) after preferential contacting with an exploratory filopodium. In contrast, inhibitory GABAergic synapses are present on dendritic shafts, nerve cell somata, and axon initial segments, lacking postsynaptic thickening, and arise from axon–dendrite

contacts with no apparent protrusive activity. At the ultrastructural level, excitatory contacts are asymmetric with an electron-dense postsynaptic density opposing a presynaptic active zone, whereas inhibitory contacts appear relatively symmetrical, with presynaptic vesicles clustered opposite a synaptic cleft without a robust postsynaptic density. During developmental stages neural circuit development is regulated by the balance of excitatory and inhibitory neurotransmission (Zhang et al., 2011), so that disruption of this balance leads to aberrant states, which cause severe dysfunction when chronically unresolved (Marin, 2012).

An increased ratio of excitation/inhibition (E/I) is observed in sensory, mnemonic, social, and emotional systems of autistic patients where it is thought to contribute to the prevalence of poor signal-to-noise ratios, resulting in hyperexcitable, non-tunable cortical circuits (Gatto and Brodie, 2010). These results suggest a shift in the excitation–inhibition ratio favoring an elevated preponderance of glutamatergic connections with inhibitory insufficiency. Excitation-dominant synaptic imbalance may underlie the pathophysiology of other intellectual disabilities. Fragile X syndrome exhibits significant GABAergic deficits leading to hyperexcitability as well as synaptic imbalance neurophysiology (Coghlan et al., 2012). The opposite is observed in Down syndrome (Dierssen et al., 2009; Dierssen, 2012). Various Down syndrome mouse models exhibit a reduced ratio of hippocampal excitation–inhibition, leading to overinhibition with an increased number of inhibitory synapses as well as a reduced density of excitatory synapses. Moreover, large morphological changes are seen in the granular cell dentate gyrus to the CA3 pathway in Ts65Dn mice along with a reduction in synapse density, and reduction of mushroom spines with multivesicular bodies in the middle molecular layer of dentate gyrus. As a consequence, the Ts65Dn dentate gyrus shows enhanced GABAergic synaptic transmission, owing to increased presynaptic release of GABA and increased postsynaptic GABAB receptor–Kir3.2 signaling (Best et al., 2012).

Abnormal GABAergic neurotransmission in the prefrontal cortex of individuals with schizophrenia has also been suggested to cause the cognitive disturbances (Lewis et al., 2012). Indeed, deficits in cortical inhibition have been reported both *in vivo* and in analyses of postmortem brain tissue from patients with schizophrenia, and cognitive functions such as working memory, which is clearly altered in schizophrenic patients, seems to depend on normal interneuron performance. It was originally suggested that the GABAergic deficits that are observed in schizophrenia might be caused by a deficit in the number of interneurons in the prefrontal and cingulate cortices that was speculated to reduce GABAergic inputs to pyramidal cells. The subsequent finding that such patients had increased GABAA receptor binding activity in pyramidal cells was thought to be consistent with this idea, but other studies failed to find similar interneuron reductions in all individuals with schizophrenia. It is now accepted that GABAergic deficits preferentially occur at the level of specific synapses. Interneurons mediate the precise gating of information through specific signaling pathways by controlling—both spatially and temporally—the amounts of excitatory and inhibitory inputs that individual neurons receive. Thus, the

disruption of the balance between excitation and inhibition produced by interneuron reduction has been suggested to lead to gating defects that are related to cognitive impairment (Vogels and Abbott, 2007).

Little is known how the E/I ratio is dynamically adjusted through the postnatal critical periods, when the strength of excitatory and inhibitory synapses is rapidly changing. Some authors have suggested that the tightly regulated E/I ratios in adults' cortex is a result of drastic changes in relative weight of inhibitory but not excitatory synapses during critical period, and the local inhibitory structural changes are the underpinning of altered E/I ratio across postnatal development (Zhang et al., 2011). Mutation of genes that normally sculpt and maintain the excitatory/inhibitory balance results in severe dysfunction, causing neurodevelopmental disorders including autism, schizophrenia, and ID (van Spronsen and Hoogenraad, 2010; Yin et al., 2012). For example, altered GAD67 expression is found in postmortem brain tissue from individuals affected of several neurodevelopmental disorders and those with childhood-onset schizophrenia, suggesting interneuron anomalies. Postmortem studies revealed that neurons in autistic patients present reduced level of glutamic acid decarboxylase (GAD), the rate-limiting enzyme in GABA synthesis. GABAA receptors are also reduced at mRNA and protein levels, showing altered $\alpha 1-5$ and $\beta 1$ subunits in the parietal cortex (Brodmann area [BA]), $\alpha 1$ in the frontal cortex (BA 9), and $\alpha 1$ and $\beta 3$ in the cerebellum of autistic patients postmortem tissue (Coghlan et al., 2012). Genetic studies of subjects with ASD show abnormalities among gene loci containing synaptic imbalance candidates, including the GABA $\beta 3$ receptor subunit and genes encoding the neurorexin, neurexins, and Shank proteins (Kohl and Paulsen, 2010). Such mutations may result in defective synaptic connections and/or functional synaptogenesis, leading to the selective loss of either excitatory or inhibitory synapses, without compensatory changes, or genetic conditions that actively favor the formation or maintenance of one class of synapse relative to the other.

In fact, the E/I imbalance may also affect the shape of the dendritic spines, because the plastic changes in the neuronal cytoskeleton are triggered in mature neurons in response to excitatory neurotransmission (for review see Bosch and Hayashi, 2012). Glutamate is one of the excitatory neurotransmitters that can induce long-term potentiation (LTP) mainly driving the strengthening of the connection between a presynaptic and postsynaptic neuron for a long period. The binding of glutamate to the *N*-methyl-D-aspartic (NMDA) receptor increases Ca^{2+} levels and triggers short-lasting activation of proteins, such as CamKII, that can phosphorylate the α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor to modulate insertion of more AMPA receptors at the postsynaptic membrane. The gain or loss of AMPA receptors at the postsynaptic membrane is related to the strength of the synapse and also the morphology of the spines. Long-term depression (LTD) is the opposite process, being the weakening of the synapse, reflected by a reduced number of ion receptors at the postsynaptic membrane. Glutamatergic synapses also undergo dynamic changes during postnatal brain maturation.

These activity-dependent rearrangements of the actin network mediate structural changes of dendritic spines and can be mediated by certain proteins. For example, activity-regulated cytoskeleton-associated protein (Arc) (also termed Arg3.1) is an immediate-early gene (IEG) induced in response to sensory experience, learning, LTP, spatial exploration, and novelty, and might be a good candidate for the excessive AMPA receptor internalization. It has been suggested that Arc is an mRNA target of FMRP and that the protein levels of Arc are increased in the absence of FMRP. Arc synthesis is required for mGluR-LTD induction by increasing the AMPA receptor internalization rate. Therefore, Arc may play a major role in the excessive AMPA receptor internalization and altered protrusion morphology in FXS (Niere et al., 2012). Genetic factors involved in these processes might function in synaptic plasticity, learning, enrichment, exercise, and neurogenesis. Also, the DSCR1 gene overexpressed in fetal and adult DS brains inhibits calcineurin, which is involved in synaptic plasticity and has a role in the transition from short- to long-term memory through perturbation in long-term potentiation and long-term depression (Hoeffler et al., 2007). Other interesting examples are drebrin, an actin-binding protein thought to regulate assembly and disassembly of actin filaments, thereby changing the shape of spines, the levels of which are reduced in the early second trimester in the brains of patients with Down syndrome (Weitzdoerfer et al., 2001) and Dyrk1A (Altafaj et al., 2008; Martinez de Lagran et al., 2012), and are associated with altered synaptic plasticity and learning and memory deficits. Changes in levels of expression of these genes may lead to changes in the timing and synaptic interaction between neurons during development, which can lead to suboptimal functioning of neural circuitry and signaling at that time and in later life.

CONCLUSIONS

Brain development is a non-linear dynamic process in which small initial differences may yield large later effects. The basic layout of the brain is established by genetic programs and intrinsic activity and is actively refined by the environment as well as gene-environment interaction. This takes place in an age-sensitive manner with underlying mechanisms including developmental changes in gene expression, epigenetic modifications, synaptic arborization, pruning, and behavioral maturation. A hypothesis that is gaining predominance proposes that a spectrum of diseases such as schizophrenia, autism, and intellectual disabilities may have common deficits that explain their overlapping phenotypes and genetics. In this context, the idea is gaining support that the disruption of general developmental processes, alteration of the establishment of neural circuits in the developing brain and neural plasticity, or the imbalance of excitation and inhibition in specific neural circuits might be responsible for some of the clinical features of these disorders. Recent studies in animal models demonstrate that the molecular basis of such disorders is linked to common defects in development leading to schizophrenia, autism, or intellectual disabilities (Box 74.1).

BOX 74.1 NEURODEVELOPMENTAL DISORDERS REVISITED

The translation of discoveries in basic neuroscience to clinical problems has been frustrating owing in part to the reliance on categorical, symptom-based diagnostic systems, such as the Diagnostic and Statistical Manual of Mental Disorders (DSM; <http://www.dsm5.org/>) and the International Classification of Diseases (ICD). These systems have been very useful for increasing the reliability of clinical diagnoses, but could complicate the search for genetic, behavioral, and neural elements that define etiology and pathogenetic mechanisms. An alternative conceptualization and classification has been proposed in the Research Domain Criteria initiative (RDoC; <http://www.nimh.nih.gov/research-funding/rdoc/index.shtml>). The Research Domain Criteria initiative is aimed at establishing new ways of classifying psychopathology based on dimensions of observable behavior and neurobiological measures.

Since 2007, the diagnostic and categorization criteria in psychiatry have been extensively revised based on comprehensive review of scientific advancements, targeted research analyses, and clinical expertise. The release of the final, approved DSM-5 is expected in May 2013. In DSM-5 the category of Neurodevelopmental Disorders contains diagnoses that were listed in DSM-IV under the chapters of Disorders Usually First Diagnosed in Infancy, Childhood, or Adolescence, and Anxiety Disorders. Among the recent revisions is the proposal to now include two superordinate categories of Language Disorder and Speech Disorder and one category for Social Communication Disorder. Speech Disorder now includes specifiers for the specific type of speech difficulty. Learning Disorder has been changed to Specific Learning Disorder, and the previous types of Learning Disorders (Dyslexia, Dyscalculia, and Disorder of Written Expression) are no longer being recommended. The type of Learning Disorder will instead be specified as noted in the diagnosis. Finally, a category of ADHD Not Elsewhere Classified has been added (see Table 74.1). The RDoC scheme, in contrast, is represented as a two-dimensional matrix with rows representing the "dimensions of observable behavior and neurobiological measures," such as "cognition" that includes attention, perception, working memory, declarative memory, language behavior, and cognitive (effortful) control, and columns representing various "units" (levels) of analysis, including genes, molecules, cells, circuits, behaviors, or paradigms (see Table I in Sarah et al., 2012).

DISCLOSURES

Dr. Dierssen's laboratory is supported by the Spanish Ministry of Science and Innovation SAF2010-16427, FIS PS09102673-(CureFXS), and PI11/00744, Jérôme Lejeune Foundation, Fundación Areces and Alicia Koplowitz, FRAXA Foundation and Generalitat de Catalunya SGR1313 and CIBERER, an initiative of the Instituto de Salud Carlos III (ISCIII). The funders had no role in preparation of the manuscript.

Dr. Martínez. The funders had no role in preparation of the manuscript.

75 | FUNCTIONAL CONNECTIVITY: APPLICATION TO DEVELOPMENTAL DISORDERS

LUKE BLOY, RAGINI VERMA, AND TIMOTHY P.L. ROBERTS

MOTIVATION FOR FUNCTIONAL CONNECTIVITY

The human brain consists of approximately 100 billion neurons, organized into a vastly complex network of interconnections. This network, consisting of both local neural circuits and long distance fiber pathways, is thought to provide the anatomical substrate allowing for the distributed interactions between brain regions (Hagmann et al., 2007; Sporns, 2011). Although neural anatomy has been extensively studied using cerebral dissection, relatively little is known about this complex set of connections, which mediate brain function and give rise to the richness of human behavior and experience. Chemical tracing, in which markers are locally injected into the cortex and their subsequent distribution is observed, has facilitated the probing of this network, yielding connectivity information in many animal models (Markov et al., 2011). However, the invasiveness of this technique necessarily precludes its use in human subjects, particularly within a clinical setting.

Noninvasive imaging (Kwong et al., 1992) and electrophysiological techniques have been developed to probe specific aspects of brain function and dysfunction, providing exquisite spatial maps of functional centers (typically using task-performance functional magnetic resonance imaging [fMRI]) and temporal characteristics, such as evoked response components and their amplitude modulation and latency shifts (typically using electroencephalography [EEG], or its magnetic counterpart, magnetoencephalography [MEG]). However, these descriptions are inadequate in fully accommodating the complex dynamic interplay, in space, time, and frequency band, that represents our present understanding of brain functional activity, in terms of structurally and functionally connected networks of neuronal ensembles. The evolution of non-invasive imaging techniques, in order to provide such descriptions, can be seen to have advanced from single-modality methods of identifying functional localization, specialization, and segregation, through real-time measures of activity itself (in terms of neuronal current amplitude and oscillatory power), through multimodality integration of structural, spatial, functional, and spectro-temporal approaches.

Thus, when considering the brain as a dynamic system, it is perhaps more appropriate to progress from brain “maps” toward brain “movies,” allowing the time domain to represent the spatially distinct, but interacting, activity fluctuations. But what underlies the communication and connectivity

between these spatially separate centers, or nodes, of activity? To address this question, the concepts of “connectomes” have been introduced, first to describe the node-to-node structural connectivity (for pairwise nodes distributed throughout the brain), and more recently to describe the relationship between activity at such pairs of nodes (Sporns, 2011). Experimentally, this approach to establishing the nature and complexity of functional connectivity draws primarily on resting state scans, either using functional MRI (rs-fMRI) or EEG/MEG, with a variety of measures of connectivity being constructed (perhaps, the simplest is a simple correlation of two regions’ time courses), ultimately feeding mathematical models of connectivity (often drawing upon graph theoretical constructs) and quantification.

Although there are many compelling rationales for taking this approach to *describe* the functional relationships within the healthy brain, as well as in disease/neuropsychiatric disorders, it is worth considering how functional connectivity might be mediated at the cellular and molecular level. The inhibitory activity of the neurotransmitter γ -aminobutyric acid (GABA) released by inhibitory interneurons, upon the excitatory pyramidal cells (driven primarily by the excitatory neurotransmitter glutamate) might well be a source of modulation of local circuit activity, with measureable short- and long-range sequelae. Thus by observing (at a macroscopic level) the nature of functional connectivity, we might be able to infer (at a microscopic level) regional imbalance in excitation/inhibition, with the prospect of gaining molecular insights into the neurobiological basis of disease, and with the longer-term goal of identifying targets (at a molecular as well as substrate level) for novel interventions. Although this remains a hypothesis, both speculative and incomplete, this argument provides an additional motivation for a comprehensive and detailed, spatio-spectro-temporal characterization of human brain functional connectivity.

MEASURING NEURONAL CONNECTIVITY

The last two decades have seen the development of a number of analysis techniques seeking to move beyond the localization and identification of brain regions that are utilized during specific neurological processes. These new approaches focus on elucidating the degree of interconnectedness between disparate brain regions involved in these processes. By acknowledging

the vast interconnectedness of the brain and attempting to measure the structural and functional connectivity between distinct regions, the utilization of these methodologies enable the realization of a more holistic picture of brain function as it relates to normal and pathological development. This effort is the logical extension of the research focused on investigating functional segregation of the brain and essentially seeks to understand the means of information transfer between these functional units, as well as how this information transfer can be modulated by development and/or pathology.

The direct signaling between distant brain regions is achieved via the afferent and efferent axonal fibers that project between them. Action potentials traveling down these axons synapse on the dendrites of neurons in the destination regions. Although the exact investigation of this anatomical connectivity, at the axonal/synaptic scale, is difficult because of the dynamic nature of synaptic connections and the small spatial scales involved, the investigation of *structural connectivity* at the scale of axonal fiber bundles is possible via a careful modeling of the neuronal white matter. Alternatively, methods have been developed that focus on using spatiotemporal patterns of functional activity to investigate connectivity in the brain. Two types of methods have been proposed that take this second approach. The first, quantifies the *functional connectivity* between two regions based on the statistical relationship (Friston et al., 1993) of their respective functional activity time courses. Alternatively, the second method, *effective connectivity*, attempts to move beyond identifying regions that show similar patterns of activity. It seeks to quantify the causal influence that one neural assembly has over another (Friston et al., 1994) allowing for various hypotheses of neural communication to be tested.

A number of neuroimaging modalities have been used to non-invasively investigate brain connectivity and function. Both *functional* and *effective connectivity* rely on temporal measurements of neuronal activity, which are available from a number of modalities. Of these functional modalities, we focus on those that have been widely adopted, namely, fMRI and the methods of electrophysiology, MEG and EEG. These three methods are inherently non-invasive, requiring no additional contrast agents, and interestingly offer the most extreme tradeoffs between spatial and temporal resolution. The excellent spatial resolution provided by fMRI (2 to 3 mm) allows for the detailed investigation of interregional connectivity, but suffers from its low temporal resolution (typically one to three seconds). Alternatively, EEG and MEG possess excellent temporal resolution (<1 ms), which facilitates an in-depth investigation of neuronal dynamics, but with limited spatial resolution (roughly mm-cm). In contrast, only diffusion weighted MRI (DW-MRI) is able to provide *in vivo* information relating to structural connectivity. This section provides an overview of the methods and imaging modalities that enable the investigation of brain connectivity.

STRUCTURAL CONNECTIVITY

DW-MRI has emerged as the most prominent *in vivo* imaging methodology used to investigate neuronal white matter (WM)

organization and fidelity. The contrast provided by DW-MRI is sensitive to the diffusion of water molecules as they traverse through their microenvironment. Cell membranes and other obstacles impede this motion, reducing the measured signal along directions perpendicular to these boundaries. By acquiring a set of DW-MRI images, each sensitive to the diffusion in different directions, insight can be gained relating to the local diffusion process and, in turn, into the local microstructure that gives rise to it. For instance, in highly ordered tissues such as those consisting of bundles of coaligned axons, the diffusion process is less restricted along the axonal pathway than perpendicular to it, resulting in anisotropic (directed) diffusion, whereas in less ordered tissues, in which the diffusion barriers are more randomly oriented, there is no dominant orientation of the diffusion process, resulting in an isotropic or spherical diffusion process.

At present, the most prominent form of DW-MRI, diffusion tensor imaging (DTI), consists of modeling the local diffusion process with a Gaussian distribution fully characterized by a 3×3 symmetric matrix, the diffusion tensor (DT). An eigensystem analysis can be used to diagonalize the DT, identifying the principal diffusion directions (the eigenvectors), as well as the diffusivity in those directions (the eigenvalues, λ s). This yields information concerning both the shape and orientation of the diffusion process. Additionally, many scalars have been introduced to quantify the amount of anisotropic diffusion that is present in each voxel. For instance, linear anisotropy (CL), planar anisotropy (CP), and spherical anisotropy (CS), have been proposed (Westin et al., 2002) to measure different types of anisotropy in each voxel. However, the most widely accepted measure remains the fractional anisotropy (FA) (Basser and Pierpaoli, 1996). Fractional anisotropy is defined at each imaging voxel, in terms of the eigenvalues of the local DT as

$$FA = \sqrt{\frac{3(\lambda_1 - \bar{\lambda})^2 + (\lambda_2 - \bar{\lambda})^2 + (\lambda_3 - \bar{\lambda})^2}{\lambda_1^2 + \lambda_2^2 + \lambda_3^2}}$$

where $\bar{\lambda}$ is the mean of the eigenvalues.

Fractional anisotropy is a measure of the local severity of the diffusion anisotropy and is often used as a surrogate measure for tissue fidelity/integrity, owing to its relationship with axon myelination (Madler et al., 2008) within WM regions.

The DT model is not the only DW-MRI model currently being used to capture aspects of WM tissue structure and organization. More complex approaches have also been proposed (Tuch, 2004) that have similar goals of capturing the directionality and shape of the diffusion process and thus of the underlying anatomical microstructure. These methods typically require the acquisition of additional data, with prolonged acquisition times, and therefore have only recently been explored within clinical research.

There are two analysis pathways that utilize DW-MRI to investigate structural brain connectivity. The first uses network models to represent the structural interconnectedness of the brain, while the second infers deficiencies in connectivity from group based statistical analysis of diffusion measures such as fractional anisotropy.

NETWORK MODELS: THE STRUCTURAL CONNECTOME

The structural connectome (Hagmann et al., 2007; Sporns et al., 2005), is a network model of the brain consisting of a set of interconnected brain regions that are chosen a priori. For each pair of regions, the degree of structural connectivity between them is computed using tractography algorithms (Bastiani et al., 2012). These tractography algorithms are used to extract complete fiber pathways from the directional information, for instance, the eigenvectors of the DT model, obtained from the DW-MRI model at each voxel. The simplest of these algorithms works by starting at a seed location and moving in the direction indicated by the DW-MRI model. This deterministic process is repeated until the pathway leaves the white matter or until other stopping criteria are met, such as visiting a subthreshold FA location or generating a pathway with a large turning angle. More complex tractography methods also exist. Some use probabilistic methods to determine the next step taken in each pathway, whereas others seek to determine the most efficient path between any of the regions.

By seeding these algorithms at locations in the white matter determined by parcellation algorithms, the set of fibers that traverse the brain can be modeled. The end points of each computed fiber can then be used to examine the structural connections between the cortical and subcortical regions. A number of measures have been proposed to quantify the degree of structural connectivity. The most straightforward simply counts the fibers connecting two regions, essentially treating

each computed fiber as a surrogate for an axonal bundle. Other approaches compute path integrals of scalar indices, such as FA, along each fiber connecting two regions yielding measures representing the fidelity of the structural connection between them. This information, coalesced in the *structural connectome*, allows the investigation of the global patterns of structural connections (Hagmann et al., 2007; Sporns, 2011). Figure 75.1 pictorially depicts the steps of parcellation, tractography, and network matrix generation, in creating a structural connectome. The structural connectome also provides an initial network representation of brain connectivity that is amenable to additional mathematical and graph theoretical analysis.

In addition to the statistical analysis of each individual connectivity strength (Zalesky et al., 2010a), a task made difficult by the large number of possible pairwise connections, these networks have been investigated using topological properties (Rubinov and Sporns, 2010), such as small worldedness and characteristic path length. Topological measures can be used to summarize the local and global properties of the connectome and provide a key to the understanding of the organization of the structural connectivity in individuals or how this organization can be affected by development or pathology. Table 75.1 lists some of the local and global properties that have been computed from these connectivity matrices that represent the network.

The most common of these topological properties are the global measures, which provide a single number to quantify the overall connectivity of a subject. There are three global measures used to capture the efficiency of the connectome.

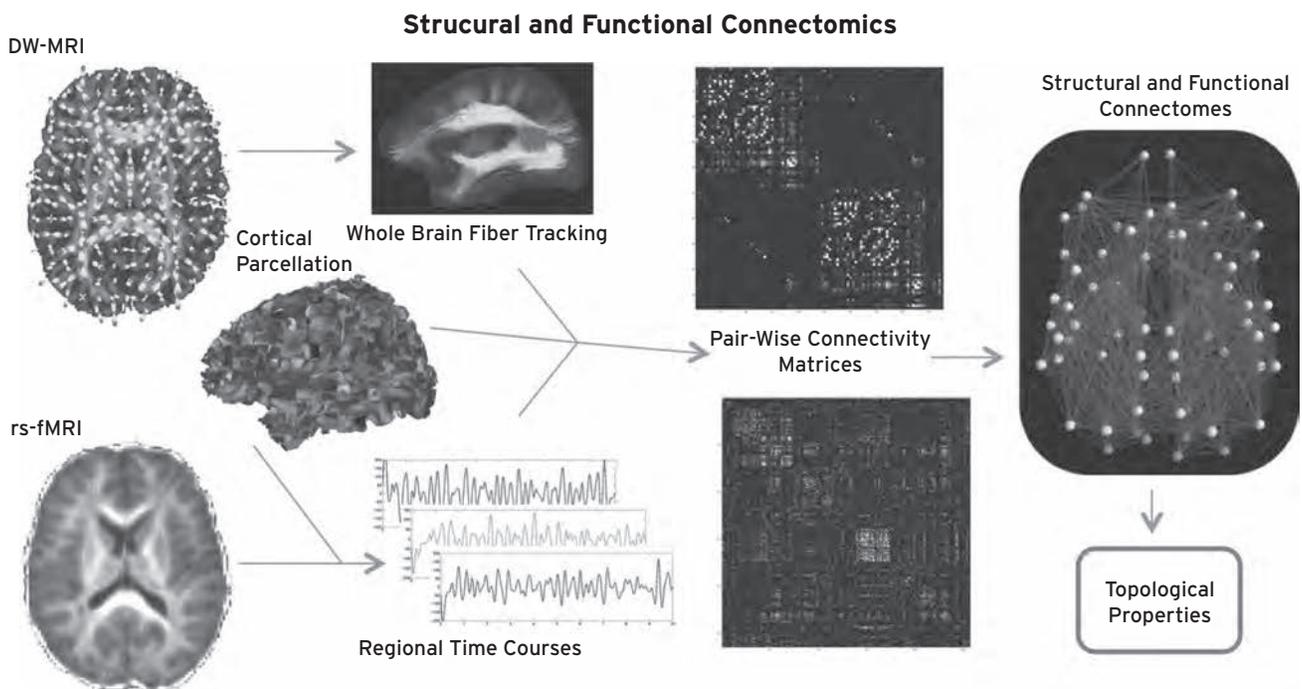

Figure 75.1 Functional and structural connectomics. The computation of structural and functional connectomes begins with the acquisition of either DW-MRI or rs-fMRI datasets and the parcellation of the cortex into the regions of interest (ROIs). Each modality undergoes specific preprocessing to remove artifacts. For DW-MRI, tractography algorithms are used to identify anatomical pathways connecting the ROIs and information related to these is collected into the pairwise connectivity matrix. Using the rs-fMRI datasets, ROI time courses are extracted and the pairwise connectivity matrix is formed by computing the temporal correlation between each ROI time course. These connectivity matrices can then be combined into a joint structural/functional connectome that can be used in subsequent analysis to represent the brain networks of the subject. (See color insert).

TABLE 75.1. Topological properties of connectivity networks

GLOBAL FEATURES	LOCAL FEATURES (DEFINED ON NODE <i>i</i>)
<p>Density $D = \frac{\sum_{i \in N, j \in N, i \neq j} a_{ij}}{N(N-1)}$</p>	<p>Degree $k_i = \sum_{j \in N} a_{ij}$</p>
<p>Characteristic path length</p> $C = \frac{1}{n} \sum_{i \in N} \frac{\sum_{j \in N, j \neq i} d_{ij}^w}{n-1}$	<p>Local efficiency</p> $\eta_i = \frac{1}{2} \sum_{j \in N} \frac{\sum_{h \in N, h \neq i} (w_{ij} w_{jh} [d_{jh}^w (N_i)^{-1}])^{\frac{1}{3}}}{k_i (k_i - 1)}$
<p>Global efficiency</p> $E = \frac{1}{n} \sum_{i \in N} \frac{\sum_{j \in N, j \neq i} (d_{ij}^w)^{-1}}{n-1}$	<p>Vulnerability $V_i = \frac{E - E_i}{E}$</p> <p>E_i is the global efficiency without node i</p>
<p>Modularity</p> $Mod = \sum_{u \in M} \left[e_{uv} - \left(\sum_{u \in M} e_{uv} \right)^2 \right]$ <p>M is the number of modules, e_{uv} is the links proportion connecting nodes in modules u to module v</p>	<p>Betweenness centrality</p> $B_i = \frac{1}{(n-1)(n-2)} \sum_{h, j \in N, h \neq j, j \neq i, h \neq i} \frac{\rho_{hj}(i)}{\rho_{hj}}$ <p>$\rho_{hj}^{(i)}$ is number of shortest paths between h and j passing through i</p>
<p>Transitivity $T = \frac{\sum_{i \in N} 2t_i}{\sum_{i \in N} k_i (k_i - 1)}$</p>	<p>Strength $k_i^w = \sum_{j \in N} w_{ij}$</p>
<p>Assortativity $A = \frac{L^{-1} \sum_{i, j \in L} k_i k_j - \left[L^{-1} \sum_{i, j \in L} 0.5(k_i + k_j) \right]^2}{L^{-1} \sum_{i, j \in L} 0.5(k_i^2 + k_j^2) - \left[L^{-1} \sum_{i, j \in L} 0.5(k_i + k_j) \right]^2}$</p>	<p>LEGEND</p> <p>N is set of all nodes, n is number of nodes, d_{ij} is shortest path between i and j, a_{ij} is the connection status between i and j, w is weight of link, t_i is the number of triangles around i, L is set of all links, and l is number of links.</p>

The *density* of the network is the ratio of the number of found connections to the total possible number of connections and is a general measure of how overtly connected the network is. The *characteristic path length* is the average number of connections required to connect any pair of regions. Finally, the *global efficiency* is related to how well the nodes are able to communicate. Similarly, there are three measures that capture the modularity of the network: *modularity*, *transitivity*, and *assortativity*. Topological measures can also be used to examine local (regional) features as well. These include local versions of *efficiency* and *degree*, as well as measures that focus on the resilience (*betweenness centrality*) and fault tolerance (*vulnerability*) of the entire network to disruptions of a particular region.

VOXEL- AND TRACT-BASED CONNECTIVITY

A second approach to the investigation of *structural connectivity* has focused on identifying population differences in DW-MRI derived scalar measures (most typically FA) used for representing local white matter tissue fidelity. (Note: It is not appropriate to generally consider this “integrity,” as there are normal developmental changes in microstructural organization that should not be interpreted as changes in “integrity” with its associated semantic interpretation.) Localizing these differences enables

the identification of altered white matter tissue structure and the ability to infer differences in the connectivity of the pathways passing through those regions. There are a number of spatial scales in which this approach has been successfully used. Population differences have been investigated at both the voxel and regional level, by aligning the images of each subject to a common spatial coordinate frame or anatomical atlas and then performing group-wise statistical analysis at each voxel or on average scalar measures extracted from each atlas defined region. Similar approaches have been undertaken, using fiber tractography to define specific anatomically relevant pathways, such as the acoustic radiations, which are then used to define regions for statistical analysis, as discussed, or alternatively, statistical differences in scalar indices can be investigated along the length of the pathway (Goodlett et al., 2009).

LIMITATIONS

DW-MRI allows researchers to infer the organizational structure of neuronal WM that is largely governed by the underlying organization of axonal fibers. Although it is sensitive to these small structures, the spatial resolution of DW-MRI images is generally on the order of 2 mm. Thus the signals that are measured, as well the models that are used to represent the local structures, are all ensemble averages of the many fiber bundles contained in each voxel.

This scale discrepancy leads to many voxels containing tissue of diverse microstructure, encompassing complex fiber organization and geometry. Current estimates suggest that as many as two-thirds of the WM voxels (Behrens et al., 2007) show evidence of multiple, differently oriented fiber populations. Thus the models that are used to represent this organization must be able to accurately capture all of this complexity. The DT is able to accurately measure a single diffusion direction, making it well equipped to handle many of the major fiber pathways in the brain. However, in regions where multiple fibers intersect, more complex models are needed to reflect these geometries. Although a number of such models have been put forward, including high angular resolution diffusion imaging (HARDI) and diffusion spectrum imaging (DSI), there is no consensus on the optimal acquisition protocol and the analytic modeling.

Related to the issues arising from low spatial resolution and modeling is the need to improve our understanding of the biological basis for many of the diffusion scalars that are routinely used as measures of connectivity (Jones, 2010). For instance decreases in the FA of voxels containing only a single well-organized fiber population may have different root causes than observed FA decreases in voxels containing multiple fiber populations, each with different orientation.

Finally, as the field of structural connectomics matures, and studies move beyond examining topological properties of brain networks to investigating these networks on a connection by connection basis, the biological basis of these connection strengths and the topological measures computed from the networks will need to be investigated. There will also need to be a search for consensus in determining the optimal combination of tractography (Bastiani et al., 2012) methods, region parcellations (Zalesky et al., 2010), and connectivity measures (Bassett et al., 2011) to be used to create and analyze the network.

FUNCTIONAL MAGNETIC RESONANCE IMAGING–BASED CONNECTIVITY

Functional magnetic resonance imaging (fMRI) is a magnetic resonance imaging technique that is used to measure brain activity by detecting changes in the flow and oxygenation of blood. The blood-oxygen-level-dependent (BOLD) signal contrast provided by fMRI allows researchers to investigate the hemodynamic response to local increases in oxygen metabolism caused by neuronal activity. Images of these hemodynamic responses are acquired, typically every one to three seconds generating a time series for fMRI data. The high spatial resolution of fMRI (typically, 2 to 3 mm) makes it extremely well suited for investigating the roles and functions of brain regions, offering valuable insights into the functional segregation of the brain. With the broadening of research interests beyond basic functional localization, novel fMRI analysis methodologies have been developed that strive to characterize and quantify the degree of functional integration and communication that occurs between brain regions.

There are two experimental paradigms that are often used in fMRI investigations of neural connectivity. The most widely used fMRI-based connectivity methodology, resting state fMRI (rs-fMRI), centers on quantifying the degree of temporal synchrony between distant brain regions, during rest (Biswaly, 1995), typically over the course of two to five minutes. Low-frequency (<0.1 Hz) BOLD signals of distant gray matter regions have been shown to have strong correlations through a wide variety of resting states, including eyes closed, or eyes open with simple fixation. The initial rs-fMRI studies (Biswal et al., 1995) demonstrated high correlation of the low-frequency BOLD signals between the left and right primary motor network areas, illustrating not only that these signals were able to capture the spontaneous activity that occurs during rest, but that regions known to functionally interact have similar temporal signatures at rest. Subsequent studies have successfully replicated this finding in the motor cortex, but also demonstrated high temporal correlations between regions of other known functional networks, such as the primary visual network, auditory network, and higher-order cognitive networks (Rosazza and Minati, 2011).

Alternatively, a number of studies focus on quantifying the neural connectivity between distant brain regions while the subject is actively performing a specified task. By manipulating the task being performed, experimenters can exert a degree of control over which cognitive processes and neural networks are being activated during a specific experiment. Although many connectivity analysis methods are applicable to either experimental paradigm, often particular analysis methods have been adopted based on the type of fMRI data used. For instance, the majority of studies using the *functional connectivity* measures, temporal correlation, independent component analysis, and so on, have focused on measuring intrinsic connectivity that occurs during rest. The *effective connectivity* measures, like dynamic casual modeling (DCM) and Granger causality (GC), which attempt to capture directional or causal nature of the interactions between different regions, have typically made greater use of the task-driven paradigm.

TEMPORAL CORRELATION

Several techniques have been described seeking to identify the spatial patterns of functional connectivity based on the BOLD signal. The most straightforward of these involves extracting the time series from a seed region of interest (ROI) and determining the temporal cross-correlation between this signal and those extracted from other brain voxels. This process generates maps of voxels that are functionally connected with the seed region. Although the dependence of an a priori definition of the seed region hinders the simultaneous investigation of multiple systems or the exploration the interaction of many regions, it does facilitate the simple extraction of networks with known function or those affected by certain pathologies.

One of the brain networks most studies using ROI-based temporal correlations focus on is the default mode network (DMN). The DMN is a network of brain regions including the medial prefrontal cortex, medial temporal lobe, and the

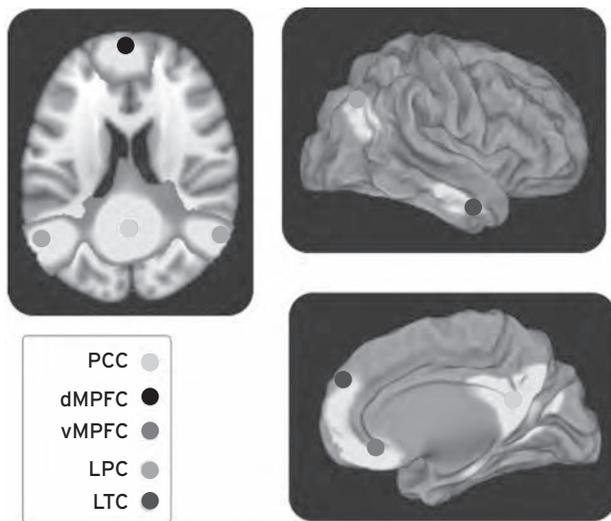

Figure 75.2 Default mode network. Temporally correlated activity in regions of the default mode network (DMN) has been shown to increase during non-goal-oriented activities and to decrease during goal oriented activities. The areas of the DMN is illustrated via a group averaged ($n = 225$) temporal correlation map generated by using the posterior cingulate cortex (PCC) as the seed region. The prominent regions of the DMN, the dorsal and ventral medial prefrontal cortexes (dMPFC and vMPFC), the lateral temporal cortex (LTC), and the lateral parietal cortex (LPC) are clearly indicated as being positively correlated with activity in the PCC. (See color insert).

posterior cingulate cortex. Figure 75.2 illustrates the DMN computed from 225 healthy subjects; rs-fMRI datasets from each subject were first spatially aligned. A seed region was placed in the posterior cingulate cortex and used to generate correlation maps to the other voxels of the brain. The average correlation map is shown in Figure 75.2, clearly identifying the main regions participating in the DMN. Connectivity between these regions has been robustly demonstrated in subjects not performing specific tasks (Fox and Raichle, 2007), and deactivated during the performance of goal-orientated tasks. Although the biological function of the DMN remains unresolved, its relationship to a number of neurodevelopmental disorders has become a major topic of research.

FUNCTIONAL CONNECTOMICS

A number of more holistic approaches have been put forth, seeking to examine the simultaneous interaction of many regions. Similar to the generation of structural connectomes, functional connectomes have been extracted from rs-fMRI (Yeo et al., 2011). As with the structural connectome, the functional connectome depends on a predefined set of regions (see Fig. 75.1). Time courses are extracted from each region and a correlation matrix is constructed, called the functional connectome. Clustering algorithms can be applied to identify highly interconnected subnetworks, or hierarchical topological maps of a subject's functional connectivity. Alternatively, topological properties, such as small worldedness, can be computed from these matrices (as in the diffusion-based structural connectivity matrices) and used to summarize the overall

functional connectivity patterns of the subject (Rubinov and Sporns, 2010). Table 75.1 shows some of the local and global properties that can be computed from these network matrices and used for subsequent statistical analysis of functional connectivity, analogous to structural connectivity.

INDEPENDENT COMPONENT ANALYSIS

An additional technique used for analyzing rs-fMRI data is the utilization of independent component analysis (ICA) to automatically discover highly interconnected networks of brain activity (Calhoun et al., 2008). As opposed to relying on a priori seed regions, ICA makes use of sophisticated algorithms to simultaneously analyze the entire rs-fMRI dataset (the time series of every voxel), and to decompose it into statistically independent components. This process yields spatial maps for each component, in addition to the time series for that component, allowing both the spatial extent and the temporal properties of each component to be characterized and analyzed. The temporal properties of fMRI noise and signal arising from neuro-anatomical systems are typically quite different, allowing ICA to isolate the two. Although this trait is extremely useful, it is typically up to the user to identify which component is noise and which correspond to actual networks, introducing the possibility for user bias. Relatedly, the results of ICA are often dependent on the number of components that are used in the decomposition. These issues combined with the vagaries introduced by the complexity of the decomposition process, can make biological interpretation of spatial maps and time series returned by ICA difficult. As a tool for hypothesis generation (for subsequent more focused exploration), this methodology, nonetheless, has considerable utility and promise.

Other approaches have been proposed to extract the dominant components and networks for resting state connectivity matrices. One popular approach is to attempt to increase the biological interpretation of the resulting components by imposing certain traits that are expected from physiologically based networks. For instance, by ensuring a decomposition that promotes positive connection values (Ghanbari et al., 2012), methods can be developed that extract subnetworks with direct connectivity interpretability. Similarly, decomposition algorithms can be developed that seek to identify components that maximally distinguish between patient and control populations (Batmanghelich et al., 2012), possibly shedding light on the neurologic underpinnings of disease.

DYNAMIC CAUSAL MODELING

Dynamic causal models (DCMs) are generative models of brain responses (Friston et al., 2003). They are used to describe the relationship between the unobserved neuronal states and the measured fMRI time courses. These models are governed by parameters that are constrained by a prior distribution that reflects empirical knowledge about the range of possible parameter values. Fitting a model to a given dataset involves

determining the statistically optimal set of parameter values that best fit the observed data. When the model being fit includes interactions among different anatomical regions, the values of these parameters can tell us the degree to which these areas are interacting. It is important to recognize that the central goal of DCM is not necessarily to examine the effect elicited by an experimental condition, but serve as a means of comparing the possibility of alternative biologically meaningful models. Thus one of its principal applications is the investigation of models in which many regions interact to elicit a particular response.

Although there is considerable flexibility in the types of models that can be used, there are a number of traits that are common across many DCMs. First, DCMs are, by definition, dynamic; part of the modeling centers around describing, either linearly or nonlinearly, the temporal dynamics of the underlying neuronal responses. Second, DCMs describe how the dynamics in one region interacts with that of another region and is modulated by experimental stimuli or spontaneous activity. The final central piece of any DCM model is a biologically realistic forward model relating the unobserved neuronal response to the observed fMRI response. In fMRI-based studies, these models typically attempt to describe the local hemodynamic response to the underlying activity via a realistic vascular model that incorporates properties such as vascular expansion, arterial volume, and blood flow. One of the principal strengths of DCMs is the ability to compare different models based on their suitability to account for various datasets, leading to improvements in hemodynamic models, as well as models of brain connectivity.

GRANGER CAUSALITY

As opposed to techniques such as DCM, which require the testing/validation of full models, data-driven techniques do not make any assumptions about the underlying model or require a priori information concerning the spatiotemporal interactions of the various regions. Granger causality mapping is a data-driven approach that uses vector autoregressive (VAR) models of fMRI time courses extracted from two brain regions to quantify the ability of one time series to predict the other. Granger causality is built explicitly around the ideas of temporal precedence, if including past time points from region x 's time series improves the prediction of the current value of a different region y 's time series, then x can be thought of as causing y . In fMRI this process can be used to compute Granger causality maps (GCMs) that indicate the causal sources or targets of a preselected seed region (Roebroeck et al., 2005).

Granger causality makes use of VAR modeling to model each time series,

$$x(t) = \sum_{i=1}^p A_i x(t-i) + \varepsilon(t),$$

where A_i is the set of mixing coefficients at time lag i and $\varepsilon(t)$ is white noise. The core of the VAR model is that the current value of the time series $x(t)$ is modeled as a linear combination of the

most recent p values. For two such time series, the Granger causality can be computed in terms of their respective VAR models. It should be noted that although the predominant use of Granger causality has centered on the VAR models, it is possible to formulate it in a more general nonlinear modeling framework (Stephan and Roebroeck, 2012).

LIMITATIONS

All of the fMRI-based connectivity methodologies discussed here have utilized the BOLD signal time series to examine the dependence or synchrony between anatomically disparate regions, each arriving at some measure of connectivity. In the case of fMRI-based functional connectivity, in which statistical relationships between time courses are used to determine the degree of connectivity, it is important to consider the existence of nuisance signals that may obfuscate the underlying neuronal signal and lead to spurious findings.

Because of the low temporal sampling rate of fMRI (around 0.5 Hz), many of the relatively higher-frequency components of cardiac and respiratory oscillations are aliased into the low-frequency rs-fMRI data set (<0.1 Hz), leading to spurious connectivity findings, because these signals affect the global signal. Although these are certainly of concern, because they are global signals, their effect can be adequately mitigated by regressing each voxel's time course with the mean global time course or from the mean time course of central WM regions in which no neuronal activity is occurring.

The primary nuisance signal revolves around the possible confounds that arise from subject motion. As can be imagined, even small amounts of motion, on the order of a few millimeters, can cause pronounced changes in the signal values of many voxels. Furthermore, because these signal changes are caused by gross subject motion, they are coincident in time and can lead to increases in temporal correlation. Recently, the effect of motion has been experimentally demonstrated to have significant impact of rs-fMRI-based connectivity measures (Satterthwaite et al., 2012; Van Dijk et al., 2012). This issue is particularly acute, as compliance in neuropsychiatric patient populations is generally more difficult, resulting in higher degrees of motion in patient populations than in control populations, introducing possible systematic biases into the connectivity analysis. Thus if there are group differences (patients vs. controls or younger vs. older subjects) in motion, there may appear to be group differences in functional connectivity. Whether these are authentic functional connectivity differences or entirely spurious consequences of the motion differences requires more thorough analysis (Van Dijk et al., 2012).

A final issue that is important to consider is that the BOLD signal is a direct measure of the hemodynamic response, which is coupled to the underlying neuronal activity via metabolism. Because the hemodynamic response is slow, compared with the underlying neuronal activity, it typically obfuscates the high temporal dynamics of the underlying neuronal signal. Thus fMRI is limited not only by scanner sampling rate, but also ultimately by the physiological origin of the signals. This

relegates fMRI to the investigation of relatively slowly changing signals, hindering its ability to quantify higher-frequency synchronizations. Furthermore, regional differences in the time course and shape of hemodynamic response function of the brain's vascular system (Ances et al., 2008), in principle, additionally confound measures of connectivity derived from such signals.

MEASURING CONNECTIVITY WITH ELECTROPHYSIOLOGY

Unlike the preceding fMRI-based neuroimaging methods, which are sensitive to secondary measures of neural activity such as the hemodynamic response, the magnetic and electrical signals measured by MEG and EEG are directly generated by neural activity. There are two clear benefits to using MEG/EEG for measuring functional and effective connectivity. First, the direct sensitivity to neuronal activity decreases the dependence on metabolic activity and vascular response, which can confound fMRI measurements. Second, and more important,

the high temporal resolution of these methods, typically less than 1 ms, allows much better characterization of the temporal dynamics of neuronal systems. As the methodologies for determining functional and effective connectivity are largely based on determining statistical relationships between the time courses of different brain regions, the increased temporal resolution offered by these electrophysiological methods makes them excellent choices to the investigation of neuronal connectivity (Fig. 75.3). Furthermore, the collection of data with high temporal resolution allows separate characterization of activity in different spectral bands (e.g., delta 0.5 to 4 Hz, alpha 8 to 13 Hz), as well as assessment of such phenomena as cross-frequency coupling (or phase-amplitude coupling), wherein activity in one frequency band may be modulated by activity in another.

Electrophysiology has been used to investigate brain connectivity since the 1960s. During this time the methods that have been utilized to investigate it have grown in complexity to take better advantage of the available high temporal resolution. In addition to their use in fMRI, all the mentioned functional connectivity analysis methodologies are applicable to

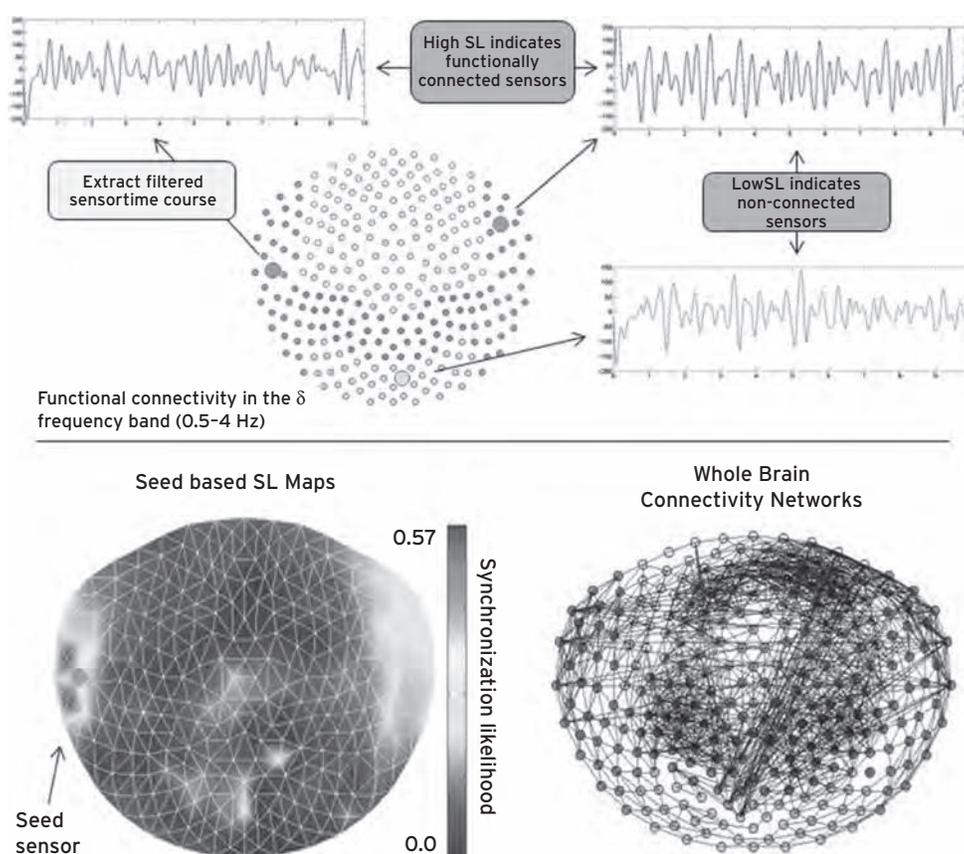

Figure 75.3 MEG based functional connectivity. Measuring function connectivity with electrophysiologic modalities like MEG proceeds by extracting time courses of interest from the MEG sensor data. The high temporal resolution of MEG allows users to focus on connectivity within particular frequency bands; for instance, this figure focuses on connectivity in the delta (0.5 to 4 Hz) frequency band. The high resolution also allows for quantifying functional connectivity using complex measures, such as synchronization likelihood (SL). These measures can be computed on time courses from selected regions, shown at the top. Functionally connected sensors, such as those above the right and left motor areas, indicated by purple time courses, have higher SL values, whereas the SL between non-functionally connected regions, such as the occipital lobe and motor areas, have lower SL values. Maps showing connectivity to a particular seed region can also be computed. Similarly, whole brain networks can be determined by examining all of the pair-wise connectivity measures. (See color insert).

electrophysiological time courses (Sakkalis, 2011), and so will not be recapitulated here. Additional methodologies have been developed that take better advantage of the temporal resolution available, which we introduce briefly in the following.

PARTIAL DIRECTED COHERENCE

Like Granger causality, partial directed coherence (PDC) is an effective connectivity technique that seeks to measure directed (causal) relationships between the time series of two regions. It accomplishes this by using a multivariate vector autoregression (MVAR) model. As opposed to GC, based on VAR models, which only examine the relationship between two autoregressive models, the utilization of an MVAR model estimates a full linear model, including interactions between all of the time courses. For instance, let the set of all the regional time courses be represented as $\mathbf{x}(t) = [x_1(t), \dots, x_n(t)]^T$, where $x_1(t)$ is the time course for region 1 and so on. The MVAR model is

$$\mathbf{x}(t) = \sum_{i=1}^p \mathbf{A}_i \mathbf{x}(t-i) + \boldsymbol{\varepsilon}(t),$$

where \mathbf{A}_i is the matrix of mixing coefficients, including the interaction terms, and $\boldsymbol{\varepsilon}(t)$ is a multivariate Gaussian noise. In contrast with GC, a time domain approach, PDC is defined in the frequency domain. It requires the computation of the Fourier transform of the set coefficient matrices (\mathbf{A}_i s), resulting in a coupling matrix defined across the frequency domain ($\mathbf{A}(f)$). The PDC between any two channels is then computed from this Fourier transform (Sameshima and Baccala, 1999) as

$$\frac{\overline{\mathbf{A}}_{ij}(f)}{\left(\overline{\mathbf{A}}_{i:}^H(f) \overline{\mathbf{A}}_{:j}(f)\right)^{\frac{1}{2}}}$$

where $\overline{\mathbf{A}}(f) = \mathbf{I} - \mathbf{A}(f)$ and H represents conjugate transpose matrix operation.

MAGNITUDE SQUARED COHERENCE

Magnitude squared coherence (MSC) is the second most widely used method for examining functional connectivity from either MEG or EEG signals, after linear cross correlation. The MSC between two time courses $x(t)$ and $y(t)$ is defined as

$$MSC_{xy}(f) = \frac{|S_{xy}(f)|^2}{S_{xx}(f)S_{yy}(f)},$$

where $S_{xy}(f)$ is the cross spectral density function, the Fourier transform of the cross correlation between $x(t)$ and $y(t)$, and $S_{yy}(f)$ and $S_{xx}(f)$ are the respective autospectral density functions. Magnitude squared coherence provides a means to quantify the similarity between the time courses at each frequency. Typically, Welch's method is used to compute the cross and auto spectral density functions. This consists of dividing $x(t)$

and $y(t)$ into a number of segments by appropriate windowing techniques and then using the discrete FT in each segment. The frequency response is then averaged, across all the segments, to generate the $MSC(f)$. During this process, care must be taken to ensure the stationarity of both time series during each segment.

PHASE SYNCHRONIZATION: THE PHASE LOCKING VALUE

In addition to the linear methods like cross-correlation, ICA and MSC that have been discussed, a group of non-linear methods have developed out of the field of nonlinear dynamics and chaos theory (Stam, 2005). Of this group, the phase locking value (PLV) has emerged as a prominent choice to measure the phase synchrony between two signals. Phase synchrony is defined when the difference between the instantaneous phase, $\phi(t)$, of the two signals, x and y , being compared, remains constant, $|\phi_x(t) - \phi_y(t)| = \text{const}$. The instantaneous phase of each signal can be estimated using either the Hilbert transform or via wavelet convolution (Ghuman et al., 2011). Once the instantaneous phases have been estimated, the PLV can be computed as

$$PLV = \left| \frac{1}{N} \sum_{k=0}^{N-1} e^{i(\phi_x(k\Delta t) - \phi_y(k\Delta t))} \right|$$

where N is the length of the signal, Δt is the sampling period, and $|\cdot|$ represents the magnitude of a complex number. The PLV generates a normalized number, between 0 and 1, which is sensitive to the stability of the phase relationship between the two signals.

CROSS MUTUAL INFORMATION

Cross mutual information is able to capture both linear and non-linear relationships between time series by measuring their interdependence using concepts derived from information theory. The mutual information of two observations (X , Y) is defined as

$$I(X, Y) = \sum_y \sum_x p(x, y) \log \left(\frac{p(x, y)}{p_x(x)p_y(y)} \right)$$

where $p(x, y)$ is the joint probability distribution of X and Y , and $p_x(x)$ and $p_y(y)$ are marginal probability distributions. This computation is typically difficult because of the need to correctly estimate these probability distributions (Tsiaras et al., 2011).

GENERALIZED SYNCHRONIZATION

In addition to measuring the synchrony between time signals with respect to their phases, a number of approaches have

been suggested that define synchronization in a more general context (Quiñan Quiroga et al., 2002). The majority of these methods make use of time-delay embedding to compute feature vectors, for example, a vector consisting of the next n time points of a signal, at each time point. These vectors are used to describe the short time dynamics of the underlying system that is being measured. Information regarding the synchronization of two signals can be extracted by examining how these feature vectors repeat within each, and how the repeatability patterns of each signal are correlated. One of the more widely utilized measures of generalized synchronization is synchronization likelihood (SL) (Montez et al., 2006). The SL technique assumes that two signals are synchronized if the repetition pattern of one signal coincides with the repetition pattern of the second signal. Suppose that the number of pattern repetitions in each of the two signals is n_{ref} and the number of time instants that is shared between the two patterns of repetitions is $n_{k_1k_2}$ then SL is defined as $n_{k_1k_2} / n_{ref}$, which is a measure of coupling between the two signals. Figure 75.3 shows SL connectivity maps between different regions of the brain.

LIMITATIONS

As with the fMRI- and structural-based measures of connectivity, the use of electrophysiology in determining the likelihood of connections is not without limitations. In most cases, the connectivity methods described in the preceding have been used on time courses acquired directly from the MEG or EEG sensors. These sensors measure fluctuations in the magnetic fields or electrical potentials at the surface of the head. The activity of multiple brain regions contribute to the measured surface field, hindering the direct brain-level interpretation of sensor-level connectivity (Schoffelen and Gross, 2009), because the recordings of two sensors may be driven by a single brain region leading to a false detection of connectivity.

A number of source localization methods exist (Salmelin and Baillet, 2009) that determine time courses for specific regions of the brain, opening up the possibility of performing connectivity analysis within the source space, avoiding the interpretation issues that pervade the analysis of sensor-level connectivity. Methods include multiple regional source current dipole modeling, spatial filtering with beamformers, and L1- and L2-minimum norm estimation. Care, however, must be taken when choosing a source localization methodology, as many methods make assumptions about the statistical relationship between the time series of the computed sources and may have a significant effect on the measured connectivity.

APPLICATIONS IN NEURODEVELOPMENTAL DISORDERS

The study and quantification of brain connectivity offers researchers unique insight into the structure, organization, and fidelity of the neuronal circuits that facilitate our cognitive functions and complex behavior. Recently, there has been a change

in the perspective concerning the biological underpinnings of many neuropsychiatric disorders. Increasingly, the models of these disorders, specifically developmental disorders, are moving away from focusing on the localized dysfunction of specific anatomical regions. Instead, these models stress the interconnectedness of the functional units of the brain, hypothesizing that the etiology of many disorders arises from abnormal network patterns of communication and connectivity.

As connectivity based analysis methods have advanced to the point where neuronal connectivity can routinely be investigated *in vivo*, its successful use in illuminating the underlying processes of several neurological and neurodegenerative diseases has become more pronounced. Although this field is in its infancy, it is evident that it holds considerable promise, motivating its increased adoption within clinical research programs. Here we highlight some of the insights these approaches have garnered into normal development, as well as, into developmental disorders such as autism spectrum disorders, schizophrenia, attention deficit/hyperactivity disorder, obsessive compulsive disorder, and Tourette syndrome.

TYPICAL DEVELOPMENT

The investigation of normal brain development is a very active area of research. The overarching goal is that by better characterizing and understanding normal neuronal development, we are better able to identify deviations, such as delays or periods of accelerated growth, from normal developmental progression that are associated with particular disorders (Shaw et al., 2010). Furthermore, an increased understanding of the interactions between genetic and environmental factors and development trajectories, better enables researchers to identify the underlying biological factors that drive deviations from this process and thus may illuminate underlying endophenotypes of specific disorders.

Although longitudinal studies focused on structural connectivity are still rare, there have been a number of cross-sectional studies to investigate WM development. DTI lifespan studies have shown that FA values in WM increase during adolescence and early adulthood, peaking roughly around 33 years of age (Hasan et al., 2007). This parabolic increase is followed by an equally gradual decrease. Not all fiber pathways develop with identical FA trajectories; pathways connecting the frontal and temporal lobe develop latest (Lebel et al., 2012), whereas those thought to involve more critical processing, such as, the corpus callosum (CC), the inferior longitudinal fasciculus (ILF), and the fornix develop earlier.

Structural connectome models have also been utilized to study differences in the organizational and topological properties of the neural networks with age. Gong et al. (2009) focused on changes across the entire adult lifespan (19 to 84 years), finding decreases in cortical regional efficiency, particularly in the parietal and occipital neocortex, with increases in the frontal and temporal regions. Global efficiencies did not show significant changes. Hagmann et al. (2010) focused on childhood and adolescent development (2 to 18 years), finding increases in global efficiency, node strength, and decreases in clustering

coefficient. This suggests that the overall effect of development on structural network properties is increased network integration and decreased segregation.

This theme of decreased local connectivity, combined with an increase in long-range connectivity as we mature from childhood through adolescence, is also borne out from the rs-fMRI literature. Studies focusing on the DMN in children have shown that although the anatomical regions participating in the DMN are the same as in adults, there are differences in the degree of connectivity between them, specifically lower connectivity between the mPFC and the PCC was seen in children (Supekar et al., 2010). Similar findings have emerged from studies focused on more global connectivity patterns. In a metaanalysis of rs-fMRI (Power et al., 2010), studies focused on connectivity within specific age groups illustrate the general trend of decreasing local (short-range) connectivity and increasing global (long-range) connectivity with age (Fair et al., 2009). Development has also been investigated using electrophysiology, for instance, EEG-based connectivity as measured with synchronization likelihood showed a similar developmental trajectory as those measured using WM volume (Smit et al., 2012), whereas topological properties were indicative of a decrease in randomness with development.

SCHIZOPHRENIA

One of the dominant hypotheses concerning the etiology of schizophrenia centers on disruptions of neuronal connectivity (Bullmore et al., 1997), making the study of brain connectivity of particular interest. As with normal development, the focus of many structural connectivity studies has been on identifying differences in regional measures of WM fidelity, typically FA, between schizophrenic and control populations. The most consistent of these findings indicate abnormal tissue structure in the cingulate, the CC and frontal WM, whereas the superior longitudinal fasciculus (SLF), the inferior fronto-occipital fasciculus (IFOF), and the uncinate fasciculus have also been implicated. Topological analysis of whole brain structural connectivity networks of schizophrenic patients as compared with controls has also been performed, demonstrating decreases in global network efficiency with decreases in regional efficiency found in frontal regions and limbic regions (Wang et al., 2012; Zalesky et al., 2011).

fMRI-based connectivity methodologies have also been extensively used in the study of schizophrenia. Evidence for dysconnectivity in schizophrenia has been found involving various brain regions (Honey et al., 2005; Zhou et al., 2007). Network-based differences have also been observed, for instance those involving the prefrontal/temporal regions and the DMN (Whitfield-Gabrieli et al., 2009). Additionally, a number of whole brain functional connectome studies have demonstrated altered topological properties in the networks of schizophrenics. In general these studies have found that the complex brain networks in schizophrenia are less hierarchical, have decreased small-world indices, and are less efficiently wired (Lynall et al., 2010).

Connectivity analysis, using MEG- and EEG-based measures, has also been performed. Mutual information computed between EEG time courses, acquired during rest, showed significant increases both within and between hemispheres. Magnetoencephalography-based mutual information demonstrated a relationship between connectivity in the β band and performance in a working memory task (Bassett et al., 2009). Finally, there is a growing body of evidence of altered γ oscillations in schizophrenia (Gandal et al., 2012). For instance, a sensor-based EEG study using phase locking and coherence during a gestalt perception task (Spencer et al., 2003) demonstrated deficits in γ synchrony as well as abnormal coherence patterns.

AUTISM SPECTRUM DISORDERS

The autism spectrum disorders (ASDs) are developmental disorders characterized by impaired social interaction, impaired communication abilities, and repetitive behaviors. Increasingly, they are being viewed as disorders of functional networks (Welsh et al., 2005). There is a growing body of neuroimaging research supporting the hypothesis that ASD could be a disorder of impaired or altered connectivity (Courchesne and Pierce, 2005), specifically, a decrease in the long-range connectivity between the frontal lobe and the rest of the brain and an increase short-range intrafrontal lobe connectivity.

DW-MRI studies of ASD have shown alterations in local WM organization. Although there has been some variability in reported findings, the predominant pattern is one of compromised WM of the frontal and temporal lobes (Ameis et al., 2011; Sundaram et al., 2008). Tract and region-based analysis has implicated the ILF, IFOF, and SLF (Nagae et al., 2012), in addition to differences in the CC and, to a lesser extent, the cortical spinal tract. These findings clearly suggest altered structural connectivity between the frontal and temporal lobes.

Rs-fMRI studies have also generated evidence of altered connectivity in ASD. Studies focusing on the DMN have shown the regions of the DMN to be less strongly connected (Weng et al., 2010) in subjects with ASD compared with controls. Decreases in the connectivity of social and emotional processing networks have also been observed using rs-fMRI (Ebisch, et al., 2011). Decreased functional connectivity in ASD between frontal and posterior regions has been found as well during a variety of tasks (Just et al., 2012).

Finally, studies using electrophysiology to measure connectivity in ASD have also been undertaken. Electroencephalography-based studies of sensor level MSC (Murias et al., 2007b) have indicated both increased and decreased connectivity in a number of frequency bands. Decreases in delta band functional connectivity, measured using synchronization likelihood between frontal and occipital EEG sensors has also been demonstrated (Barttfeld et al., 2011). Magnetoencephalography-based connectivity in ASD has been investigated using mutual information, PDC and MSC, with the goal of extracting useful biomarkers (Tsiaras et al., 2011) potentially able to aid in

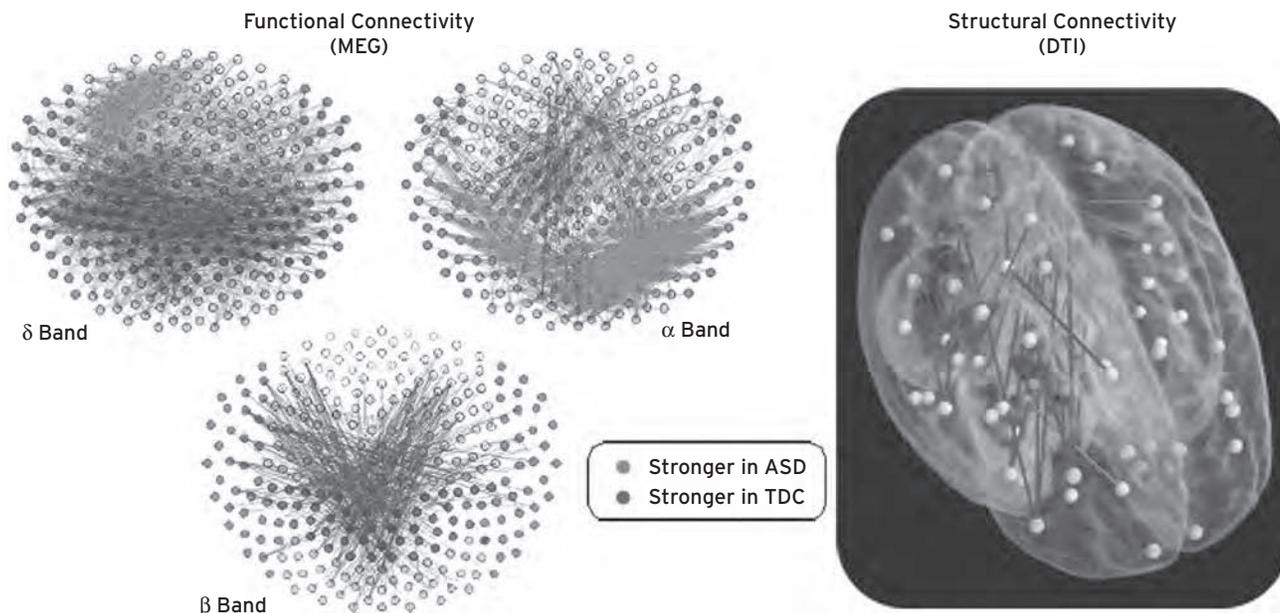

Figure 75.4 Structural and functional connectivity differences between ASD subjects and TDCs. Probabilistic tractography was used to compute DTI-based structural connectivity networks for each subject, which were then subjected to statistical analysis. Synchronization likelihood was used to compute functional connectivity networks in five frequency sub-bands of resting state MEG time courses. Shown are the significant different connections in the δ (0.5 to 4 Hz), α (8 to 13 Hz), and β (13 to 30 Hz). Light gray lines indicate connections that are stronger in the ASD population (predominantly shorter range frontal delta-band connections and posterior alpha-band connections), whereas dark gray lines indicated stronger connections in the TDC population (predominantly longer range and interhemispheric connections). (See color insert).

early diagnosis, prognosis, and stratification for treatment. Differences in the dominant components of MEG-based synchronization likelihood connectivity networks have also been shown (Ghanbari et al., 2012), with ASD subjects lacking a clear interhemispheric connectivity component, but having elevated local frontal delta- and posterior alpha-band connectivity. Figure 75.4 shows representative structural and functional connectivity differences between ASD subjects and typically developing controls (TDCs).

ATTENTION DEFICIT/HYPERACTIVITY DISORDER

One of the most common neurodevelopmental disorders affecting children and adolescents (and, indeed, adults) is attention deficit/hyperactivity disorder (ADHD). Attention deficit/hyperactivity disorder is commonly characterized by impaired attention and concentration, along with increased hyperactivity and impulsivity. Although pharmacological intervention is often successful, the neuronal underpinnings of the disorder remain poorly understood.

A number of rs-fMRI studies (Castellanos and Proal, 2012; Konrad and Eickhoff, 2010) have used ROI-based temporal correlations to examine differences in the connectivity of the default mode network (DMN). Activity in the DMN has been found, driven by decreases in connectivity between the anterior cingulate, the posterior cingulate, and the precuneus. Similarly, ICA analysis of a working memory task (Wolf et al.,

2009) demonstrated decreased connectivity in adults with ADHD, of the anterior cingulate, ventrolateral prefrontal cortex, and superior parietal lobule, as well as increased connectivity in right prefrontal regions, and the left dorsal cingulate, and left cuneus.

Structural connectivity studies of ADHD have shown abnormal structural connectivity in a number of pathways thought to be involved in ADHD symptomatology. Decreases in the FA of the right cingulum and right SLF, both pathways related to executive function, have been demonstrated in ADHD subjects (Makris et al., 2008). Similarly, FA decreases were found in the cortical spinal tract (Hamilton et al., 2008) and the premotor WM regions (Ashtari et al., 2005). Overall, these results support the hypothesis of abnormal structural connectivity in the attention, motor, and executive function networks.

Electrophysiology studies of ADHD have focused primarily on the investigation of differences in local parameters such as spectral power, computed from the time series of each sensor (see Barry et al., 2005 for a comprehensive review). Because source localization techniques have improved, these types of studies have begun to focus on brain regions implicated by other neuroimaging techniques. For instance, Wilson et al. (2011) investigated resting state MEG in the DMN, finding broadband differences in the medial prefrontal cortex activation. More complex connectivity-based analyses are just beginning to be used to study ADHD. Studies using EEG coherence (MSE) to measure connectivity have found differences in intrahemispheric and interhemispheric coherences (Murias et al., 2007a).

OBSESSIVE COMPULSIVE DISORDER

Obsessive compulsive disorder (OCD) is a highly prevalent anxiety disorder that typically presents during childhood or adolescence. Obsessive compulsive disorder is generally characterized by the presence of persistent intrusive thoughts, feelings, and impulses (obsessions), as well as repetitive behaviors (compulsions) such as excessive washing/cleaning, checking, or counting. A growing body of structural and functional neuroimaging research has focused on interactions among the thalamus, striatum, and frontal cortices as being abnormal in subjects with OCD (Del Casale et al., 2011).

More recently, fMRI-based functional connectivity studies have focused on regions participating in the fronto-striatal-thalamic networks in the hopes of better characterizing the nature of their involvement in OCD. Fitzgerald et al. (2011) utilized a seed-based rs-fMRI paradigm to illustrate reduced connectivity among the dorsal striatum, thalamus, and cingulate, while also finding increased connectivity between the dorsal striatum and the medial frontal cortex. Using a task-based fMRI paradigm focused on risk aversion, Admon et al. (2012) found decreased functional connectivity between the amygdala and anterior cingulate, in addition to decreased connectivity between the nucleus accumbens and the orbital frontal areas. Similarly altered interactions between the frontoparietal networks and the DMN have been illustrated using ROI-based rs-fMRI (Stern et al., 2012). Structural connectivity findings based on DW-MRI have been more heterogeneous (Fontenelle et al., 2009), with some studies reporting increased FA in OCD patients (Gruner et al., 2012; Li et al., 2011), whereas others (Admon et al., 2012; Garibotto et al., 2010; Nakamae et al., 2011) report lower FA values.

TOURETTE SYNDROME

Tourette syndrome (TS) is a neuropsychiatric developmental disorder characterized by multiply unwanted physical and vocal tics. Similar to the neuroimaging studies of OCD, many studies of connectivity in TS have focused on the connectivity of frontal regions thought to participate in planning and impulse control.

A number of studies have used rs-fMRI to investigate connectivity in TS. Worbe et al. (2012) used ICA to identify three corticobasal networks (motor, associative, and limbic). ROIs were then placed within these networks and correlation-based connectivity measures were computed. The authors found increased global integration, increased connection strength, and lower characteristic path lengths in all three networks of TS patients. Similarly Church et al. used rs-fMRI to investigate connectivity in task-control networks (Church et al., 2009). They compared these networks with normative data collected on developing adolescents and found that the networks of patients with TS were characterized by *immature* functional connectivity. A task-based fMRI has also been used to investigate connectivity in TS. Wang et al. (2011) used ICA to extract activity that was correlated to both spontaneous and stimulated tics. Using Granger causality, computed between the

major ROIs of the ICA networks, the authors showed increases in activity and interregional causality among the regions of the motor pathway. Increased connectivity in the motor system has also been observed using coherence measures computed from MEG data (Franzkowiak et al., 2012). Structural connectivity differences have also been observed in TS. Whole brain analysis of DTI-based scalar metrics have shown decreased FA in the corpus callosum, forceps minor, and internal capsule as well as increase in mean diffusivity in the corticostriatal projections (Govindan et al., 2010; Jackson et al., 2011; Neuner et al., 2010). Probabilistic tractography has also been utilized to quantify connectivity differences in TS, showing decreased connectivity in the fronto-thalamic-striatal networks (Makki et al., 2009).

CONCLUSIONS

Taken together, it can be seen that an emerging body of endeavor and research is focused on advancing our description of brain function to incorporate the dynamics of spatial networks of coordinated regions throughout the brain. In so doing, it is clear that the field is embracing both spatial and spectrotemporal descriptors of brain activity, as well as recognizing the need for increasingly sophisticated mathematical modeling to integrate data, as well as to reduce it to quantifiable metrics of connectivity globally, and of individual connections themselves. As the methodology advances, clinical applications incorporate these analyses providing an increasingly rich description, and ultimately an increasing neurobiological understanding of neuropsychiatric disorders. As with all emerging technologies, the opportunity for erroneous confounds is prevalent, requiring due consideration of both acquisition and analysis steps. Given the multidisciplinary nature of this effort, it seems that “highly connected” teams of clinicians, imagers, and mathematicians are a prerequisite to the successful development of the field.

ACKNOWLEDGMENTS

The authors would like to thank Yasser Ghanbari, Madhura Ingahalikar, and Alex Smith in creating the synchronization likelihood and ASD-TD group differences figure, and Ted Satterthwaite for his work on default mode networks that made the figure possible. Dr. Roberts would like to thank the Oberkircher family for the Oberkircher Family Chair in Pediatric Radiology.

DISCLOSURES

Dr. Bloy has no conflicts of interest to disclose.

Dr. Verma receives grant support from the NIH (R01 MH092862, R01 MH073174, and R01 MH079938),

Dr. Roberts serves on the Medical Advisory Board of Prism Clinical Imaging for which he has received stock options in that company. He had also received compensation from Elekta

for educational presentations. He receives grant support from NIH (R01 DC008871), Simons Foundation, Nancy Lurie Marks Family Foundation, and Seaside Therapeutics.

CHARLES E. SCHWARTZ, FIORELLA GURRIERI, AND GIOVANNI NERI

Genetic syndromes that include intellectual disability (ID) as one component manifestation are each individually rare but, taken together, constitute a large group of causally heterogeneous and phenotypically variable conditions. It is difficult, if not impossible, to establish their exact number, given the existence of many “private” conditions, especially those caused by chromosomal imbalances. It is equally hard to provide prevalence estimates, except for some syndromes that are more prevalent and better known, such as Noonan syndrome, Fragile X syndrome, DiGeorge syndrome, Rett syndrome, and Williams syndrome, to mention just a few. Fortunately, significant information can be derived from open access databases (e.g., OMIM—Online Mendelian Inheritance in Man at <http://www.ncbi.nlm.nih.gov/omim>, Orphanet at <http://www.orpha.net>, and DECIPHER at <http://decipher.sanger.ac.uk>) that collect and store relevant data from the medical literature.

From the point of view of the clinical geneticist, who deals with these rare patients and their families, a useful nosological classification of ID syndromes is by genetic etiology. Knowledge of the genetic cause is the sine qua non for accurate counseling and estimate of recurrence risks. However, even with the help of the most advanced technology, such as chromosome microarray (CMA) and whole exome or other forms of next-generation sequencing, the cause remains unknown probably in one-third or more of the cases seen in genetic clinics. The main etiological classes are listed in Table 76.1, together with tentative prevalence estimates among live born.

Understanding the genes underlying ID is also of great interest for neurobiological studies because they can lead to a molecular and cellular understanding of pathobiology, and gene products represent potential therapeutic targets. One of the most well-known examples of these possibilities arise from Fragile X syndrome, in which animal models with disruptions of the causal gene (*FMR1*) have led to an understanding of synaptic deficits in the disorder, and to novel therapeutics that are beginning to show promise (see, e.g., Berry-Kravis et al., 2012).

The diagnostic approach to the patient who is affected with a syndromic form of ID requires the application of a number of steps. Short of a “gestalt” diagnosis, which may occasionally apply to cases of well-known syndromes, the approach includes the collection of a (at least) three-generation family tree, prenatal and postnatal history, physical examination, relevant imaging data of brain, heart, kidneys, and so on, and functional data, such as EEG. Laboratory tests can be specific for the diagnosis of given syndromes in the presence of a specific clinical

suspicion. Otherwise, CMA and analysis of the *FMR1* gene are usually considered first-line tests. Next-generation sequencing is becoming more and more applicable to those cases in which all other approaches failed to reach a causal diagnosis. In the end, it should be made clear to the parents and caregivers alike that lack of a causal diagnosis does not preclude the application of symptomatic, as well as rehabilitating treatments, as deemed appropriate on the basis of the phenotypic manifestations and the patient’s needs.

This chapter briefly describes a few selected examples of ID syndromes. The selection was made with the purpose of illustrating various molecular pathways and/or cellular compartments whose disruption as a consequence of genetic mutation cause a disruption of a developmental pathway and, ultimately, an ID syndrome.

This arbitrary selection leaves out numerous syndromic ID conditions even though their causative genes have been identified after incredible research. To get a feel of the genetic burden in ID, some estimates have been attempted: X-linked intellectual disability (XLID) accounts for 5% to 10% of ID in males. More than 150 syndromes, the most common of which is the Fragile X syndrome, have been described. A large number of families with nonsyndromal XLID, 95 of which have been regionally mapped, have been described as well. Mutations in 102 X-linked genes have been associated with 81 of these XLID syndromes and 35 forms of nonsyndromal XLID (Lubs et al., 2012). The distinction between syndromic and non-syndromic ID is not precise, and several genes, initially identified in syndromic conditions, have later been associated with non-syndromic forms (e.g., *ARX*, *CASK*, *JARID1C*, *FGD1*, and *ATRX*).

As for autosomal ID, mutations in approximately 450 genes have been reported, of which 50 genes are associated with non-syndromic ID and 400 genes are associated with syndromic ID (van Bokhoven, 2011). In spite of the rapid progress in disease gene identification, it is difficult to predict how many additional ID genes remain to be identified. Based on the number of approximately 100 known XLID genes (syndromic as well as non-syndromic), a total of 1,500 to 2,000 genes might be a reasonable estimate (van Bokhoven, 2011). The lack of knowledge is even more expansive when it comes to the biological consequences of these mutations on brain functions. Mutant genes encode proteins with a variety of functions including chromatin remodeling, presynaptic and postsynaptic activity, intracellular trafficking, neurogenesis, and neuronal migration. Interestingly, most of the pathways and about half of the genes identified as being involved in ID have also been found

TABLE 76.1. Etiological classification of intellectual disability syndromes

CAUSE	PERCENTAGE
Genomic imbalance (detected cytogenetically or by array-CGH)	20
Mendelian mutations	7
Environmental	23
Unknown but likely of genetic origin	50

(From Curry et al. (1997); Mefford et al. (2012); Ropers (2010); Winpenninckx et al. (2003).)

to be altered in patients with autism spectrum disorders (ASD) suggesting that these two neurodevelopmental disorders share a common genetic basis (Betancur, 2011).

In the following sections, the selected syndromes are grouped by mode of inheritance: autosomal dominant, autosomal recessive, and X-linked.

AUTOSOMAL DOMINANT

CARDIO-FACIO-CUTANEOUS SYNDROME

Cardio-facio-cutaneous syndrome (CFCS) was first described by Reynolds et al., in 1986. Twenty years later came the demonstration that it is caused by disruption of the RAS-ERK signaling pathway (Narumi et al., 2007; Rodriguez-Viciana et al., 2006), placing it nosologically within the group of RASopathies (Rauen et al., 2010). Although initially it was considered by some authors to be a variant of the Noonan syndrome, the discovery of the causal genes proved it to be a distinct entity, as maintained by Neri et al. (1991).

The incidence of the syndrome is unknown. Since 1986, about 100 cases were reported in the medical literature and more than 100 unpublished cases are known to CFC International, Inc., a family support group operating worldwide (<http://www.cfcsyndrome.org>). This number probably accounts for a fraction of cases because it excludes most mildly affected individuals. All affected subjects to date are sporadic, most likely because of new dominant mutations, as supported by the observation of a paternal age effect (Roberts et al., 2006).

Cardio-facio-cutaneous syndrome has a distinctive clinical presentation starting at pregnancy, which can be uneventful, but is often marked by polyhydramnios. Hypotonia and serious and often longstanding feeding difficulties are hallmarks of the early postnatal period. Feeding problems are especially troublesome, with poor sucking, aspiration, gastroesophageal reflux, oral aversion, hyperemesis, and gastrointestinal dysmotility, leading to serious and long-lasting failure to thrive. These problems are significant enough to require nasogastric tube feeding, or gastrostomy tube placement in some cases. Assisted feeding may be required into middle childhood or beyond. The physical phenotype is characterized by short stature with relative macrocephaly, distinctive facial appearance with high forehead, bitemporal narrowing, downslanting and wide-spaced palpebral

fissures, ptosis, short nose with depressed nasal root, low-set ears with creases on the lobes, sparse curly hair, sparse or absent eyebrows and lashes, ectodermal findings especially follicular keratosis, hyperkeratosis, hyperelastic skin, cutaneous vascular malformations, pigmented nevi, and congenital heart defects, pulmonic stenosis, hypertrophic cardiomyopathy, and atrial septal defects being the most frequent. Intellectual disability, of moderate to severe degree, is almost invariably present. Many children display tactile defensiveness, short attention span, irritability, stubbornness, and obsessive behavior. A minority act aggressively toward others. Nonetheless, parents often comment on a warm and loving personality and an enjoyment of social interactions, particularly music and dance. Epilepsy can be a serious complication in about one-third of cases. It can present as infantile spasms, and absence, generalized, or partial complex seizures. On brain imaging, ventriculomegaly, reduced white matter, and thinning of the corpus callosum are the most common findings. Life expectancy is shortened on average because of the early death of individuals with severe cardiac involvement (Armour and Allanson, 2008).

Noonan syndrome and Costello syndrome, especially the former, are the main differential diagnoses, and there is marked phenotypic overlap among the three conditions. Individuals with Noonan syndrome have normal intelligence or mild psychomotor involvement, less common and less severe failure to thrive, and a history of bleeding disorder. Differences between Costello syndrome and CFCS include skin papillomata, deep palmar and plantar creases, a significant likelihood of chaotic atrial arrhythmia or multifocal atrial tachycardia, and most important, an increased risk of malignant tumors such as rhabdomyosarcoma, transitional cell carcinoma of the bladder, and neuroblastoma.

In 2006, Niihori et al. and Rodriguez-Viciana et al. discovered the genes whose mutations cause CFCS. These are *BRAF*, *KRAS*, *MEK1*, and *MEK2*. Their protein products are components of the RAS-ERK signaling pathway, which is implicated in growth factor-mediated cell proliferation, differentiation, and apoptosis, and plays a crucial role in embryonic development. *RAS* genes encode GTP-binding proteins that function as on-off switches to activate or inhibit downstream molecules. *BRAF* mutations account for the majority of mutation-positive cases (65.8%), followed by *MEK1* and *2* and, more rarely, *KRAS*. Dysregulation of the RAS/ERK pathway is the common underlying mechanism of the phenotypic relatedness of CFCS to Noonan and Costello syndrome, whose genes encode proteins that are also part of the RAS/ERK pathway (Fig. 76.1; Table 76.2).

The role of the RAS/ERK pathway in cellular function is the subject of several recent reviews, including Tidyman and Rauen (2009). In terms of the role of this pathway in the dynamic aspects of CNS function, there is good evidence for a critical role of RAS/ERK signaling in synaptic plasticity and, hence, in learning and memory processes (Mazzucchelli and Brambilla, 2000). This impact on synaptic plasticity is very likely directly related to the impairments in intellectual functioning, and the frequent manifestations of autism spectrum disorder in CFCS.

BRAF and *KRAS* somatic mutations are often reported in human cancers. These are thought to be stronger

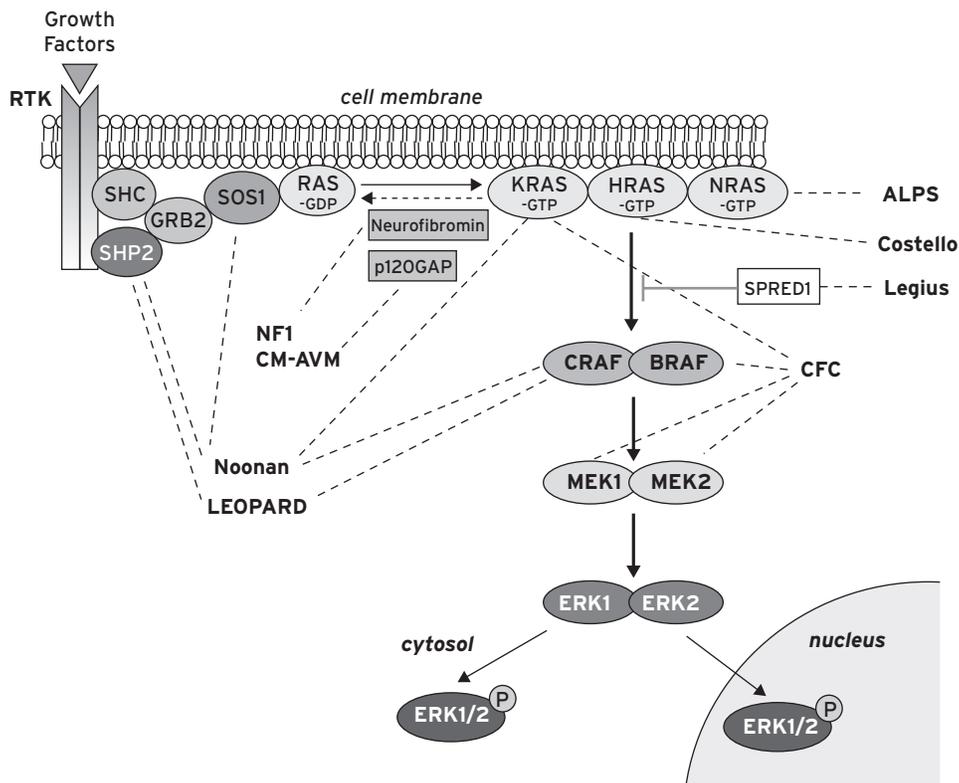

Figure 76.1 The RAS/mitogen-activated protein kinase (MAPK) signaling pathway. This pathway is critical for cell proliferation, differentiation, motility, apoptosis, and senescence. The dashed lines indicate the genes associated with various developmental syndromes. Of interest, some of the syndromes can result from a mutation in more than one of the genes in this pathway. (Adapted from Tidyman, W.E. and Rauen, K.A. (2009). *The RASopathies: Developmental syndromes of Ras/MAPK pathway dysregulation*. *Curr. Opin. Genet. Dev.* 19:230–236. Used with permission from Elsevier.)

TABLE 76.2. The RASopathies: syndromes and genes*

SYNDROMES	OMIM	GENES
Noonan	163950	<i>PTPN11, KRAS, RAF1, SOS1, NRAS</i>
Noonan-multiple lentiginos	151100	<i>PTPN11, BRAF, RAF1</i>
Costello	218040*	<i>HRAS</i>
Cardio-facio-cutaneous (CFC)	115150	<i>BRAF, MEK1, MEK2, KRAS</i>
Noonan-like with anagen hair	607721	<i>SHOC2</i>
Noonan-like, with or without juvenile myelomonocytic leukemia	613563	<i>CBL</i>
Neurofibromatosis 1	162200	<i>NF1</i>
Legius (neurofibromatosis type1-like syndrome)	611431	<i>SPRED1</i>

*Costello syndrome is autosomal dominant. OMIM number needs updating.

gain-of-function mutations that would be embryo-lethal if present in the zygote. In CFCS, mutations are milder, compatible with (abnormal) development. The same is thought to be true for Noonan and Costello syndrome mutations. Yet, one

would expect that patients affected with these syndromes would be more prone to cancer. This is true for Costello syndrome, but not for Noonan and CFCS, with some exceptions. However, it must be noted that all RASopathies patients may one day benefit from the intensive search of new cancer drugs acting as inhibitors of the RAS/ERK pathway, such as lonafarnib, sorafenib, statins, and so on. If and when an effective pharmacological treatment will become available based on these premises, it will be an example of successful translational medicine.

KABUKI SYNDROME

Kabuki syndrome (KS, OMIM #147920), first described in 1981 with the designation of Kabuki make-up syndrome, is characterized by ID, unusual face, large and protruding ears, and postnatal growth delay (Niikawa et al., 1981). The prevalence was estimated at 1:32,000 in the Japanese population (Niikawa et al., 1988), a figure likely to apply also to other ethnicities. Based on the observation of a large number of patients, Niikawa et al. (1988) established the following diagnostic criteria: (1) typical face with long palpebral fissures and eversion of the lateral third of the lower eyelid; arched eyebrows, sparse or notched in their lateral third; depressed nasal tip; large, protruding ears; (2) skeletal anomalies, including cleft and butterfly vertebrae, narrow intervertebral spaces, scoliosis, brachymesophalangy of hands and fifth finger clinodactyly;

(3) persistence of fetal pads on fingertips; (4) mild-to-moderate ID; (5) postnatal growth delay. The neonatal period is characterized by feeding difficulties, which may require tube feeding or gastrostomy, and consequent failure to thrive (Adam, et al., 2011).

A host of different physical anomalies can be present, adding to the complexity of the phenotype (Adam et al., 2011). Nearly half of the individuals with KS have a congenital heart defect, especially coarctation of the aorta (Kawame et al., 1999). Almost three-fourths have a highly arched palate, and one-third have a cleft lip and/or palate. Hypodontia is common, with missing lateral and central incisors. Hearing loss is also common, usually caused by chronic otitis media, but a few patients with true sensorineural hearing loss have been observed. Gastrointestinal anomalies are rare, whereas the genitourinary system is affected in about 25% of individuals with KS. Reported anomalies include fused and/or misplaced kidneys, duplication of collecting system, hypospadias, and cryptorchidism in males (Adam et al., 2011). In females, premature thelarche is fairly common. Brain structural anomalies seem to be rare, with the possible exception of Chiari I malformation, that has been reported in several patients. Immune dysfunction with hypogammaglobulinemia has been reported in a significant proportion of patients (Hoffman et al., 2005).

Most patients with KS have hypotonia, joint laxity, and delay of motoric development. The neuropsychiatric manifestations of KS are interesting. Although mild to moderate ID is reported in more than 90% of patients, the personality of KS children is usually described as pleasant and easy. Verbal and nonverbal reasoning, as well as receptive language seem to represent an area of relative strength, as opposed to expressive language and visuospatial orientation, which show considerable impairment (Mervis et al., 2005). In contrast with many other ID syndromes, autism or autistic spectrum disorders have been reported only rarely. Epilepsy is not a major concern, affecting less than one-third of patients with KS, who tend to respond well to antiepileptic medication.

Kabuki syndrome is an autosomal dominant disorder, with most cases caused by new mutations of the *MLL2* gene, a gene of 54 exons, encoding MLL2, a large protein of 5,262 amino acid residues, which belongs to the SET family of proteins. MLL2 is a histone 3 lysine 4 (H3-K4) methyltransferase, a regulator of gene transcription through epigenetic modulation. H3-K4 methylation is an epigenetic mark of euchromatin, favoring gene transcription. H3-K4 demethylation signals a transition from euchromatin to heterochromatin, inhibiting gene transcription. Loss of *MLL2* in mice causes cellular apoptosis and growth retardation, resulting in embryo lethality. The causative role of *MLL2* in KS was discovered in 2010 by Ng et al., who reported mutations in 10 unrelated patients utilizing whole exome sequencing. Mutations are found in about three-fourths of tested patients. The majority are nonsense or frameshift mutations, predicting a truncated protein and suggesting that haploinsufficiency is the underlying pathogenic mechanism. Mutations are distributed over the entire length of the gene, but are more prevalent in the 3' exons, leading to loss of the SET domain. Some canonical cases of KS without

MLL2 mutation suggest possible genetic heterogeneity of the syndrome.

There are more than 25 known histone methyltransferases in the human genome and several (including *NSD1*, discussed in the following section) have been implicated as genes involved in developmental delay syndromes. There are a similar number of histone demethylase genes, and some of these have also been implicated in developmental delay syndromes.

SOTOS SYNDROME

Sotos syndrome (SoS OMIM #117550) is characterized by overgrowth of prenatal onset persisting during the first years of life, advanced bone age, and characteristic facial features (Baujat and Cormier-Daire, 2007). Birth weight averages 4,200 g in males and 4,000 g in females, whereas mean birth length is 55.6 cm in males and 57.3 cm in females. The newborn period is affected by poor feeding and congenital hypotonia, the latter persisting into adult life. Occipitofrontal head circumference (OFC) tends to exceed the 97th centile by the age of one year. Final height is usually within normal range because of the advanced bone age, present in 84% of patients with SoS. Advanced bone age is common to many overgrowth syndromes, including Weaver and Beckwith-Wiedemann syndrome. However, SoS can be distinguished for the presence of a peculiar (disharmonic) metacarpophalangeal profile. Hand and foot length is often above the 97th centile; dental eruption can occur early; puberty can be precocious. Facial characteristics consist of marked frontal bossing (in 97.5% of patients), high frontal hairline (97.5%), frontoparietal balding, downslanting palpebral fissures (90%), narrow bitemporal diameter, full cheeks, and high palate (70%). The face gradually lengthens with age and the jaw becomes more prominent, with a pointed chin. Pes planus is frequent, and strabismus is found in nearly 40% of patients. The IQ is below average (mean of 78, ranging from 40 to 129), with delay in expressive language. Autistic behavior or other psychological problems, including abnormal social behavior and anxiety, may also be noted (Baujat and Cormier-Daire, 2007; Sarimski, 2003). Seizures have been reported to occur in 50% of cases. Brain magnetic resonance imaging can show a typical pattern of anomalies, including prominence of the trigonus (90%) and the occipital horns (75%), as well as ventriculomegaly (63%). The supratentorial extracerebral fluid spaces and those of the posterior fossa are increased for age in 70% of patients (Schaefer et al., 1997). Heart defects (i.e., septal defects and patent ductus arteriosus) are observed in 8% of patients with SoS, but seem to be as frequent as 35%–41% in patients of Japanese ethnicity. Gastrointestinal and urogenital anomalies have also been reported. Upper respiratory tract infections, especially otitis media, are frequent and may lead to conductive hearing loss. As in most overgrowth syndromes, increased risk of cancer is a concern. Cohen critically reviewed neoplasms reported to occur with SoS (Cohen, 2003). One-third of patients with neoplasia, all males, developed lympho-hematological malignancies (lymphoma or leukemia), which seem to represent the most frequent neoplasias in SoS. Many cases occurred after the

age of five (10/22; 45%) or 10 years (4/22; 18%). Thus, it is not easy to give an overall recommendation for cancer surveillance in SoS.

The most frequent cause of SoS was discovered by Kurotaki and colleagues in 2002, who found rearrangements of the *NSD1* gene in SoS patients harboring a chromosomal translocation, encompassing band 5q35. They also identified one nonsense, three frameshift, and 20 submicroscopic deletions of the same gene among 42 sporadic cases (77%). This initial observation was followed by many other reports, confirming that haploinsufficiency of *NSD1* is the major cause of SoS (Niikawa, 2004). A recurrent 2.2-Mb microdeletion at 5q35, including *NSD1* and adjacent genes, is the primary cause of SoS in Japan, accounting for more than 50% of cases. In Europe and United States intragenic mutations cause 60% to 80% of SoS cases, whereas microdeletions are responsible for no more than 10% of cases. Partial *NSD1* deletions, encompassing one or more exons, were detected in SoS cases (6%) without *NSD1* mutation or 5q35 microdeletion (Douglas et al., 2005). In general, children carrying an *NSD1* deletion have severe ID, with no language, major delay in motor milestones, and autistic features. By contrast, in patients carrying *NSD1* point mutations, ID is usually mild to moderate with verbal skills being more affected. There have been suggestions that *NSD1* mutations may also cause the Weaver syndrome, a view that is hard to maintain after the discovery that the original cases of Weaver syndrome are caused by mutation of the *EZH2* gene (Gibson et al., 2012).

The function of the *NSD1* gene (nuclear-receptor-binding SET-domain-containing protein 1) is not entirely clear. Its protein product is likely to act as transcriptional regulator of other genes by various mechanisms, including methylation of histone lysines H3-K36 and H4-K20 (see the preceding), as well as interaction with the transcriptional repressor Nizp1. One may hypothesize that haploinsufficiency of *NSD1* could result in silencing of putative growth regulating genes, the final consequence being accelerated growth. A growth-related role of *NSD1* is further supported by its expression in fetal tissues (Kurotaki et al., 2001).

AUTOSOMAL RECESSIVE

BARDET-BIEDL SYNDROME

This condition was first described in 1866 by Laurence and Moon as an entity characterized by ID, hypogenitalism, retinopathy, and late onset paraplegia. The same clinical phenotype was independently described by Bardet in 1920 and Biedl in 1922. Because of this, the syndrome has been often named with two different eponyms: Laurence–Moon syndrome and Bardet–Biedl syndrome (BBS). Because of the considerable phenotypic overlap, it has been suggested that the two conditions are allelic. Bardet–Biedl syndrome is now the overall used term. Bardet–Biedl syndrome is a pleiotropic genetic disorder with significant clinical variability.

Inheritance is mostly autosomal recessive, although in some instances BBS may be an oligogenic disorder. The prevalence of BBS varies markedly between populations: from 1:160,000 in

northern European populations to 1:13,500 in isolated Arabic populations in which a higher level of consanguinity exists.

Bardet–Biedl syndrome is genetically heterogeneous: 16 BBS genes accounting for approximately 80% of clinically diagnosed BBS have been identified so far. The majority of pathogenic mutations are found in *BBS1* and *BBS10* (23.2% and 20%, respectively). Genotype–phenotype correlations are poor. Some genes seem to have ethnic specific frequency but no mutated genes are detected exclusively in a single ethnic population (Hjortshoj et al., 2010). Whereas most patients show regular autosomal recessive inheritance, in several instances (about 10%) a triallelic pattern of inheritance (three mutations in BBS genes are required for the phenotype to be manifest, or alternatively a third disease locus acts as a modifier) is observed (Beales et al., 2003; Eichers et al., 2004). This irregular pattern of inheritance may raise problems in counseling the parents of affected BBS children for recurrence risk. It has been suggested to counsel anyway according to the autosomal recessive recurrence risk (Abu-Safieh et al., 2012). All the BBS genes encode proteins that are part of the BBsome, localized at the base of the primary cilium and involved in the organization of ciliogenesis and maintenance of the cilium. Overall, BBS can be considered a disease of immotile cilia. Defects in immotile cilia are characterized clinically by retinitis pigmentosa, polydactyly, situs inversus, learning difficulties, and cystic kidneys, liver, and pancreas (Gerdes et al., 2009) (Table 76.3).

The BBS phenotype evolves with age and therefore the diagnosis is not usually suspected until late childhood. The only typical feature at birth may be postaxial polydactyly, rarely associated with brachydactyly or syndactyly. The most common diagnostic finding, which should prompt investigation for BBS, is the development of rod-cone dystrophy. This usually manifests around five years of age but may be present at two. Clinically, patients with BBS experience a gradual onset of night blindness, followed by photophobia and loss of central and color vision. Obesity is another major clinical finding (72%–86% of patients with BBS) mostly developing after the first year. Type 2 diabetes and other signs of metabolic syndrome are frequently observed. Hypogonadism, delayed puberty, hypogenitalism, and infertility are other issues. Speech problems and developmental delay (that can involve specific areas) are common in BBS. Behavior is an issue, as BBS patients may show obsessive-compulsive behavior, difficulties in socialization, autistic features, or psychosis. Renal abnormalities can be a major cause of morbidity and mortality. The renal abnormalities are variable but classically manifest with cystic tubular disease and anatomical malformations. Conductive hearing loss secondary to chronic otitis media is frequent and may worsen the speech defect. Other manifestations include heart malformations and cardiomyopathies, gastrointestinal issues (Hirschsprung disease), hypodontia and enamel hypoplasia, anosmia, ataxia, and poor coordination (Forsythe and Beales, 2012).

It has been suggested that some phenotypic manifestations also occur in mutation heterozygotes, specifically, obesity, increased risk for renal cancers and malformations, as well as retinal dysfunction (Beales et al., 2000; Kim et al., 2007).

(From Waters, A.M., Beales, P.L., 2011. Ciliopathies: An expanding disease spectrum. *Pediatr Nephrol.* 26(7):1039–1056; Huber, C., Cormier-Daire, V., 2012. Ciliary disorder of the skeleton. *Am. J. Med. Genet. C. Semin. Med. Genet.* 160(3):165–174.)

Because of the many issues in BBS, a multidisciplinary approach is required to manage this pleiotropic condition. Because there is not yet a targeted treatment, the clinical intervention should be focused on symptoms as they arise. In particular, the renal function needs to be monitored and the risk for diabetes insipidus (which is frequent in BBS) should be taken into account. Ophthalmological follow-up is also recommended.

The clinical features of BBS significantly overlap with the manifestations of other ciliopathies. Among those, Alstrom and McKusick-Kauffman syndromes manifest significant overlap with BBS. However, hearing loss and absence of polydactyly differentiate Alstrom syndrome from BBS, and the high prevalence of urogenital anomalies in McKusick-Kauffman syndrome that normally lacks obesity, rod-cone dystrophy, and learning difficulties differentiate this latter condition from BBS.

It is interesting to consider how ciliopathies may contribute to mental illness; several genes in this group have been associated with developmental delay syndromes, including ID and ASD. The means by which cilia are involved in neurodevelopmental processes and by which ciliopathies lead to neurodevelopmental disorders are areas of active research. In addition to the role of motile cilia in mobilizing cerebrospinal fluid, primary cilia, found on most neurons and astrocytes, play roles as modulators of signal transduction during both brain development and homeostasis (Lee and Gleeson, 2011).

COHEN SYNDROME

Cohen syndrome (CS) is a rare autosomal-recessive disorder, first described in 1973, characterized by hypotonia, obesity,

ID, characteristic facial appearance, and narrow hands and feet. There is consistent clinical heterogeneity, particularly evident when comparing patients of different ethnic backgrounds, especially when evaluating specific system phenotypes separately, such as the ophthalmic and central nervous systems (Douzgou and Petersen, 2011). The incidence of CS is unknown; however, this condition is overrepresented in Finland owing to the peculiar population structure in genetic isolates. The Finnish CS phenotype is remarkably homogeneous, whereas clinical variability is the rule in non-Finnish patients with CS. Some ethnic group shows peculiarities; for instance, the Amish CS neonatal phenotype is characterized in 50% of cases by respiratory distress syndrome, jaundice, and acidosis, whereas a high-pitched voice and an age-related loss of the left ventricular function have been recurrently reported only in the Finnish CS cohort.

The inheritance is autosomal-recessive and the causative gene, named *VPS13B* or *COH1*, encodes a Golgi-associated matrix protein required for Golgi integrity (Kolehmainen et al., 2003; Seifert et al., 2011). The mutational spectrum is wide and mutations can be present in different portions of the gene; missense, non-sense, and frameshift mutations as well as intragenic deletions have been found in CS patients. Non-Finnish patients are almost always compound heterozygotes (Katzaki et al., 2007). Not much is known of the pathogenesis of CS, but because high levels of urinary hyaluronic acid have been reported, it has been suggested that CS is a connective tissue disorder.

Typical craniofacial features include down-slanting palpebral fissures, thick eyebrows, convex profile of nose, and short

philtrum with open mouth and prominent lips exposing the upper central incisors. These features become more evident as the child gets older. In addition, patients with CS exhibit short stature, generalized hypotonia, truncal obesity (evident after five years), delayed puberty, and cryptorchidism. Related to hypotonia is the frequent finding of kyphoscoliosis. Microcephaly can be of prenatal onset and ID, moderate to severe, is usually observed. Seizures are rare and a happy affectionate predisposition is typical.

The hands and feet are narrow, with slender fingers and joint hyperextensibility. Ophthalmological involvement is quite constant. Myopia can develop in up to 90% of patients, and retinal pigmentary degeneration can occur in late childhood in about 80% of cases. However, these lesions only rarely lead to blindness. Neutropenia is also a recurrent, although not constant, laboratory finding. Among these clinical features, some can be considered good indicators for the presence of a mutation in the causative gene: postnatal microcephaly, chorioretinal dystrophy, and neutropenia. It has been suggested that, given the large size of the gene, the mutational analysis should not be indicated in the absence of these features. The follow-up of young patients could be a satisfactory alternative unless there are reproductive issues (El Chehadeh et al., 2010).

The phenotype in CS is quite distinctive, although large-scale mutational analysis has documented the existence of atypical cases. In any case, the diagnosis may be not evident until late childhood when the cardinal features of the condition manifest. A group of ID conditions to be considered as those of syndromes with hypotonia, obesity, and mental retardation, including Prader-Willi syndrome, which clearly has a completely different natural history and clinical appearance. If the phenotypic appearance is not straightforward, quantitative genomic alterations should be ruled out by CMA before considering the diagnosis of non-typical CS.

SMITH-LEMLI-OPITZ SYNDROME

Smith-Lemli-Opitz syndrome (SLOS, #OMIM 270400) was first described in 1964, as a multiple congenital anomalies-mental retardation (MCA-MR) syndrome characterized by microcephaly, peculiar face, developmental delay, syndactyly between the second and third toe, and genital anomalies (Smith et al., 1964). The clinical presentation may be variable in severity, ranging from neonatal death to survival into childhood and adolescence with severe ID and behavioral impairment.

Smith-Lemli-Opitz syndrome is a rare disorder (estimated incidence is between 1:20,000 and 1:60,000 in different populations), but it is not possible to rule out a higher incidence because of mildly affected individuals in whom the condition is difficult to recognize. In any case, it is considered among the most frequent autosomal recessive disorders, with an estimated carrier frequency of 1% to 2% in the general population.

The inheritance is autosomal recessive and the causative gene, named *DHCR7*, encodes the 3-beta-hydroxysterol-delta-7-reductase, an enzyme converting 7-dehydrocholesterol into cholesterol. This defect leads to high plasma levels of 7-dehydrocholesterol and low cholesterol (Irons et al., 1993).

Therefore, the clinical manifestations of SLOS are caused by a defect in cholesterol biosynthesis, a metabolic pathway that is crucial during embryonic development from early on (Porter and Herman, 2011). Because cholesterol is also required for the proper function of the sonic hedgehog (SHH) pathway, some clinical manifestations commonly related to SHH dysfunction, such as holoprosencephaly, can be observed in SLOS. The mutational spectrum of the SLOS gene is wide and mutations in the transmembrane domain or the C-terminal region have been associated with milder phenotypes.

Prenatally, growth retardation, oligohydramnios, and decreased fetal movements can be observed as well as breech presentation and perinatal asphyxia. Increased nuchal translucency can be detected by ultrasound (Quelin et al., 2012). Low birth weight is almost always present and failure to thrive is experienced in a high percentage of patients. Death in the neonatal period may occur because of severe feeding difficulties and hepatic dysfunction. Those who survive into childhood usually have short stature and severe intellectual impairment associated with behavioral issues, including autism, aggressiveness, sleep disturbances, and hyperactivity.

Physical anomalies in SLOS can be present in almost any part of the body (DeBarber et al., 2011; Nowaczyk et al., 2012). The brain is often underdeveloped with microcephaly and a constellation of anomalies, including holoprosencephaly, agenesis of the corpus callosum, ventricular dilatation, and cerebellar vermis hypoplasia. Reduced myelination in the cerebral hemispheres, cranial nerves, and peripheral nerves also occur. The face appears round-shaped with hypertelorism, down-slanting palpebral fissures and ptosis, upturned and wide nose, and micrognathia. The mouth shows broad alveolar ridges, small tongue, and rarely lingual cysts. Strabismus and cataract can also be observed. The extremities are also commonly affected, showing most frequently second to third toe syndactyly, postaxial polydactyly, and shortness of the first metacarpals and metatarsals. Positional foot abnormalities are often present as well as hip dislocation. Abnormalities of the external genitalia, mostly reflecting a failure of masculinization, are frequently observed, including cryptorchidism, hypospadias, micropenis, bifid scrotum, ambiguous genitalia, and even sex reversal. The urinary tract can be obstructed or hypoplastic and renal dysplasia (cysts or hypoplasia) can be present. Cardiovascular malformations occur in about 50% of the patients, mostly PDA, VSD, ASD, or tetralogy of Fallot. Other findings include pancreatic islet cells hyperplasia, unilobate lungs, and photosensitivity.

The clinical diagnosis can be confirmed with a biochemical test measuring plasma concentrations of cholesterol (that are usually very low in SLOS) and 7-dehydrocholesterol (increased in SLOS). High levels of 7-dehydrocholesterol can be detected in the amniotic fluid and chorionic villus specimens as well (Kratz and Kelley, 1999).

Supplementary cholesterol is rationally expected to supply the tissues and also reduce the toxic levels of 7-dehydrocholesterol. Simvastatin, aimed at further decreased sterol synthesis, has been also used as potential therapy. Although reported in the literature, the beneficial effects on behavior of dietary cholesterol supplementation have not been formally

documented through a randomized clinical trial. Larger studies are still needed to clearly demonstrate the utility of treatment of this metabolic disorder (Tierney et al., 2010).

Chromosomal disorders should be ruled out in newborns with features compatible with the SLOS phenotype. Also, some clinical overlapping exists with Meckel syndrome (in which the cystic kidney dysplasia is typical) and Pallister-Hall syndrome (in which the finding of a hypothalamic hamartoblastoma is quite unique).

X-LINKED

ALLAN-HERNDON-DUDLEY SYNDROME

Allan-Herndon-Dudley syndrome (AHDS, OMIM #300523) was first described in 1944 and was the second X-linked ID syndrome to appear in the literature (Allan et al., 1944). The authors described a large North Carolina (USA) family with 24 affected males over multiple generations. The major clinical findings were hypotonia, muscle hypoplasia, general muscle weakness, which resulted in a “limber neck” (noted by family members), dysarthria, and ataxia. Speech was also limited and there was significant developmental retardation.

The incidence of AHDS is unknown. It is considered one of the more prominent X-linked conditions with more than 25 families having been described, most from the United States and Western Europe. A review of most of the families found that in half of them, there was only one affected male (Schwartz and Stevenson 2007). This same review allowed for a good clinical description of AHDS and an idea of the natural history of the syndrome.

Initially, males with AHDS have birth measurements within the normal range. Most maintain normal postnatal growth. However, muscle hypoplasia was evident early in life and persisted into adulthood.

Facial features appear to be consistent across families. A myopathic face or hypotonic facial appearance with an open mouth and tented upper lip is usually present. There is bitemporal narrowing in most males and the face becomes tall and narrow in adulthood. The ears appear to be simple and cupped.

Neurologically, males with ADHS are hypotonic at birth. The postnatal weakness persists and progresses to spasticity with age. Dystonia and athetoid movements are present. Hyperreflexia becomes evident in adulthood.

Cognitive function is delayed from early in life. There is significant delay in acquiring language and all males with AHDS have severe ID.

The gene for AHDS was mapped to the Xq13-q21 region of the X chromosome when Schwartz and colleagues re-studied the original family (Schwartz et al., 1990). In 2004, both Dumitrescu and colleagues (2004) and Friesema and colleagues (2004) reported families and unrelated males who presented with neurological findings similar to those observed in AHDS. Additionally, the affected individuals had decreased serum T4 levels and significantly elevated serum levels of T3. However, TSH levels in serum were in the high normal

range. Both groups identified mutations in the monocarboxylate transporter 8 gene (*MCT8*, *SLC16A2*) in their patients. Subsequently, Schwartz and colleagues (2005) showed that mutations in *MCT8* were also present in their collection of families with AHDS.

MCT8 is critical for the metabolism of thyroid hormone in the brain. The protein functions as a transporter of T3 into neurons. Without T3, many genes within the neuron are not properly regulated. Thus, the presence of severe cognitive impairment in AHDS patients is not unexpected. However, other aspects of the clinical phenotype observed in AHDS patients do not reflect a defect in thyroid function. Additional studies are needed to explain this disconnect.

The presence of elevated serum T3 levels provides a convenient method for testing for AHDS in at-risk individuals such as males with hypotonia and developmental delay. The prevalence of *MCT8* is not known, but with a reliable and rapid test, many AHDS families have been identified. Thus, the prevalence of AHDS may be high relative to other X-linked intellectual disability syndromes.

ALPHA-THALASSEMIA INTELLECTUAL DISABILITY SYNDROME

Alpha-thalassemia intellectual disability or ATRX syndrome (OMIM #301040) is an X-linked recessive condition first noted clinically by Weatherall and colleagues in 1981 when they reported an association of hemoglobin H inclusion bodies in patients with ID. The possibility that this represented an X-linked syndrome was evident by 1990 when Wilkie and colleagues (1991) reported additional patients who did not have any abnormality of the alpha-globin genes located at 16p. The patients were all males and presented with a common phenotype of microcephaly, a hypotonic face (hypotelorism, small triangular nose, tented upper lip, open mouth) and severe ID with mild hemoglobin H disease.

Since the initial descriptions by Weatherall et al. (1981) and Wilkie et al. (1991), many additional patients and families with ATRX have been characterized and a fairly comprehensive review was compiled by Gibbons and Higgs (2000). The clinical spectrum of ATRX consists of hypotonia present in infancy, distinctive facial features of an open mouth with a tented upper lip and prominent lower lip, small upturned triangular nose, and hypertelorism. These facial features become “coarser” with age. Some patients have skeletal anomalies and urogenital anomalies such as cryptorchidism and hypospadias. Speech is severely delayed and maybe absent. There is growth delay and microcephaly is present. One feature noted in the original patients, hemoglobin H inclusion bodies, is not consistently present. Thus, although this was thought to be a useful test for ATRX, many proven cases are not positive for this finding and the test is no longer routinely done in males suspected of having ATRX.

Once ATRX was considered to be an XLID syndrome, Gibbons and colleagues mapped the gene to Xq12-q21.3 by linkage analysis in 1992 (Gibbons et al., 1992). They identified the candidate gene, *XNP* (X-linked nuclear protein) in 1995 (Gibbons et al., 1995). The availability of a gene test allowed

screening of XLID syndromes linked to the Xq13-q21 region as well as some syndromes whose clinical phenotype overlapped with ATRX. As a result, other XLID syndromes were shown to also result from mutations in *XNP*: Carpenter–Waziri, Holmes–Gang, and Chudley–Lowry. Two families with the diagnoses of Juberg–Marsidi and Smith–Fineman–Myers syndromes were found to have mutations in *XNP* (Villard et al., 1996, 2000). However, the families first described with these syndromes (Juberg and Marsidi, 1980; Smith et al., 1980) have not been tested for *XNP* mutations. In fact, the original Juberg–Marsidi family was recently found to have a mutation in the *HUWE1* gene, whereas *XNP* testing was negative (Abidi and colleagues, unpublished data).

The prevalence of ATRX is unknown in the general population. However, close to 200 males with ATRX syndrome have been reported; thus, it is reasonable to expect the prevalence to be relatively high, about 1% to 2% in males with ID.

One clinical feature that is now considered a hallmark of ATRX is that female carriers of an *XNP* mutation have highly skewed X-inactivation, which probably explains the lack of a clinical phenotype in these females. This distinction, skewed X-inactivation and lack of clinical findings in carriers, allows one to clinically differentiate ATRX from another XLID syndrome, Coffin–Lowry (OMIM #303600). This is critical since both can be confused in early childhood.

Some attempt has been made to construct a genotype/phenotype correlation because of the clinical spectrum of the syndrome and the number of patients with mutations. Unfortunately, this correlation has proved to be less than successful. There does appear to be some association between the loss of the C-terminal end of the protein and the presence of severe urogenital abnormalities (Gibbons and Higgs, 2000). Also, Badens and colleagues (2006) did observe that mutations in the PHD-like domains tended to result in more severe psychomotor delay and more severe urogenital abnormalities. However, overall, no clear genotype/phenotype association has been observed.

One recent observation has been made that may be significant. A fairly common R37X mutation has been found in families who present with a milder form of ATRX (Abidi et al., 2005; Guerrini et al., 2000). This may result from the presence of a small amount of full-length protein as detected by Western blotting and the utilization of an initiation site downstream from the mutation (Abidi et al., 2005; Howard et al., 2004). The *XNP/ATRX* gene was initially cloned and partially characterized by Stayton and colleagues in 1994 (Stayton et al., 1994). They determined it was homologous to members of the helicase II superfamily. Picketts and colleagues (1996) characterized the *XNP/ATRX* protein further establishing it was a member of the SNF2-like subgroup of proteins, contained helicase domains, a nuclear localization signal, and a C-terminal glutamine-rich region characteristic of a transcription factor. Villard and colleagues (1997) further determined the protein has three zinc finger motifs in the 5' end of the gene. Last, Gibbons and colleagues (1997) identified a cystine-rich motif, similar to a putative PHD zinc finger domain, in the N-terminal region. With the presence of these various domains, it is not surprising that the *XNP/ATRX* protein has chromatin remodeling and DNA translocase activities (Gibbons et al., 2003) and with its widespread expression in during embryogenesis (Stayton et al., 1994)

mutations in *XNP* give rise to a multisystem syndrome. This places *ATRX* into a class of ID and ASD genes that affect regulation of gene expression.

OPITZ–KAVEGGIA SYNDROME (FG SYNDROME)

Opitz–Kaveggia syndrome, better known as FG syndrome (FGS, OMIM #305450) is an X-linked recessive syndrome first reported in 1974 (Opitz and Kaveggia, 1974). The report was based on a single family with macrocephaly, ID, distinctive facial features, hypotonia, broad thumbs, and imperforate anus. The facial features were comprised of hypertelorism, small ears, frontal upsweep of the hair, broad forehead, and down-slanted palpebral fissures. Additionally, partial agenesis of the corpus callosum was found in one of the affected males, but this analysis was not conducted in all affected individuals.

Since the initial FGS description, many other families have been reported to have clinical features of FG syndrome. These publications had expanded the FGS phenotype and led to the identification of multiple FG syndromic loci on the X-chromosome. Genetic heterogeneity as well as clinical variability made the clinical diagnosis difficult and at the same time rather common among males with ID, macrocephaly, and constipation. This was the situation until 2007 when Risheg and colleagues identified the same mutation (c.2881C>T, p.R961W) in the *MED12* gene in six families with an FGS diagnosis (Risheg et al., 2007). The six families included a male from the original family of Opitz and Kaveggia.

After the identification of the *MED12* mutation, many males with a diagnosis of FGS were screened for mutations in *MED12*. This did lead to the identification of other males with the same R961W mutation, but it became evident that it was difficult to confirm the FGS diagnosis in males with a rather non-specific phenotype (Lyons et al., 2009). Based on these results and the fact that the original family had the R961W *MED12* mutation, it was proposed that only males with this alteration be designated as having Opitz–Kaveggia syndrome. To simplify the diagnosis, Clark and colleagues (2009) developed a clinical algorithm for diagnosis based on a clinical evaluation of 23 patients with the R961W mutation as compared with 48 patients who had a clinical diagnosis of FGS but were mutation negative.

The clinical features of Opitz–Kaveggia syndrome are defined as a male with intellectual disability, developmental disability, small ears, a characteristic face (long narrow face with a tall forehead, upsweep of the frontal hairline, open mouth), congenital anomalies of the corpus callosum, anus, heart or skeleton, macrocephaly, early hypotonia, constipation, and an affable, eager-to-please personality (Clark et al., 2009; Graham et al., 2008; Lyons et al., 2009).

The utilization of the clinical diagnosis algorithm developed by Clark and colleagues (2009) has already proved to be useful. Rump and colleagues (2011) screened *MED12* in a Dutch family with three affected male cousins based on the males fitting the clinical criteria for Opitz–Kaveggia syndrome. They found a novel *MED12* mutation, C.2873G>A (p.G958E) in the family. This mutation is three amino acids away from the R961W mutation and is in the same stretch of the highly conserved Leu-Ser rich domain of the *MED12* protein.

The prevalence of FGS is unknown. Before the identification of *MED12* as a causative gene, the FGS diagnosis was not uncommon in males with ID, macrocephaly, and constipation; thus, it was thought to be a significant contributor to X-linked ID. Now, it is likely to be a relatively rare XLID entity, probably not exceeding 0.5% of males with ID. Gene testing over the next few years will better address this point. However, it needs to be noted that another syndrome, Lujan syndrome (OMIM #309520) also has a mutation (p.N1007S) in *MED12* (Schwartz et al. 2007) and at least two other *MED12* mutations have been identified in FGS patients (Schwartz et al., unpublished data). Thus, although the FGS associated *MED12* mutation may be rare, other mutations in the gene may be responsible for ID in the male population.

The *MED12* protein is a member of the large mediator complex that plays an important regulatory role in the activity of RNA polymerase II (Knuesel, Meyer, Donner, et al., 2009). Mediator also acts as to regulate transcription initiation (Knuesel, Meyer, Bernecky, et al., 2009). Recently, it was shown that Mediator is part of a protein interaction network comprised of G9a histone methyltransferase and REST (RE1 silencing transcription factor) (Ding et al., 2008). This network suppresses neuronal gene expression in non-neuronal cells. Of interest, Ding et al., (2008) have shown the R961W *MED12* mutation disrupts the REST corepressor function of Mediator, suggesting a pathologic basis for the *MED12* mutation.

CONCLUSIONS

There seems to be a common denominator to the pathophysiology of the ID syndromes described in this chapter, expandable to many other conditions, all being disorders of development. All causative genes are in essence “master” genes affecting the expression of other genes either by disrupting signaling pathways, affecting chromatin structure, or altering structures (e.g., the cilium) that are essential for the normal functioning of the cell. The knowledge gained points investigators to other gene defects to explore in patients who do not harbor mutations in the presumptive candidate gene based on the phenotype. In spite of the complexity of the mechanisms involved, the knowledge of the molecular details and protein interactions promises to open the way to pharmacological interventions aimed at specifically correcting or at least ameliorating the basic defect or its metabolic consequences in ID syndromes.

ACKNOWLEDGMENTS

We thank Debra Marler for assisting with the preparation of the manuscript. Dedicated to the memory of Ethan Francis Schwartz, 1996–1998.

DISCLOSURES

Dr. Schwartz: To my knowledge, all of my possible conflicts of interest and those of my coauthors, financial or otherwise,

including direct or indirect financial or personal relationships, interests, and affiliations, whether or not directly related to the subject of the chapter, are as follows. I am funded by NICHD and SCDDSN (South Carolina Department of Disabilities and Special Needs). This work was supported in part by a grant from the National Institutes of Health (NICHD) [HD26202 to C.E.S.].
Dr. Gurrieri: No conflicts of interest to disclose.

Dr. Neri: No conflicts of interest to disclose.

77 | AUTISM SPECTRUM DISORDERS

ALEXANDER KOLEVZON, A. TING WANG, DAVID GRODBERG,
AND JOSEPH D. BUXBAUM

The understanding of autism has evolved dramatically since Kanner and Asperger's original description of the disorder in 1943–44. Autism is characterized by social and language impairments, and restricted and repetitive behaviors and interests. The autism spectrum was historically defined to encompass autistic disorder, Asperger syndrome, and pervasive developmental disorder not otherwise specified (PDD-NOS) and is referred to collectively as autism spectrum disorder (ASD) in this chapter. In the next iteration of the Diagnostic and Statistical Manual for Mental Disorders Fifth Edition (DSM-5) due to be released in May 2013, the nomenclature will shift to Autism Spectrum Disorder to define pervasive developmental disorders currently described in DSM-IV. The first section on phenotype in this chapter describes the clinical features in detail.

The diagnosis of ASD is based on clinical observations of language and behavior, and important shifts in the standard of care have occurred to allow for younger age of diagnosis and earlier intervention. Evidence from studies of behavioral therapy is emerging to support its efficacy in facilitating gains in cognitive functioning, adaptive behavior, and reducing symptom severity. In addition, our knowledge of the neurobiology of ASD has improved in recent years, and much of this gain has been derived from neuroimaging studies, reviewed in the neuroimaging section.

Twin studies in ASD carried out since the 1970s and more recent genetic analyses have come to demonstrate autism as primarily a genetic disorder. Today, most scientists recognize that rare variations in the genetic code account for a significant proportion of cases. Rare variants have been discovered through high-resolution genetic techniques like chromosome microarray (CMA) and next generation or massively parallel sequencing (MPS) and the field is currently in a phase of exponential discovery that is expected to explain a larger proportion of causes of autism in the near future. The section on genetics that follows describes current advances in genetic discovery in ASD.

Understanding the etiological cause of autism is extremely significant for families for several reasons. First, it can provide a medical diagnosis, and in each case, depending on the cause, these genetic aberrations may be associated with other medical comorbidity that will be important to treat and monitor. Second, it can provide families with estimates of recurrence risk for the purpose of family planning. Finally, identifying the cause of autism provides opportunities to develop cellular and animal model systems to better understand the neurobiology

of the disorder and develop targeted novel therapeutics. The final section on therapeutics in this chapter reviews the current state of the evidence in the behavioral and pharmacological treatment of ASD and endeavors to suggest future directions.

PHENOTYPE

The phenomenology of ASD includes the behavioral signs and symptoms described in the current DSM as well as a broadening array of medical and underlying genetic abnormalities. Autism spectrum disorders have traditionally been characterized as having three symptom domains, including communication deficits, social interaction deficits, and repetitive patterns of behavior (American Psychiatric Association, 2000). However, recent evidence suggests that impairments in communication and social interaction are inseparable and may be more accurately conceptualized as one domain (Frazier et al., 2012; Gotham et al., 2007). Accordingly, the proposed DSM-5 revisions combine delays or deviation in social and communicative functioning into a single category (A), alongside a category for repetitive restricted behaviors (B). To explore the phenomenology of ASD, this section first outlines the core features common to those individuals who meet ASD diagnostic criteria, and then describes additional features that contribute to the heterogeneity of the disorder, finishing with a description of medical comorbidities.

CORE FEATURES

Deficits in social communication represent the cardinal features of ASD and manifest as impairments in social-emotional reciprocity, deficits in nonverbal communication, and compromised capacity to develop and maintain age-appropriate relationships with peers. An individual's language skills, which are not contained in the new diagnostic criteria, must be considered *alongside* the social and communicative impairments. For example, a child with delayed language skills may have minimal social impairments, whereas a highly verbal child may only interact by using stereotyped speech or delayed echolalia.

The term joint attention refers to a cluster of behaviors that share the common goal of communicating with another person about a third entity nonverbally. This typically involves eye gaze, gesturing, and showing (Volkmar, 2011). From as early as 12 months, infants with ASD show a lack of interest in the human face and a proclivity to attend to non-social stimuli as opposed to those with social salience (Klin et al., 2009). This

gravitation toward non-social stimuli is thought to complicate the interdependent development of joint attention and communication skills. Subsequent early signs of ASD typically involve delays in social communication skills, such as delayed pointing, failure to respond to name, and lack of cooing, babbling, and word production. Over the course of development, these social and communicative deficits typically persist and lead to reduced or total lack of sharing and social interaction as well as impairments in the use and perception of non-verbal social cues.

The repetitive or restricted patterns of behavior of ASD, grouped together into Category B of the proposed DSM-5 criteria, comprise stereotypic or repetitive movements and/or use of speech, insistence on routines, unusual or encompassing preoccupations, and abnormal sensory responses to the environment.

Stereotyped and repetitive motor mannerisms are highly heterogeneous and can be subdivided across multiple dimensions, including fine or gross motor, simple or complex, and with or without objects. Examples are hand flapping, finger flicking, whole-body rocking, and walking on tip-toe. Motor mannerisms are reported in 37% to 95% of individuals with ASD (Filipek et al., 2000). A significant body of research provides evidence for a sensory function of stereotypies (Cunningham and Schreibman, 2008), and repetitive self-injurious behaviors such as head banging, self-biting, or self-pinching are more common in individuals with intellectual impairment. Repetitive speech can take the form of delayed or immediate echolalia, as well as stereotyped speech, which is often characterized by overly formal or idiosyncratic expressions.

Unusual or encompassing preoccupations typically involve interest in the nonfunctional and physical aspects of objects. Such preoccupations may result in stimulation of various sensory modalities such as visual, tactile, vestibular, taste, and smell. Higher functioning individuals may exhibit unusual preoccupations with things such as metal objects, street signs, and toilets. Encompassing preoccupations with areas of circumscribed interests may take over one's life, supplant all other interests or hobbies, and affect functioning in other domains. In addition, individuals may exhibit unusual interests and develop expertise in arcane topics; alternatively, they may exhibit isolated splinter skills, and demonstrate exceptional abilities in areas such as music, drawing, and memory.

A significant proportion of people with ASD exhibit sensory symptoms, which can include heightened or reduced sensitivities to noise, light, or touch as well as paradoxical responses to stimuli such as high and low thresholds for pain. Clinical studies examining rates of sensory symptoms in school-age children with autism report a range from 42% to 88%; scores on the Sensory Profile in young children with autism were significantly higher than in children with other developmental disorders, and high scores were correlated with stereotyped interests and behaviors (Wiggins et al., 2009).

PATTERNS OF ONSET

Children may present in the first year of life with delays in all core domains, whereas some children develop typically and

then plateau, and approximately 25% to 30% exhibit frank regression between 12 and 36 months (Ozonoff et al., 2011). The loss of skills observed in regression can occur in the setting of previously typical development or superimposed on an already aberrant developmental trajectory (Ozonoff et al., 2005). Early identification of children at risk for developing ASD is first accomplished through the use of screening tools with high sensitivity and confirmed using the DSM with semi-structured observational tools and parent interviews.

COGNITIVE DEFICITS

A range of cognitive deficits characterize children with ASD. Recent surveillance studies indicate lower rates of intellectual disability—between 45% and 60%—compared with those reported in the 1990s (CDC, 2012; Johnson and Myers, 2007). Lower IQ scores are relatively stable and are associated with worse outcome as well as with a greater risk of developing a seizure disorder in adolescence (Johnson and Myers, 2007; Volkmar et al., 2007). Regardless of the level of general intellectual functioning, the cognitive profile of individuals with ASD is uneven, with marked “scatter” and pockets of skill across cognitive domains (Volkmar et al., 2007). Individuals typically perform better on tasks that require rote, visuospatial, or stimulus-bound perceptual processes as opposed to tasks that require more abstract thinking or higher-order, language-based conceptual processes (Dawson et al., 1998; Minshew et al., 1994; Ozonoff et al., 1991). Accordingly, nonverbal performance (PIQ) is usually stronger than verbally mediated performance (VIQ).

INATTENTION, HYPERACTIVITY, AND IMPULSIVITY

Symptoms of inattention, hyperactivity, and impulsivity are common in individuals with ASD, and may be the primary reason for referral among less impaired patients. In a survey of 487 children and adolescents with ASD, greater than 50% had moderate to severe symptoms of inattention and hyperactivity. In another sample of 101 children with ASD, 95% exhibited attention deficit, 50% demonstrated impulsive behavior, and 75% were found to manifest symptoms consistent with attention deficit hyperactivity disorder (ADHD) (Goldstein and Schwebach, 2004; Lecavalier, 2006). The presence of ADHD symptoms in children with ASD is particularly important to clarify because comorbidity may predict greater impairment in activities of daily life and higher rates of hospitalization than otherwise exist for children with ASD alone.

MEDICAL COMORBIDITY

In approximately 10% to 25% of patients, there is an identifiable medical condition or recognized syndrome associated with the ASD phenotype. Such conditions are typically associated with more severe comorbid global developmental delay and are in some cases considered to be the cause of the ASD symptomatology.

Perhaps the best known association is that of epilepsy. The occurrence of epilepsy in autism is higher than in the general

population and there is growing recognition that a subset of ASD patients have epileptiform EEG abnormalities in the absence of clinical seizures (Spence and Schneider, 2009). Depending on the study, 5% to 44% of individuals with ASD have seizure activity. Individuals with more severe intellectual disability are more likely to have epilepsy than those with greater language and cognitive skills (Tuchman and Rapin, 2002). Conversely, behaviors characteristic of autism have also been reported in pediatric patients with different epileptic syndromes. The complex relationship between seizure activity and ASD symptomatology can be seen in children with Landau Kleffner syndrome (LKS). Landau Kleffner syndrome presents with normal development until school age, when children typically develop acquired epileptic aphasia. The loss of previously acquired language milestones and loss of verbal comprehension can take the form of ASD-like symptomatology.

There are many medical genetic conditions associated with ASD. For a comprehensive review, see Betancur (2011) with a few examples noted here. Fragile X syndrome is the most commonly known genetic cause of ASD and intellectual disability in males. The phenotype includes cognitive delays, macrocephaly, large pinnae, hyperorchidism, hypotonia, and joint hyperextensibility. As many as 30% to 50% of individuals with genetically confirmed Fragile X syndrome demonstrate some characteristics of ASD (Rogers et al., 2001).

Additional common causes of ASD are Phelan–McDermid syndrome, Angelman syndrome and 15q duplications, and Rett syndrome. Phelan–McDermid syndrome (PMS) involves a deletion or mutation of the terminal region of chromosome 22 and there is very good evidence for a central role for the loss of SHANK3 as a major determinant for the neurobiological phenotypes in PMS (Buxbaum, 2009). Loss of a functional copy of SHANK3 appears to be second only to Fragile X syndrome in frequency as a monogenic cause of ASD, with estimates of 0.5% to 1% of ASD (Betancur, 2011).

Children with Angelman syndrome, which involves either a 15q deletion or imprinting error, are often nonverbal and present with global developmental delay, hypotonia, wide-based ataxic gait, seizures, and progressive spasticity (Veltman et al., 2005). Many meet criteria for ASD, as do individuals with a duplication of this region (Betancur, 2011).

Females with a mutation of the *MECP2* gene (Rett syndrome) can present with an ASD-like regression; individuals typically exhibit a phenotype characterized by microcephaly, seizures, and hand-wringing stereotypies (Johnson and Myers, 2007). Duplication of this region can also present with an ASD phenotype (Betancur, 2011).

Tuberous sclerosis (TSC) is a neurocutaneous disorder characterized by hypopigmented macules, fibroangioma, kidney lesions, central nervous system hamartomas, seizures, intellectual disability, and autistic and/or ADHD-like behaviors. An estimated 17% to 60% of patients with TSC have ASD (Numis et al., 2011). However, although it is often reported that the rate of TSC in ASD approaches 1%, this is not supported by recent data and the rates of TSC in patients ascertained for ASD are likely to be very low.

Phenylketonuria, often associated with the ASD phenotype in the past, is now considered a rare cause of ASD and ID in

the United States because it is preventable through newborn screening and dietary intervention. This serves as an important reminder that there are possibly additional genetic alterations underlying ASD that might be amenable to disease-modifying interventions.

NEUROIMAGING

Although a diagnosis of ASD is made based purely on behavioral symptoms, it is widely accepted that these symptoms have a neurodevelopmental origin. Over the last 20 years, neuroimaging studies have made great contributions to our understanding of the neurobiological underpinnings of the disorder (see Fig. 77.1). There is considerable heterogeneity in the brain phenotype of individuals with ASD, but structural and functional imaging studies have begun to elucidate brain–behavior relationships and move toward developing plausible neural biomarkers of ASD. Here, we summarize emerging themes, recent developments, and promising approaches within the structural and functional neuroimaging literature.

STRUCTURAL NEUROIMAGING

The structural brain imaging field has been plagued by contradictory findings owing in part to variability in both methodology and sample characteristics. However, in recent years, efforts to better understand the effects of age and development on brain structure in ASD have yielded some consistent patterns. The most replicated finding so far is that of increased brain volume in early childhood. Cross-sectional studies across the lifespan suggest that the brain is enlarged by two years of age, but normal or reduced in size by adolescence and adulthood. Taken together with research indicating that head circumference is normal or smaller at birth, these data suggest a period of rapid brain overgrowth in infancy and toddlerhood that is likely followed by a period of arrested growth and perhaps an accelerated rate of decline from adolescence to adulthood (Courchesne et al., 2011). Longitudinal studies have confirmed the findings in young children (e.g., Hazlett et al., 2011), but more work is needed that follows the same individuals through adulthood to confirm the later part of the proposed growth curve.

An important part of understanding brain enlargement in ASD is examining whether there are specific regions that are disproportionately affected. Evidence suggests that there is a gradient, such that the frontal and temporal cortices are most affected and occipital the least (see Courchesne et al., 2007 for a review). With respect to specific brain structures, the *amygdala* has received much recent attention. Although earlier studies yielded highly inconsistent findings, including enlarged size, reduced size, and no difference relative to controls, a metaanalysis revealed that age is an important factor to consider, with enlargement occurring in younger, but not older individuals with ASD (Stanfield et al., 2008). A recent longitudinal study found that the amygdala was enlarged by about 6% by three years of age and, moreover, the magnitude of enlargement was even greater one year later (9%) (Nordahl et al., 2012). Together with earlier evidence from the same

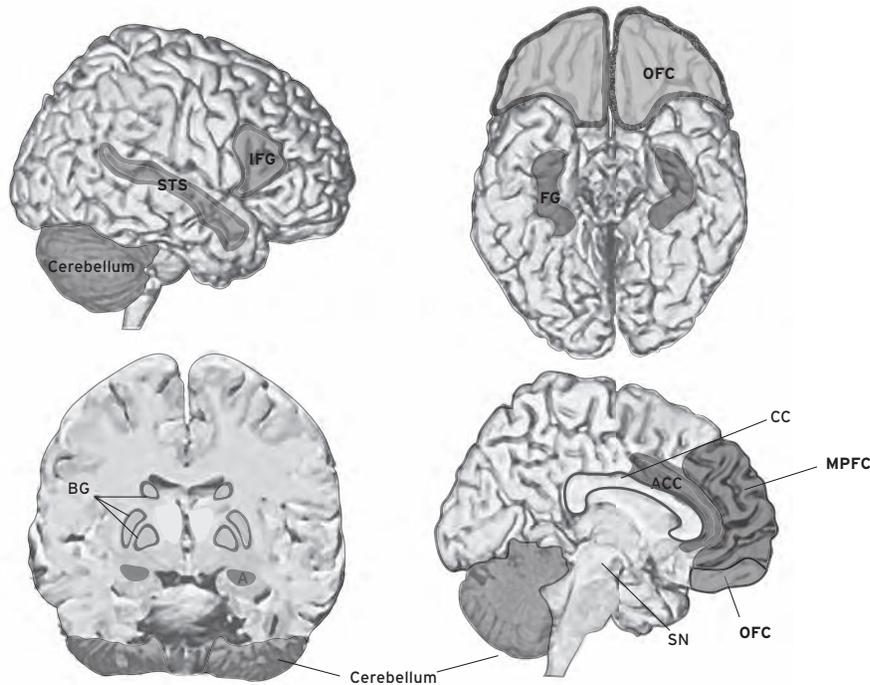

Figure 77.1 Brain areas commonly found to be structurally or functionally abnormal in autism. Regions in bold are considered to be part of the social brain. Structural Differences: **A**, amygdala; **BG**, basal ganglia; **Cerebellum**. **CC**, corpus callosum. Functional Impairment: **ACC**, anterior cingulate cortex; **A**, amygdala; **FG**, fusiform gyrus; **IFG**, inferior frontal gyrus; **STS**, superior temporal sulcus; **MPFC**, medial prefrontal cortex; **OFC**, orbitofrontal cortex. (Adapted from Amaral et al. (2008) used with permission from Elsevier.)

group that the amygdala is enlarged by approximately 14% in middle childhood, this suggests that overgrowth of the amygdala begins before age three and continues to accelerate over the next several years. Importantly, abnormal enlargement of the amygdala has been correlated with both the severity of autism symptoms (Schumann et al., 2009) and joint attention abilities (Mosconi et al., 2009), considered to be a pivotal deficit in ASD. Developing such links is critical for understanding brain–behavior relationships and the role of structural abnormalities in the etiology of autism.

Another region that is reportedly enlarged in autism is the *caudate nucleus*, which has been associated with the severity of repetitive behaviors (e.g., Hollander et al., 2005). The *cerebellum* has been widely studied, but findings have been inconsistent. Although a metaanalysis confirmed earlier reports of reduction in cerebellar vermis volumes, there was significant heterogeneity in the data, with age and IQ found to be important factors (Stanfield et al., 2008). Metaanalyses have also revealed that the *corpus callosum* is reduced in autism (Frazier and Hardan, 2009; Stanfield et al., 2008), suggesting that inter-hemispheric connectivity is impaired. Finally, it is noteworthy that regions thought to play a key role in social cognition and found to be functionally aberrant, such as the fusiform gyrus, the superior temporal sulcus, and the pars opercularis of the inferior frontal gyrus, have also been observed to have structural abnormalities (see Stigler et al., 2011 for a review).

The finding of enlarged brain volume also leads to the question of whether the increase reflects changes in cortical thickness or cortical surface area. These measures are

important because they are likely related to distinct biological mechanisms. Cortical thickness is hypothesized to reflect dendritic pruning and arborization or myelination, whereas cortical surface area varies with cortical folding and is thought to depend on the division of progenitor cells in the embryological periventricular area; cortical volume is the product of these two measures. Although newer technology allows for the automated measurement of cortical volume, thickness, and surface area simultaneously, applications to ASD are still in their infancy. In the largest cross-sectional study of this nature to date, Raznahan and colleagues (2010) examined the relationship between age, cortical volume, thickness, and surface area in males with ASD and healthy controls ages 10 to 65 years. They found that within frontal, temporal, and inferior parietal cortices, cortical volume, and thickness decreased significantly with age in healthy controls, but not in the ASD group, such that these measures were reduced relative to controls in childhood, but larger by adolescence and adulthood. However, no such abnormal trajectories were noted in cortical surface area. In contrast, a recent longitudinal study in young children ages two to five years did not find differences in cortical thickness, but did note increases in cortical volume and an estimate of surface area relative to controls at both time points, suggesting that cortical surface area was enlarged before two years of age in the ASD group (Hazlett et al., 2011). Given their potential to shed light on the distinct biological processes underlying brain overgrowth, studies that clarify the relative contributions of cortical thickness and surface area have great potential.

DIFFUSION TENSOR IMAGING

Diffusion tensor imaging (DTI) is a technique that probes the integrity of white matter fibers in the brain. The organization of axons in parallel bundles and the myelination of their sheaths restricts the diffusion of water, producing anisotropic diffusion. Most DTI studies in children and adults with ASD have found reduced fractional anisotropy, usually interpreted as lower coherence and organization of fiber tracts, in a variety of regions (e.g., medial prefrontal, orbitofrontal, anterior cingulate, external and internal capsule, corpus callosum, temporal lobe, among others) (see Anagnostou and Taylor, 2011, for a review). However, increased fractional anisotropy has also been observed in young children with ASD, ages 1.8 to 3.3 years (Ben Bashat et al., 2007), which is consistent with the data on early brain overgrowth and further illustrates the need to consider age and developmental trajectory, when designing and parsing neuroimaging studies.

There is a dearth of prospective data on autism from the first year of life, owing to the difficulty in detecting clinical symptoms before 12 months of age (Ozonoff et al., 2010). Recent efforts focused on following infants with high familial risk for ASD are beginning to enable the detection of brain abnormalities before the emergence of behavioral symptoms. For example, Wolff and colleagues (Wolff et al., 2012) used DTI to examine the development of white matter fibers in infants who have an older sibling with autism. Infants were scanned at 6, 12, and 24 months and evaluated for ASD symptoms at 24 months. Trajectories of white matter development, as indexed by fractional anisotropy values, differed significantly in infants who went on to develop ASD compared to infants who did not. Specifically, in most of the fiber tracts evaluated, infants later diagnosed with ASD showed higher fractional anisotropy at six months compared with infants determined to have typical development, but lower values by 24 months, suggesting that a slowed rate of white matter development is associated with an eventual ASD diagnosis among infants with high familial risk. The finding that white matter abnormalities are present and identifiable before the onset of clinical symptoms is exciting because it raises the possibility of developing structural imaging biomarkers for ASD.

FUNCTIONAL NEUROIMAGING

Functional magnetic resonance imaging (fMRI) studies have had a powerful effect on our understanding of autism as a neurobiological disorder. Early fMRI studies attempted to delineate brain-behavior relationships in ASD by designing tasks that tap core symptom domains, including social cognition (e.g., face processing, theory of mind, imitation, joint attention), language (e.g., semantic sentence comprehension, pragmatic/nonliteral language, gesture), and repetitive behaviors (via executive function tasks). A recent metaanalysis revealed that abnormalities in the function of regions considered to be part of the “social brain,” such as the *medial prefrontal cortex*, *orbitofrontal cortex*, *amygdala*, *fusiform gyrus*, and *superior temporal sulcus*, are among the most well-replicated findings in the literature (Philip et al., 2012). These studies suggest that ASD is associated with a lack of specialization in systems evolved for social attunement

that are normally automatically engaged. However, so far fMRI studies cannot differentiate whether aberrant brain activity is a cause or consequence of ASD. In fact, there is some evidence indicating that individuals with ASD can show typical levels of activity in key brain regions under certain circumstances—e.g., if the task is personally relevant, allows for cognitive or explicit processing, or draws attention to key social features (see Wang et al., 2007). This suggests the possibility that reduced activity in the social brain may be a result of a lack of social attention or motivation rather than a primary dysfunction in specific brain regions. A better understanding of the circumstances in which normative neural systems are engaged could inform novel treatment approaches.

An abundance of studies have examined the functional connectivity among brain regions that participate in neural networks in ASD. The majority of studies taking this approach have found support for the underconnectivity theory of autism, as coined by Just and colleagues (2004) when they observed decreased synchronization between the time series of activation among regions involved in a sentence comprehension task. Researchers have found underconnectivity in individuals with ASD using task-based approaches, resting-state approaches, and intrinsic approaches that attempt to remove activation effects. However, the findings are not all consistent with the underconnectivity theory and methodology appears to be an important consideration in interpreting the literature; a recent survey of functional connectivity studies found that task-based approaches looking within regions of interest are most likely to support underconnectivity (Muller et al., 2011). Some studies have found increased connectivity between close-range “nonessential” regions, but these findings have been interpreted as increased noise and, therefore, contributing to aberrant connectivity by decreasing signal-to-noise ratio (see Anagnostou and Taylor, 2011, for a review). The underconnectivity theory is appealing in that it offers a unifying, systems-level model of brain dysfunction while accounting for the considerable heterogeneity of ASD (Geschwind and Levitt, 2007). However, reduced functional connectivity between long-range connections has also been observed in a variety of other disorders, including Alzheimer’s disease, schizophrenia, chronic heroin use, posttraumatic stress disorder, and dyslexia, so it is not yet clear how underconnectivity accounts for what is common and specific to ASD (see Pelphrey et al., 2011).

One limitation of the extant fMRI literature is that, traditionally, MRI studies of ASD have been restricted to high-functioning older children, adolescents, and adults owing to the fact that obtaining high quality data necessitates that the participant remain still for the duration of a scan. Recently, investigators have extended their samples to infants and toddlers by scanning during natural sleep. Although fMRI signal can be somewhat dampened during sleep, the overall pattern of activation is very similar to that obtained during the awake state. Eyler and colleagues examined brain activity in response to a bedtime story during natural sleep and found that toddlers with ASDs between 12 and 48 months showed abnormalities in lateralization of temporal activity (Eyler et al., 2012). Whereas typically developing toddlers showed the expected left-hemisphere dominant pattern of activity in response to language, children

who were later diagnosed with ASD showed reduced activity in the left temporal cortex, a deficit that became more severe with age. This finding is consistent with numerous observations of a similar lack of left-hemisphere language specialization in older children and adults, and extends this work by suggesting that such a lack of specialization emerges early and may be a fundamental aspect of ASD. Scanning during natural sleep should prove to be a useful technique for extending fMRI to even younger ages as well as lower functioning populations.

Similar to the discussion in the structural imaging section, little is known about behavior and brain activation patterns associated with autism in the first year of life, which can lead to delays in diagnosis and treatment. Several research groups are currently trying to remedy this by focusing on prospective longitudinal studies of infants at high risk for autism by virtue of having an older sibling with ASD. A recent study following this approach recorded infants' event-related potentials (ERPs) in response to gaze shifts toward and away from the infant (Elsabbagh et al., 2012). Brain responses to these dynamic gaze shifts at six to 10 months distinguished between at-risk infants who were diagnosed with ASD at 24 or 36 months from both at-risk infants who did not later develop ASD as well as low-risk controls. Significantly, these early differences in brain function were not driven by differences in attention or looking behavior, as eye-tracking data revealed similar visual fixation times on the eyes across risk groups and diagnostic outcomes. The finding that ERP responses to gaze shifts predicted clinical outcomes raises the possibility of developing brain-based screening methods that could lead to early detection and treatment, with the caveat that such a biomarker would need to be established as sensitive and specific to ASD in a population-based sample.

GENETICS

We note in the preceding some medical genetic causes of ASD. More broadly, genetic epidemiological studies have consistently supported a strong role for genetics in ASD. In the nine twin studies conducted over the past 40 years, there has consistently been clear evidence for significantly increased concordance for ASD between monozygotic twins as compared to dizygotic twins (Hallmayer et al., 2011; Lichtenstein et al., 2010; Rosenberg et al., 2009; Taniai et al., 2008). These results indicate that the closer individuals are genetically, controlling for other factors (in this case prenatal, perinatal, and postnatal environment), the more likely they are to share the trait of ASD, which is the sine qua non for a genetic disorder. A strong role for genetics is supported by family studies as well, and most estimates of heritability in ASD are placed at 80% or higher. Clarifying the precise nature of the genetic liability to ASD has remained a challenge, but recent studies have made it clear that a significant proportion of risk resides in rare genetic variants of major effect and in recent genetic variation.

COMMON GENETIC VARIATION

It is informative to consider genetic risk in two dimensions, varying from low to high effect and from rare to common

variation (Sullivan et al., 2012). Very few examples of common variants with significant deleterious effect have been described, for the simple reason that if such variants exist, any impact on reproductive fitness would lead to strong purifying selection. One well-known example of such a variant, *APOE4* as a risk allele for Alzheimer's disease, is able to persist in the population because onset of the disorder is late in life. It is therefore likely that for an early onset disorder such as ASD, *common variation* will be associated with only very small effects, and this assertion is supported by both theoretical and empirical data. With several genome-wide association studies having been completed, single nucleotide polymorphism (SNP) variation with odds ratios of above 1.2 have effectively been excluded (Devlin et al., 2011). For SNP associated with smaller odds ratios, there are insufficient sample sizes to be adequately powered to make any conclusions. Based on studies in other psychiatric disorders, most notably schizophrenia, it is likely that there will be SNP association with ASD, but without 15,000 or more samples, we are not likely to identify many of them. One important conclusion from the empirical and theoretical data is that many, and even most, of the candidate gene association studies published in ASD are very likely false-positive findings.

RARE GENETIC VARIATION

When considering rare genetic variation, one can again consider the effect size dimension (Sullivan *et al.*, 2012). Clearly, it would be enormously difficult to reliably identify rare variation associated with very weak effects, so from a practical perspective, we are restricted to a focus on rare variation with higher effect sizes. Here, the field has made enormous progress, with more loci and genes being discovered all the time.

Discovery of rare genetic variation has tracked with technology. From the early days of karyotyping, through high-resolution karyotyping, FISH (fluorescent in situ hybridization), CMA, and now MPS, discovery of ASD loci and genes has been facilitated by the emergent technology (Ledbetter, 2008). Aneuploidies were identified in patients with an ASD using karyotyping, and include Down syndrome, Turner syndrome, Klinefelter syndrome, and additional sex chromosome abnormalities (Betancur, 2011). With the advent of FISH and then CMA, some 40 recurrent microdeletions or microduplications have been associated with ASD (Betancur, 2011; Cooper et al., 2011). Some more common variants include deletions and duplications at 7q11.23 (Williams syndrome), 15q11-q13 (the Prader-Willi/Angelman region), 17p11.2 (Smith-Magenis syndrome), 22q11 (DiGeorge syndrome), and 22q13 (Phelan-McDermid syndrome) and some of these are described briefly in the preceding.

These gene dosage abnormalities, frequently referred to as copy number variation (CNV), are recurrent either because they are subtelomeric or because they are flanked by segmental duplications (also called low copy repeats or LCR) and undergo non-allelic homologous recombination. However, there are many non-recurrent CNVs that have been associated with ASD and there are emerging algorithms to reliably relate a particular CNV to an ASD, taking into account the CNV size, gene content, and *de novo*, inherited, or X-linked inheritance of the CNV. Finally, with traditional and now massively parallel

sequencing (MPS), there have been over 100 genes associated with high risk for ASD (Betancur, 2011).

Four recent studies using MPS and focusing on *de novo* single nucleotide variation (SNV) identified at least six new ASD genes (*CHD8*, *DYRK1A*, *KATNAL2*, *NTNG1*, *POGZ*, and *SCN2A*), highlighting the importance of *de novo* variation in ASD and showing how important MPS approaches will be for further gene discovery (Iossifov et al., 2012; Neale et al., 2012; O’Roak et al., 2012; Sanders et al., 2012). These studies also provided estimates for the total number of dominant ASD genes that can be identified through MPS, now placed at about 800–1000, which suggests that we have identified something in the order of 10% to 20% of ASD genes. As MPS studies accelerate on available samples, it is fairly straightforward to predict that we can readily double the number of confirmed ASD risk genes within just three years. As such genes are identified, cell and animal models can be developed to better understand pathophysiology, which can in turn lead to novel therapeutics (see the following).

MODEL SYSTEMS

Identifying genes for ASD provides an opportunity for cellular and animal models to better understand pathobiology. The high risk associated with genes identified to date means that disruption of these genes in model systems will have strong *construct validity*. A model system of choice has been the genetically modified mouse, and dozens of ASD genes have been disrupted in mouse models (Buxbaum et al., 2012). These models have shown molecular, cellular, and behavioral deficits, which can then be used to dissect out pathobiological mechanisms of ASD that in turn can aid in identifying and assessing novel therapeutics. One recent success is that of fragile X syndrome, where studies in model systems implicate glutamate signaling abnormalities in the phenotype; recent clinical trials indirectly or directly modulating glutamate signaling are showing some very exciting results (Berry-Kravis et al., 2012; Jacquemont et al., 2011). Our work with *SHANK3* (see the preceding) has led to a mouse model where we observed deficits in neuronal glutamate signaling, and evidence for less mature synapses in the hippocampus (Bozdagi et al., 2010). Recently, we have shown that clinical doses of recombinant human insulin-like growth factor 1 (IGF-1) reversed these deficits in mice, and we have recently initiated clinical trials of IGF-1 in *SHANK3* haploinsufficiency (Phelan–McDermid syndrome).

SYSTEMS GENETICS

It should be apparent that with such a complex genetic and genomic architecture for ASD, it will not be straightforward to readily identify targets for drug development. However, systems-level analyses of genes and loci providing high risk for ASD can help identify pathways that underlie an appreciable proportion of ASD risk and can also identify driver genes for such pathways. These driver genes would then represent the high-value targets for drug development. The reader is referred to recent studies on systems-level analyses in ASD, including

evidence for highly connected gene models in ASD (Kou et al., 2012; Neale et al., 2012), a broad role for targets of FMRP (the proteins coded by the fragile X gene) in ASD (Iossifov et al., 2012), and disruption of neuronal gene expression modules in ASD (Voineagu et al., 2011).

THERAPEUTICS

Behavioral interventions are the first-line treatment in ASD. A few commonly used interventions, such as those based in the principles of applied behavioral analysis (ABA), have recently developed the evidence base to be considered empirically supported treatments for ASD (Seida et al., 2009; Warren et al., 2011). There has also been a significant amount of research into pharmacological treatments in ASD, although most medicines have targeted associated features as opposed to core symptom domains (Doyle and McDougle, 2012). This strategy was effective for treatment development, in part, and led to U.S. Food and Drug Administration (FDA) indications for “irritability associated with autism” for risperidone and aripiprazole.

BEHAVIORAL THERAPY

Behavioral interventions can widely be divided into comprehensive programs, including educational models such as TEACCH (Treatment and Education of Autistic and related Communication-handicapped Children), and skill building interventions designed to target specific core or associated symptoms. In general, comprehensive programs deliver behavioral interventions early, intensively, and address several domains of functioning (e.g., language, daily living, behavior, socialization). Comprehensive programs typically enroll children for at least one year and involve parents in the training models. The most studied is Applied Behavioral Analysis (ABA; Lovaas, 1987), which utilizes basic principles of learning and conditioning to systematically teach skills and reduce problematic behaviors. Applied Behavioral Analysis breaks down skills into smaller components and applies positive reinforcement to facilitate incremental improvements in skill performance. In recent years, additional comprehensive treatment models, such as the Early Start Denver Model, have been developed using ABA principles (ESDM; Dawson et al., 2010). Early Start Denver Model integrates ABA with developmental and relationship-based approaches and has shown similar gains in cognitive development seen in traditional ABA models. In a randomized controlled trial, two years of intervention led to an average gain of 17.6 standard IQ points in the ESDM group as compared with seven points in the community treatment controls. In addition, children in the ESDM group showed greater improvements in adaptive functioning and symptom severity (Dawson et al., 2010).

In contrast to comprehensive programs, skill-building programs are focused on one domain or skill and are generally short-term treatments. For example, several skill building treatments are available for language development. One approach for non-verbal children with oral–motor praxis impairments is PROMPT (Prompts for Restructuring Oral

Muscular Phonetic Targets), in which a speech therapist uses modeling and physical manipulation of the mouth and jaw to help the child form speech sounds and awards behavioral reinforcers for successful approximations (Rogers et al., 2006). Picture Exchange Communication Systems (PECS) is an augmentative and alternative communication (AAC) intervention that involves teaching children with ASD to utilize picture symbols to communicate. Metaanalyses suggest that PECS is associated with improved communication skills and behavior (Ganz et al., 2012). Other approaches to teach functional communication in non-verbal children rely on devices using digital voice output, or adapted signs from American Sign Language. With the advent of portable electronic devices, the iPad and other tablets have recently become popular training tools, although the multitude of available applications have not been well studied.

Skill-building interventions are also used to improve socialization impairments in children with ASD. Although several models of social skills intervention exist, commonly used approaches include social skills training groups, Relationship Development Intervention (RDI), peer-mediated interventions, and Social Stories™. Social skills training groups focus on improving ASD-specific impairments through various orientations, including cognitive behavioral therapy (CBT) or play. Relationship Development Intervention is parent-directed and facilitates social learning opportunities for children in naturalistic settings. Peer-mediated interventions train typically developing peers as social interaction facilitators for children with ASD, and Social Stories™ teaches skills through detailed descriptions of social situations that embed direct statements about appropriate behavior expected from a child in a given situation.

Targeted interventions can also be applied to reduce disruptive and repetitive behaviors, such as positive behavioral support (PBS). Positive behavioral support adopts ABA principles to understand environmental triggers for behavioral problems and utilizes systematic observations and data collection known as functional behavioral assessments (FBAs). This approach assumes that disruptive behaviors can be predicted to occur based on antecedent or consequences commonly associated with that behavior. Maladaptive behaviors are believed to be maintained/reinforced because they often allow the child to avoid demands or gain access to a desired object. Once the elements of the setting and specific triggers are understood, the environment is manipulated to replace the disruptive behavior with more adaptive behavior using appropriate reinforcement.

In summary, although widely utilized, only a few behavioral interventions have been rigorously studied and the evidence base for most interventions used in practice is still emerging. Several early, intensive behavioral interventions such as ABA and ESDM are supported by encouraging data in randomized controlled trials. Other models, including social skills interventions and many language interventions, require additional rigorous evaluation. The literature to date does not address several important treatment needs, such as interventions for older individuals with ASD. In addition, moderators and mediators of treatment effects have yet to be identified.

Several collaborative projects, including the Toddler Treatment Network funded by Autism Speaks, are poised to provide valuable data to potentially fill significant gaps in the literature and improve the evidence base in guiding future behavioral treatment in ASD.

PHARMACOTHERAPY

The development of pharmacological treatments in ASD has mainly taken a symptom domain approach to broadly target associated psychiatric features, such as aggression, attention deficit and hyperactivity, and anxiety. This strategy has been only loosely related to what is known about the neurobiology of the disorders and met with mixed success. Several recent papers (Anagnostou and Hansen, 2011; Doyle and McDougle, 2012; Warren et al., 2011) have reviewed the current state of the pharmacological evidence and are cited throughout this section rather than providing individual references to the studies (and see Table 77.1). The section will also be divided into symptom domains in order to be consistent with clinical practice.

AGGRESSION

Aggression and self-injury are among the most distressing associated symptoms in ASD and are treated with a broad range of pharmacological approaches. Various mechanisms have been proposed to explain their prevalence in ASD and biochemical targets include the dopaminergic, serotonergic, adrenergic, and opioid systems, among others. In controlled clinical trials to specifically target aggression, several medications have produced significant improvement as compared with placebo, including risperidone, aripiprazole, methylphenidate, clonidine, tianeptine, and naltrexone. However, only risperidone, aripiprazole, and methylphenidate demonstrate results that have been replicated across at least two well-controlled studies (Anagnostou and Hansen, 2011; Doyle and McDougle, 2012; Warren et al., 2011).

Dopamine dysregulation has specifically been implicated in self-injurious patients with autism and dopaminergic antagonists are most commonly used to prevent the onset and maintenance of aggression and self-injury. Risperidone has the most evidence to support its use for aggression in ASD, and results are consistent across several studies. However, the risks of risperidone include significant weight gain and increased vulnerability to diabetes and cardiovascular disease later in life. At least two controlled trials support the use of aripiprazole for irritability in ASD. As with risperidone, risks of weight gain and metabolic disturbance persist with aripiprazole, although levels of serum prolactin do not appear to increase as they may with risperidone. Other neuroleptics have been studied in ASD. Small open label or retrospective studies of clozapine, quetiapine, ziprasidone, olanzapine, and at least one controlled trial with olanzapine all provide preliminary evidence to support their use to treat disruptive behaviors associated with ASD. Older studies with haloperidol have also demonstrated benefit.

Psychostimulant medications are potent dopaminergic agonists and may act to reduce aggression by increasing the availability of dopamine in the prefrontal cortex and enhancing impulse control through striatal-frontal pathways. At least two controlled

TABLE 77.1. Selected positive controlled trials of medications in ASD

MEDICATION	AUTHORS	DESIGN	SAMPLE	OUTCOME
Risperidone	RUPP (2002)	Placebo Parallel	101 children and adolescents	↓ aggression ↓ hyperactivity
Risperidone	Shea et al. (2004)	Placebo Parallel	80 children	↓ aggression ↓ hyperactivity
Aripiprazole	Owen et al. (2009)	Placebo Parallel	98 children and adolescents	↓ aggression
Aripiprazole	Marcus et al. (2009)	Placebo Parallel	218 children and adolescents	↓ aggression
Valproate	Hollander et al. (2010)	Placebo Parallel	27 children and adolescents	↓ aggression
Clonidine	Jaselkis et al. (1992)	Placebo Crossover	8 children and adolescents	↓ aggression ↓ hyperactivity
Methylphenidate	RUPP (2005)	Placebo Crossover	72 children and adolescents	↓ hyperactivity
Atomoxetine	Hafterkamp et al. (2012)	Placebo Parallel	97 children and adolescents	↓ hyperactivity
Atomoxetine	Arnold et al. (2006)	Placebo Crossover	16 children and adolescents	↓ hyperactivity
Haloperidol	Anderson et al. (1989)	Placebo Crossover	45 children	↓ hyperactivity
Fluvoxamine	McDougle et al. (1996)	Placebo Parallel	30 adults	↓ Repetitive behavior
Fluoxetine	Hollander et al. (2005)	Placebo Crossover	39 children and adolescents	↓ Repetitive behavior

trials found methylphenidate effective for symptoms of aggression and self-injury in ASD, although its effect on aggression is less reliable than on symptoms of attention deficit and hyperactivity in ASD. Notably, the largest study of methylphenidate in ASD to date did not find significant differences on irritability and aggression as compared with placebo, although benefits on hyperactivity were significant (RUPP, 2005).

ATTENTION DEFICIT AND HYPERACTIVITY

Symptoms of attention deficit, hyperactivity, and impulsivity are common in ASD (Lecavalier, 2006). Methylphenidate and atomoxetine effectively treat symptoms of ADHD in ASD, but response rates are lower than what is reported in typically developing children with ADHD alone (Hafterkamp, 2012; RUPP, 2005). Further, in ASD, symptoms of inattention may be less likely to respond than symptoms of hyperactivity and impulsivity. Treatment success may also be limited by tolerability; 18% of subjects with ASD discontinued the RUPP methylphenidate trial, and the most common side effect was irritability.

Many studies have also demonstrated efficacy for anti-psychotic medications, and risperidone in particular has consistently shown benefit for hyperactivity in ASD. However, significant concerns about the tolerability of antipsychotics

remain and suggest that benefits of these medications must be carefully weighed against the risks, especially in the absence of significant aggression.

Evidence from controlled studies of alpha-two agonists for ADHD-related symptoms in ASD is inconsistent and response rates are relatively low. Open label studies of guanfacine appear promising but additional controlled studies are needed. Alpha-two agonists may nevertheless be a reasonable alternative or augmentation strategy to stimulants and have the advantage of being well tolerated.

Based on evidence of glutamatergic dysregulation in ASD derived from genetic discovery and model systems, amantadine and other NMDA antagonists are of significant interest for the treatment of ASD symptoms. One controlled trial has been published to date with amantadine, and controlled trials are underway with memantine based on positive results from open label and retrospective reports. Despite multiple controlled trials, results with naltrexone are inconsistent and isolated positive findings should be interpreted with caution.

ANXIETY AND REPETITIVE BEHAVIORS

Restrictive, repetitive, and stereotyped behaviors are a core symptom of ASD, and targeting this domain can improve overall outcomes for affected children. Among the various

pharmacological options, serotonergic medications are widely used in part because serotonergic dysregulation in ASD is a consistently replicated finding from biochemical, pharmacological challenge, and genetic studies. Fluoxetine is the most rigorously studied serotonergic medication in ASD; numerous case reports, open-label studies, retrospective chart reviews, and small placebo-controlled trials have been published with promising results (Doyle, 2012). However, the Studies of Fluoxetine in Autism (SOFIA) enrolled 158 children and adolescents for a 14-week treatment of placebo or orally disintegrating fluoxetine, but fluoxetine was not more efficacious than placebo for reducing repetitive behaviors.

King and colleagues also published results from a 12-week, multicentered, placebo-controlled trial of liquid citalopram for the treatment of repetitive behaviors in 149 children and adolescents with ASD. No significant differences in response rates were found between the citalopram and placebo group; approximately one-third of participants were rated as responders in both groups. These results were in contrast to two previous retrospective chart reviews of citalopram in ASD, which suggested effectiveness for treating anxiety in ASD (see Doyle and McDougle, 2012).

Other serotonergic medications have also been studied for repetitive behaviors in ASD (Doyle and McDougle, 2012). Fluvoxamine may be effective for adults, but not in children. Open-label studies and case reports suggest improvement with escitalopram, sertraline, and paroxetine and results from one retrospective review of venlafaxine have been positive. Clomipramine has also been used with some success in small studies in children and adults, and several investigators have published case reports documenting improvement with mirtazapine for anxiety and compulsive behaviors in ASD. Among two small trials with buspirone, one did not find improvement in obsessive thinking, while the second found that 76% of 21 children were designated responders on the Clinical Global Impression Scale.

Children with ASD are likely more sensitive to serotonin-associated adverse effects as compared to adults and the appropriate dosing of SSRIs in children with ASD is still in question. A mean dose of only 16.5 mg/day of liquid citalopram caused considerable side effects including behavioral activation, increased energy level, impulsivity, decreased concentration, hyperactivity, and stereotypies in a large randomized controlled trial (Doyle and McDougle, 2012).

Risperidone and other atypical antipsychotics with strong affinity for serotonin receptors, particularly the 5-HT_{2A} receptor, are also used frequently to treat the repetitive behavior domain. Although atypical antipsychotics appear to be effective for reducing repetitive behaviors in ASD, their use is compromised by side effects such as sedation, weight gain, and extrapyramidal symptoms. However, in some cases, repetitive behaviors may reach levels of severity that warrant consideration of antipsychotics when safer options have been unsuccessful.

FUTURE DIRECTIONS

When examined broadly, the field of pharmacological treatment research in ASD has grown in recent years, and

significant evidence now exists to support the use of a number of different medications across several symptom domains. However, there has been little progress in targeting core symptoms of social and language impairment. Studying genetic subtypes with single gene causes of ASD, such as Fragile X syndrome, may be necessary to better understand medication efficacy in ASD more broadly. Incorporating biological markers to further characterize ASD phenotypes may also prove useful in predicting treatment response and side effects. Novel measurement instruments also need to be validated to objectively assess core symptoms in ASD. In addition, clinical trials should be designed to examine moderators of treatment response, such as age, developmental level, gender, and intellectual ability. In general, medication treatment of children and adolescents with ASD should be initiated with low starting dosages and slow titrations because these individuals are often very sensitive to side effects. Future studies will improve understanding of medication side effects in ASD and may help identify risk factors to predict which individuals are most vulnerable.

CONCLUSIONS

Autism spectrum disorders involve specific and well-defined deficits in social communication with the presence of repetitive behaviors and restricted interests. However, ASD are clinically and etiologically very heterogeneous. Neuroimaging studies are still evolving but already implicate specific brain regions and brain networks in ASD. Behavioral interventions are important first-line treatments in ASD and there is much progress needed in pharmacological treatments that target core symptoms of ASD. The research community has made great progress in identifying etiological genetic loci for ASD and it is very likely that such findings will explode over the next three to five years with the emergence of MPS. Already, small studies with MPS have identified several new genes. Understanding how the multiple, diverse ASD interact in specific molecular networks is an important means by which high-value therapeutic targets can be identified.

It is important to note that recent genetic discovery and the development of animal model systems have elucidated the neurobiology of several genes implicated in monogenic forms of ASD, including Rett syndrome, tuberous sclerosis, Fragile X syndrome and, in our center, Phelan–McDermid syndrome. These discoveries have in turn led to important opportunities for developing novel treatments. Several large- and small-scale clinical trials are underway in the United States and Europe with potentially disease-modifying medications that target core symptom domains in ASD, arising from neurobiological studies in model systems, and there is even suggestion of positive effects with compounds indirectly or directly modulating glutamate signaling in individuals with fragile X mutation (for example [Berry-Kravis et al., 2012; Jacquemont et al., 2011]). Although the state of the evidence is preliminary, these studies are the basis for enormous optimism in ASD and underscore how neurobiological approaches are likely to lead to novel therapeutics in ASD.

ACKNOWLEDGMENTS

Dr. Kolevzon would like to acknowledge the help of Dr. Latha Soorya for her contribution in researching and writing about behavioral therapy in ASD.

DISCLOSURES

Dr. Kolevzon receives grant support from Seaside Therapeutics and Hoffmann La-Roche.

Drs. Wang and Grodberg have no conflicts of interest to disclose.

Dr. Joseph D. Buxbaum has submitted a patent on therapeutics in SHANK3.

78 | NEUROBIOLOGY OF ATTENTION DEFICIT/HYPERACTIVITY DISORDER

STEPHEN V. FARAONE AND JOSEPH BIEDERMAN

Attention deficit/hyperactivity disorder (ADHD) is a highly prevalent, early onset, clinically heterogeneous disorder of inattention, hyperactivity, and impulsivity. Its impact on individuals, families, and society is enormous in terms of its financial cost, stress to families, adverse academic and vocational outcomes, and negative effects on self-esteem. Children with ADHD are easily recognized in clinics, schools, and the home. Their inattention leads to daydreaming, distractibility, and difficulties sustaining effort on a single task for a prolonged period of time. As their attention wanders from one stimulus to the next, they often leave parents and teachers with the impression that they are not listening. Their impulsivity makes them accident prone, creates problems with peers, and disrupts classrooms as they blurt out answers, interrupt others, or shift from schoolwork to inappropriate activities. Their hyperactivity, often manifest as fidgeting and excessive talking, is poorly tolerated in schools and is frustrating to parents, who can easily lose them in crowds and cannot get them to sleep at a reasonable hour.

In their teenage years, symptoms of hyperactivity and impulsivity tend to diminish, but—in the majority of cases—the symptoms and impairments of ADHD persist. The teen with ADHD is at high risk for low self-esteem, poor peer relationships, conflict with parents, delinquency, smoking, and substance abuse. A metaanalysis of longitudinal studies found that two-thirds of children with ADHD have impairing ADHD symptoms as adults (Faraone et al., 2006). Studies of clinically referred adults with retrospectively defined childhood-onset ADHD show them to have a pattern of psychosocial disability, psychiatric comorbidity, neuropsychological dysfunction, familial illness, and school failure that resemble the well-known features of children with ADHD, supporting the syndromic continuity between pediatric and adult patients with ADHD.

Throughout the life cycle, an essential clinical feature observed in patients with ADHD is comorbidity with mood, anxiety, and disruptive behavior disorders. Although spurious comorbidity can occur because of referral and screening artifacts, these artifacts cannot explain the high levels of psychiatric comorbidity observed for ADHD. Notably, epidemiological investigators find comorbidity in unselected general population samples—a fact that cannot be caused by the biases inherent in clinical samples (Scahill and Schwab-Stone, 2000).

NEUROTRANSMITTER SYSTEMS AND ATTENTION DEFICIT/HYPERACTIVITY DISORDER

Metaanalyses of pharmacotherapy for ADHD clearly document that three classes of medications reduce the overactivity, impulsivity, and inattentiveness of patients with ADHD: dopamine reuptake inhibitors (the stimulants methylphenidate and amphetamine), norepinephrine reuptake inhibitors (atomoxetine), and alpha2a receptor agonists (clonidine and guanfacine) (Faraone and Glatt, 2010). In addition to improving the core symptoms of ADHD, stimulants also improve associated behaviors, including on-task behavior, academic performance, and social functioning. These effects are dose dependent and are evident in home, school, and occupational settings. Metaanalyses and some direct comparisons suggest that amphetamine is a little more effective than methylphenidate and that both stimulants are more efficacious than non-stimulants (Faraone and Glatt, 2010).

Both stimulant drugs block the dopamine transporter and, by doing so, increase the concentration of dopamine in the synaptic cleft. Because of the distribution of dopamine transporters, these effects are most pronounced in the nucleus accumbens and dorsal striatum (e.g., Kuczenski and Segal, 2002). Although these were initially demonstrated *in vitro* and in animal studies, positron emission tomography (PET) studies in humans show that both methylphenidate and amphetamine administration increase dopamine levels in striatum. Single photon emission tomography (SPECT) and PET studies also show that methylphenidate treatment blocks the dopamine transporter. This suggests that the ultimate effect of methylphenidate's dopamine transporter blockade is to increase the rate of dopamine release.

Rat studies show that low, oral doses of stimulants increase dopamine release in striatum but not in nucleus accumbens, which suggests that oral stimulant administration should not have addictive effects on the brain (Kuczenski and Segal, 2002). Stimulant administration also increased norepinephrine in the hippocampus (important for learning and memory) and dopamine and norepinephrine in the prefrontal cortex (important for maintain executive control) (Kuczenski and Segal, 2002). Both amphetamine and methylphenidate reduce the expression of the norepinephrine transporter. Thus, the efficacy of stimulant medications for treating ADHD suggests that

dysfunction of both dopaminergic and noradrenergic systems may underlie the pathophysiology of the disorder.

Further evidence for the relevance of catecholaminergic systems comes from the efficacy of atomoxetine for treating ADHD. Atomoxetine blocks the norepinephrine transporter. Tricyclic antidepressants also block the norepinephrine transporter, but unlike atomoxetine, they also affect other neurotransmitter systems. Neuroimaging studies of primates show that clinical doses of atomoxetine would occupy the norepinephrine transporter almost completely and rat studies show that atomoxetine administration increases norepinephrine and dopamine release in the prefrontal cortex.

Guanfacine and clonidine are alpha_{2a} receptor agonists. They enhance noradrenergic transmission by stimulating postsynaptic alpha_{2a} receptors in prefrontal cortex (Arnsten, 2009). Like the stimulants (Chase et al., 2005), guanfacine also increases the expression of *FOS* mRNA (Savchenko and Boughter, 2011), suggesting that transcription regulation pathways could be a final common pathway for the activity of ADHD medications. Clonidine also decreases the activity of insulin, which would be expected to decrease the expression of both the dopamine and norepinephrine transporters, suggesting another mechanism of action for this medication.

Because the pharmacological treatment of ADHD implicates dysregulated catecholamine systems, many studies have examined catecholamine metabolites and enzymes in serum and cerebrospinal fluid. Scassellati et al. (2012) completed a metaanalysis of studies comparing ADHD and non-ADHD people on peripheral biochemical markers. They found 71 studies relevant to monoaminergic neurotransmission. After Bonferroni correction, four of these markers significantly discriminated ADHD and non-ADHD samples: increased norepinephrine, decreased 3-methoxy-4-hydroxyphenylethylene glycol (MHPG), decreased monoamine oxidase (MAO), and decreased phenylethylamine. For these significant findings, they found no evidence of publication bias or heterogeneity of effect sizes across studies. They concluded that reduced MAO activity impairs the degradation of norepinephrine and lead to lower levels of MHPG in ADHD patients and that dysregulation of the “MAO-NE-MHPG” pathway may be a compensatory response to hypo-noradrenergic synaptic activity in ADHD. Of note, phenylethylamine, which has a chemical structure that is similar to amphetamine, increases the release of dopamine, which is consistent with the idea that low levels could lead to ADHD.

Animal model studies also support the idea that catecholaminergic systems are impaired in ADHD. One approach has been the use of 6-hydroxydopamine to lesion dopamine pathways in developing rats. Because these lesions created hyperactivity, they were thought to provide an animal model of ADHD. Disruption of catecholaminergic transmission with chronic low-dose *N*-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), a neurotoxin, creates an animal model of ADHD in monkeys. Administration of MPTP to monkeys caused cognitive impairments on tasks thought to require efficient frontal-striatal neural networks, the same networks implicated in ADHD. These cognitive impairments mirrored those seen in monkeys with frontal lesions. Like ADHD

children, MPTP-treated monkeys show attentional deficits and task impersistence. Methylphenidate reversed the behavioral deficits but not the cognitive dysfunction.

Several investigators have used the spontaneously hypertensive rat (SHR) as an animal model of ADHD because of the SHR's locomotor hyperactivity and impaired discriminative performance. Studies using SHR have implicated dopaminergic and noradrenergic systems. The dopamine D2 receptor agonist, quinpirole, caused significantly greater inhibition of DA release from caudate-putamen in SHR compared with control mice. These findings were attributed to increased autoreceptor-mediated inhibition of dopamine release in caudate-putamen slices but not in the prefrontal cortex. Another study showed that the altered presynaptic regulation of dopamine in SHR led to the down-regulation of the dopamine system. The authors hypothesized this may have occurred early in development as a compensatory response to abnormally high DA concentrations.

Other SHR studies implicated an interaction between the noradrenergic and dopaminergic system in the nucleus accumbens, but have ruled out the idea that a dysfunctional locus coeruleus and A2 nucleus impairs dopaminergic transmission in the nucleus accumbens via alpha 2-adrenoceptor mediated inhibition of dopamine release. Papa et al. (1998) used molecular imaging techniques to assess the neural substrates of ADHD-like behaviors in the SHR rat. Their data showed the cortico-striato-pallidal system to mediate these behaviors. Exposure to excess androgen levels early in development led to decreased catecholamine innervation in frontal cortex and enhanced expression of ADHD-like behaviors. Carey et al. (1998) used quantitative receptor autoradiography and computer-assisted image analysis to show a higher density of low-affinity D1 and D5 dopamine receptors in the caudate-putamen, nucleus accumbens, and olfactory tubercle of SHR. Stimulant treatment normalized these receptors by decreasing the number of binding sites and increasing affinity to the control level. Gene expression studies of the SHR brain have implicated genes involved in neural development, immunity, transcription factor, monoamine neurotransmitter, metabolism, signal transduction, and apoptosis as well as genes implicated in human association studies of ADHD (e.g., Dasbanerjee et al., 2008). The SHR has also been shown to have elevated dopamine transporter density in the brain that is normalized by methylphenidate treatment (Roessner et al., 2011).

GENETICS

FAMILY STUDIES

As reviewed in detail elsewhere, family studies consistently support the assertion that ADHD runs in families (Faraone and Doyle, 2001). Table 78.1 presents eight studies providing information about rates of ADHD among the parents of ADHD probands. Table 78.2 shows rates of ADHD and hyperactivity among the siblings of hyperactive probands. There is agreement between early studies of hyperactivity and subsequent studies of ADD and ADHD. These studies find the parents and

siblings of children with ADHD to have a two- to eightfold increase in the risk for ADHD.

Attention to other psychiatric disorders in family studies of ADHD provided evidence for the genetic heterogeneity of ADHD. Results of analyses from independent samples of children with DSM-III ADD and DSM-III-R ADHD suggested that: (1) ADHD and major depression share common familial vulnerabilities; (2) ADHD children with conduct and bipolar disorders might be a distinct familial subtype of ADHD; and (3) ADHD is familially independent from anxiety disorders and learning disabilities. Thus, stratification by conduct and bipolar disorders may cleave the universe of children with ADHD into more familially homogeneous subgroups. In contrast, major depression may be a nonspecific manifestation of different ADHD subforms.

TWIN STUDIES

The occurrence of twinning creates a natural experiment in psychiatric genetics. If a disorder is strongly influenced by genetic factors, then the risk to co-twins of ill probands should

TABLE 78.2. Prevalence of attention deficit/hyperactivity disorder (ADHD) in the siblings of ADHD and control probands

**Undefined because relative risk has zero denominator.

be greatest when the twins are monozygotic. The risk to dizygotic twins should exceed the risk to controls but should not be greater than the risk to siblings.

Twin data are used to estimate heritability, which measures the degree to which a disorder is influenced by genetic factors. Heritability ranges from zero to one, with higher levels indicating a greater degree of genetic determination. Figure 78.1 presents heritability data from 15 twin studies of ADHD. These data attribute about 80% of the etiology of ADHD to genetic factors.

Freitag et al.’s (2010) review of twin studies generated several useful conclusions. They found that studies that used short rating scales with a limited amount of answer categories showed strong rater effects. Parent ratings of ADHD symptoms were more heritable than both teacher ratings and objective measures as hyperactive behaviors by Actigraph. Twin studies also showed that inattentive and hyperactive/impulsive symptoms share susceptibility genes, but each symptom domain also has a unique genetic component. Twin studies of comorbidity suggest that reading disability and inattentive symptoms share risk genes. In contrast, both classes of ADHD symptoms are strongly associated with conduct disorder.

A metaanalysis of twin studies showed that ADHD’s heritability remains constant through adolescence (Bergen et al., 2007), which suggests that changes in the mix of genetic and environmental risk factors cannot account for the age-dependent decline of the disorder (Faraone et al., 2006). However, in contrast to the constancy of heritability through adolescence, twin studies have found a lower heritability of ADHD in adult samples. In contrast to the 76% heritability of ADHD in youth, four studies have estimated the heritability of adult ADHD to range from 30% to 40% (Franke et al., 2011). These findings were unexpected given the constancy of heritability during adolescence and data from family studies showing that persistent ADHD was *more* familial than ADHD assessed in childhood. After reviewing the adult ADHD twin data, Franke et al. (2011) concluded that these discrepant findings

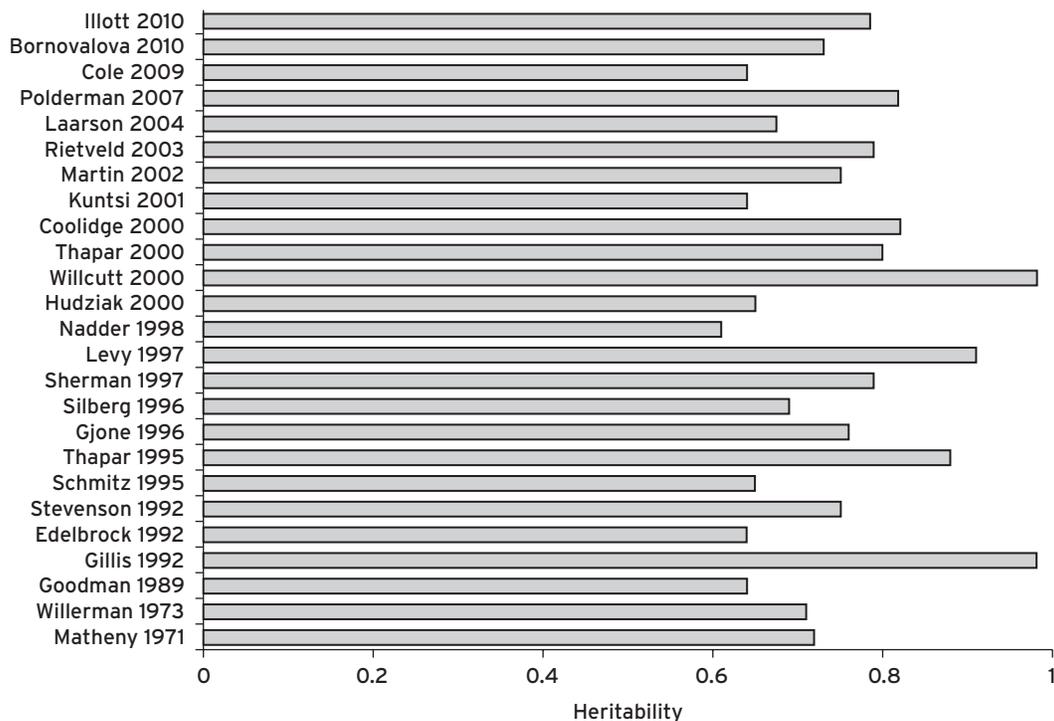

Figure 78.1 Heritability computed from twin studies of youth with attention deficit/hyperactivity disorder. (See Freitag, C.M., Rohde, L.A., Lempp, T. and Romanos, M. (2010). Phenotypic and measurement influences on heritability estimates in childhood ADHD. *Eur. Child Adolesc Psychiatry* 19, 311–323; Faraone, S.V. and Mick, E. (2010). Molecular genetics of attention deficit hyperactivity disorder. *Psychiatr. Clin. North Am.* 33, 159–180.)

could be caused by methodological issues. Most important, all the twin studies of adult ADHD used self-ratings of ADHD, whereas studies of ADHD youth typically relied on either parent or teacher reports. Notably, twin studies also show that self-ratings of ADHD by adolescents are less heritable than parent or teacher ratings of ADHD symptoms in adolescents. This led Franke et al. (2011) to conclude that self-ratings may be a poorer measure of the genetic liability to ADHD. This could occur simply because of lower reliability, which in a twin study would lower estimates of heritability.

ADOPTION STUDIES

Like twinning, the occurrence of adoption provides another useful experiment for psychiatric genetics. Whereas parents can confer a disease risk to their biological children via both biological and environmental pathways, to adoptive children they can only confer risk via an environmental pathway. Thus, by examining both the adoptive and the biological relatives of ill probands, we can disentangle genetic and environmental sources of familial transmission.

Adoption studies of ADHD also implicate genes in its etiology. Early studies showed that the adoptive relatives of hyperactive children are less likely to have hyperactivity or associated disorders than are the biological relatives of hyperactive children. The adoptive relatives of adopted ADHD probands had rates of ADHD and other associated disorders that were lower than those observed in the biological relatives of non-adopted ADHD probands and similar to those found in relatives of control probands (for details, see Faraone and Mick, 2010).

MOLECULAR GENETIC STUDIES

Molecular genetic studies use two main approaches. The candidate gene approach examines one or more genes based upon some theory (hopefully backed by empirical evidence) about the nature of the disorder. In contrast, the genome scan examines all chromosomal locations without any a priori guesses as to what genes underlie susceptibility to ADHD. In discussing these results, we will differentiate between common and rare DNA variants, using a population prevalence of less than 5% to define a variant as rare. We use the term DNA variant to refer to any piece of DNA sequence including microsatellite polymorphisms, variable number of tandem repeat (VNTR) polymorphisms, single nucleotide polymorphisms (SNPs), and copy number variants (CNVs).

Elsewhere, we have extensively reviewed the hundreds of candidate gene studies of ADHD that are now available (Faraone and Mick, 2010; Franke et al., 2011). These studies have searched for common DNA variants that increase susceptibility to ADHD. A useful summary of these studies can be found in the metaanalysis of Gizer et al. (2009). Among the many DNA variants assessed for association with ADHD, eight showed a statistically significant association with the disorder across multiple studies. These variants implicated six genes: the serotonin transporter gene (*5HTT*), the dopamine transporter gene (*DAT1*), the D4 dopamine receptor gene (*DRD4*), the D5 dopamine receptor gene (*DRD5*), the serotonin 1B receptor gene (*HTR1B*), and a gene coding for a synaptic vesicle regulating protein known as *SNAP25*. As Figure 78.2 shows, the strength of association for each of these DNA variants, as measured by the odds ratio, is fairly small, less than 1.5, which

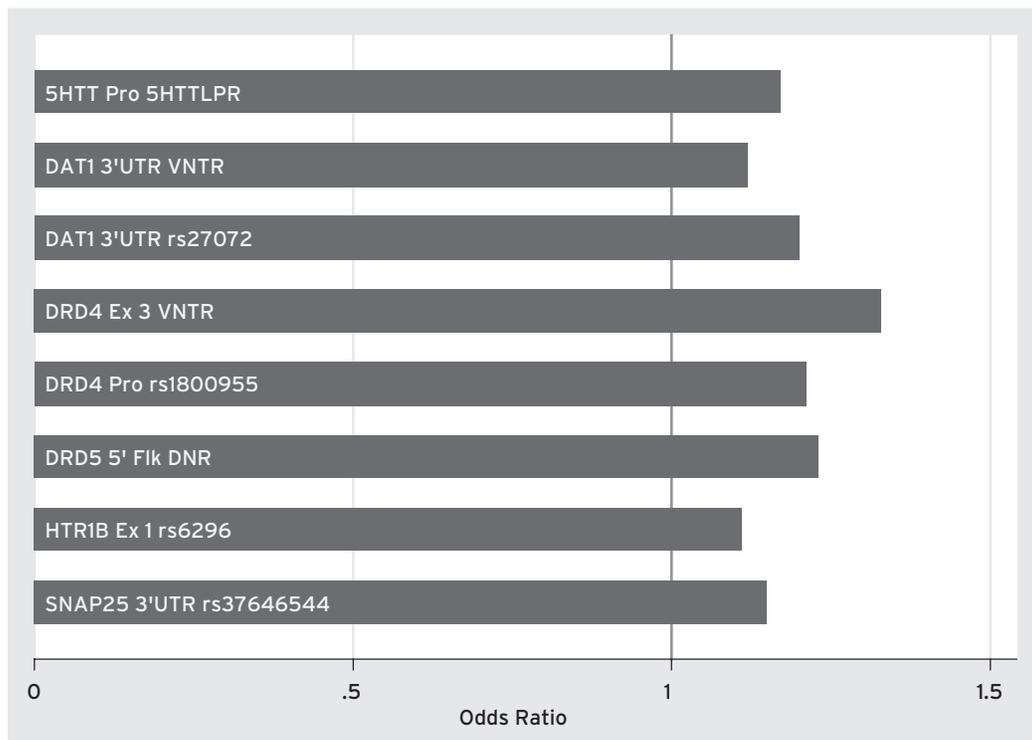

Figure 78.2 Each bar gives the name of the gene followed by the name of the variant tested for association with attention deficit/hyperactivity disorder. (Based on metaanalysis of Gizer, I.R., Ficks, C. and Waldman, I.D. (2009). Candidate gene studies of ADHD: a meta-analytic review. *Hum. Genet.* 126, 51–90.)

means that carrying one of these variants increases one's risk for ADHD by less than 50%.

GENETIC LINKAGE STUDIES

Genome-wide linkage scans examine many DNA markers across the genome to determine if any chromosomal regions are shared more often than expected among family members with ADHD. Because this methodology had been very successful for detecting disease genes for many single gene non-psychiatric disorders, it had been hoped that it would also detect genes for psychiatric disorders. To detect a disease gene, the method requires families having at least two ill family members and a gene that has a very large effect on disease manifestation. Although there is some overlap in nominally significant linkage peaks among linkage studies of ADHD, there is no evidence for the replication of a genome-wide significant finding using strict criteria. However, Zhou et al. (2008) searched for common linkage signals among these studies using Genome Scan Meta-Analysis. They reported genome-wide significant linkage for a region on chromosome 16 between 64 and 83 Mb. Although this finding is intriguing and worthy of follow-up, the lack of significant findings for other loci suggests that common DNA variants having a large effect on ADHD are unlikely to exist.

GENOME-WIDE ASSOCIATION STUDIES

In contrast with the linkage approach, the method of genome-wide association is able to detect common DNA

variants having a very small effect on disease etiology. There have been several genome-wide association studies (GWAS) of ADHD. None of these studies reported any DNA variants that achieved current guidelines for asserting genome-wide statistical significance, which require a *p*-value less than .00000005. This stringent *p*-value is needed because many SNPs must be examined to fully cover the human genome.

Given the lack of significance of these individual studies, the investigators combined their data and conducted a metaanalysis of the combined sample (Neale et al., 2010). The final sample size consisted of 2,064 trios, 896 cases, and 2,455 controls. No single SNP showed evidence for genome-wide significance, but an analysis of candidate genes suggested that they may be involved in the disorder.

THE SEARCH FOR RARE GENETIC VARIANTS

Rare variants causing ADHD were initially described in scattered, serendipitous, reports of gross chromosomal anomalies cosegregating with ADHD in only a few samples. Examples include the Fragile X syndrome, duplication of the Y-chromosome in boys, velo-cardio facial syndrome, loss of an X-chromosome in girls, and a peri-centric inversion of chromosome 3 co-segregating with ADHD symptoms. One study demonstrated that a rare familial form of ADHD is associated with generalized resistance to thyroid hormone (GRTH), a disease caused by mutations in the thyroid receptor- β gene. The thyroid receptor- β gene cannot account for many cases of ADHD because the prevalence of GRTH is very low among ADHD patients (1 in 2,500) and, among GRTH pedigrees, the

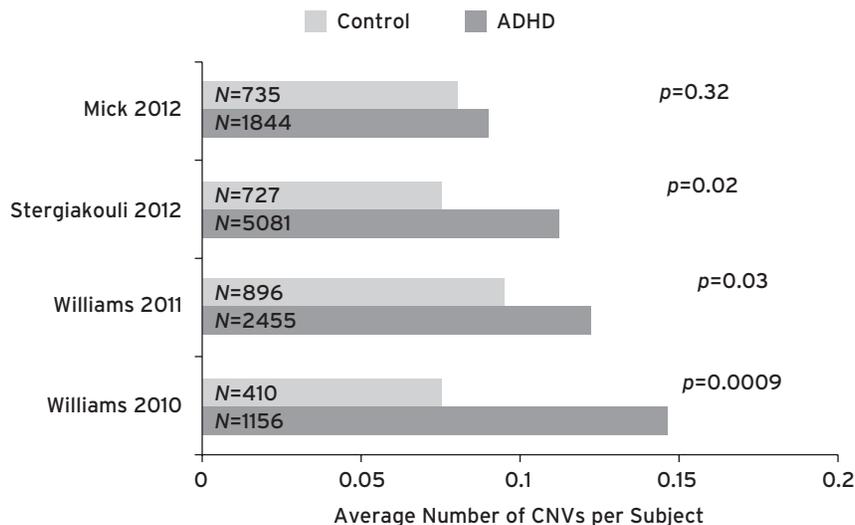

Figure 78.3 Burden of large (>500 kb) Rare copy number variations.

association between ADHD and the thyroid receptor-b gene has not been consistently found.

Most of the genotyping technologies used for GWAS can also be used to detect copy number variants (CNVs). Copy number variants are deletions and duplications of DNA segments, which typically are found in genomic regions having repetitive DNA sequences. In addition to being rare, many CNVs have clear implications for gene functioning. Because CNVs delete or duplicate a large portion of a gene, they either completely stop the production of the gene's protein or they lead to a greatly modified protein. This is likely to lead to functional consequences.

Several studies of CNVs in ADHD have now been reported (e.g., Elia et al., 2012; Williams et al., 2012). Four of these used a common method to define CNV burden, which they defined as the average number of large, rare CNVs for ADHD cases and controls. For these analyses, "large" was defined as the CNV being larger than 500 kb, and "rare" was defined as occurring in less than 1% of controls. As Figure 78.3 shows, each study found a greater burden of large, rare CNVs among ADHD patients compared with controls. This finding was significant in three of the four samples and in the combined sample. Another study using a different definition of burden found no difference between ADHD and control subjects. The burden finding suggests that one genetic cause of ADHD is the accumulation of rare deleterious genetic events across the genome.

The CNV studies have also provided insights into which biological systems are affected by rare deletions and duplications to increase the risk for ADHD. In the study by Williams et al. (2012), duplications spanning the *CHRNA7* gene at chromosome 15q13.3 were associated with ADHD in a single-locus analysis. This finding was consistently replicated in an additional 2,242 ADHD case subjects and 8,552 comparison subjects from four independent cohorts from the United Kingdom, the United States, and Canada.

Elia et al. (2012) assayed genome-wide CNVs in 1,013 ADHD cases and 4,105 controls of European ancestry. Positive

findings were evaluated in 2,493 ADHD cases and 9,222 controls of European ancestry. Copy number variants affecting metabotropic glutamate receptor genes were significantly enriched across all cohorts. Their results suggest that variations involving glutamatergic gene networks of the brain contribute to the genetic susceptibility to ADHD.

Other evidence supports a role for glutamate networks in the etiology of ADHD. In a pharmacogenomics GWAS, a SNP in *GRM7* was one of the most significant findings (Mick et al., 2008). Defects in the glutamate-stimulated release of dopamine and the functioning of glutamate receptors have been observed in a rat model of ADHD (Russell, 2003). Magnetic resonance spectroscopy in humans shows dysregulation of striatal, and anterior cingulate glutamate and glutamate/glutamine concentrations were greater in the ADHD subjects compared with controls (Dramsahl et al., 2011).

ENVIRONMENTAL RISK AND PROTECTIVE FACTORS

BIOLOGICAL ADVERSITY

The Feingold hypothesis posits that ADHD symptoms are caused by an allergic reaction to food additives. By eliminating these additives, the Feingold diet was proposed as a treatment for ADHD. Although most studies of the Feingold diet concluded it was not effective for treating ADHD, a metaanalysis concluded that the diet had a very small effect in improving ADHD symptoms (Kavale and Forness, 1983). To put these results into context, the effect of stimulant medication for treating ADHD is about nine times greater than the effect of the Feingold diet. Another series of studies examined the effect of restricted elimination diets on ADHD symptoms. The goal of restricted elimination diets is to eliminate any food to which a child might have a hypersensitivity reaction. Based on metaanalyses of randomized, placebo-controlled studies, Benton (2007) and Nigg et al. (2012) concluded that restricted elimination diets were effective for reducing ADHD symptoms.

However, in some studies, lack of fully blinded assessments may have compromised the results. Another popular theory posited that excessive sugar intake would lead to ADHD symptoms. Although some positive studies supported this idea, the bulk of systematic, controlled research did not (Wolraich et al., 1995).

Iron and zinc have been studied in ADHD because both are required for the production of norepinephrine and dopamine. In a metaanalysis, Scassellati et al. (in press) found nominally significant evidence for low serum ferritin levels (a marker of iron status) to be associated with ADHD. There was substantial heterogeneity in effect sizes across studies, but no evidence of publication bias. The same group also reported highly significant metaanalytical evidence for an association between ADHD and low peripheral zinc levels along with significant heterogeneity and no evidence of publication bias.

Some toxins have been implicated in the etiology of ADHD. Several groups have shown that lead contamination leads to distractibility, hyperactivity, restlessness, and lower intellectual functioning (e.g., Nigg et al., 2008). In a metaanalysis, Scassellati et al. (2012) found that compared with controls, patients with ADHD were more likely to have been exposed to lead. There was substantial heterogeneity across studies but no evidence of publication bias.

The literature examining the association of ADHD with pregnancy and delivery complications (PDCs) presents conflicting results, but tends to support the idea that PDCs can predispose children to ADHD. Specific PDCs implicated in ADHD include toxemia or eclampsia, poor maternal health, maternal age, fetal postmaturity, duration of labor, fetal distress, low birth weight, and antepartum hemorrhage. Notably, the PDCs implicated in ADHD frequently lead to hypoxia and tend to involve *chronic* exposures to the fetus, such as toxemia, rather than *acute*, traumatic events, such as delivery complications. Whether the chronic exposures reflect a larger cumulative “dose” or a higher probability of exposure during a critical period in gestation is unknown.

Animal studies in pregnant mice and rats have shown a positive association between chronic exposure to nicotine and hyperactive offspring. These animal studies show that chronic exposure to nicotine results in tolerance to the drug and an increase in brain nicotinic receptors. Because nicotinic receptors modulate dopaminergic activity and dopaminergic dysregulation may be involved in the pathophysiology of ADHD, it is theoretically compelling to consider maternal smoking as a risk factor for ADHD.

The smoking mother has been shown to be at increased risk for antepartum hemorrhage, low maternal weight, and abruptio placentae. Her fetus is at risk for low birth weight, which has been associated with ADHD. Because smoking increases carboxyhemoglobin levels in both maternal and fetal blood, it places the fetus at risk for a hypoxia, which also has been implicated in ADHD. Thus, it is not surprising that Langley et al.’s (2005) metaanalysis showed that children whose mothers’ smoked during pregnancy had a 2.4-fold increased risk for ADHD.

Notably, nicotine amplifies dopamine signals in striatum, interacts with dopamine receptors to cause hyperactivity in rats, and decreases the activity of the dopamine transporter

in human striatum. Moreover, ADHD is associated with an increased risk and earlier age of onset of cigarette smoking. Nicotine administration improved both ADHD symptoms and neuropsychological functioning and a nicotine analogue (ABT-418) improved ADHD symptoms. ABT-418 is a selective cholinergic channel activator that is a selective agonist for alpha4beta2 subtype nicotinic receptors. Despite these intriguing findings, studies that question the link between maternal smoking during pregnancy and ADHD suggest that more work is needed to clarify this issue (e.g., Obel et al., 2011).

PSYCHOSOCIAL ADVERSITY

Rutter et al. (1975) examined the prevalence of mental disorders in children living in two very different geographical areas. This research revealed six risk factors within the family environment that correlated significantly with childhood mental disturbances: (1) severe marital discord; (2) low social class; (3) large family size; (4) paternal criminality; (5) maternal mental disorder; and (6) foster placement. This work found that it was the aggregate of adversity factors, rather than the presence of any single one, that impaired development. Other studies also find that as the number of adverse conditions accumulates, the risk of impaired outcome in the child increases proportionally. Biederman et al. (1995a) found a positive association among Rutter’s index of adversity and ADHD, measures of ADHD-associated psychopathology, impaired cognition, and psychosocial dysfunction.

Other cross-sectional and longitudinal studies have identified variables such as marital distress, family dysfunction, and low social class as risk factors for psychopathology and dysfunction in children. For example, the Ontario Child Health Study showed that family dysfunction and low income predicted persistence and onset of one or more psychiatric disorders over a four-year follow-up period. Other work implicates low maternal education, low social class, and single parenthood as important adversity factors for ADHD. These studies suggest that the mothers of ADHD children have more negative communication patterns, more conflict with their child, and a greater intensity of anger than do control mothers.

Biederman et al. (1995b) showed that chronic conflict, decreased family cohesion, and exposure to parental psychopathology, particularly maternal psychopathology, were more common in ADHD families compared with control families. The differences between ADHD and control children were not accounted for by social class or parental history of major psychopathology. Moreover, increased levels of family-environment adversity predicted impaired psychosocial functioning. Measures indexing chronic family conflict had a more pernicious impact on the exposed child than those indexing exposure to parental psychopathology. Indeed, researchers have consistently found marital discord to predict disruptive behaviors in boys. This research shows that it is the extent of discord and overt conflict, regardless of whether the parents are separated, that predicts the child’s risks for psychopathology and dysfunction.

Thus, dysfunctional family environments appear to be a non-specific risk factor for psychiatric disorders and psychological distress. It is, however, possible that the same risk

factors that cause ADHD also contribute to family dysfunction. Reid and Crisafulli (1990) reported a metaanalysis of the impact of marital discord on the psychological adjustment of children and found that parental conflict significantly predicted a variety of child behavior problems. The Ontario Child Health Study provided a prospective example of the impact of parental conflict on children's mental health: family dysfunction (and low income) predicted persistence and onset of one or more psychiatric disorders over a four-year period.

Low maternal warmth and high maternal malaise and criticism have been previously associated with ADHD in children and an epidemiological study examining family attributes in children who had undergone stressful experiences found that children's perceptions of mothers, but not fathers, differentiated stress-resilient and stress-affected children.

An extensive literature documents maternal depression as a risk factor for psychological maladjustment and psychiatric disorder in children (Gelfand and Teti, 1990). This is consistent with the known familial link between ADHD and depression. Moreover, some have suggested that depressed mood may lead mothers to perceive their children as more deviant than warranted by the child's behavior. Richters (1992), however, reviewed 22 studies of this issue and concluded that, because of methodological problems with research in the area, there was no empirical foundation for this claim.

NEUROPSYCHOLOGICAL STUDIES

Satterfield and Dawson (1971) were among the first to propose that ADHD symptoms were caused by fronto-limbic dysfunction. They suggested that weak frontal cortical inhibitory control over limbic functions might lead to ADHD. The success of stimulant medications, and animal models implicating dopamine pathways were taken as support for this model. A review of the neurological literature (Mattes, 1980) articulating the similarities between adult patients with frontal lobe damage and children with ADHD stimulated further research in this area.

Neuropsychological tests measure features of human perception, cognition, or behavior that have been clinically or experimentally linked to specific brain functions. Although useful in developing hypotheses about brain-behavior relationships, these tests are limited in their ability to localize brain dysfunction. Nevertheless, they have several advantages. Many of these tests have been standardized on large normative populations, making it straightforward to define levels of impairment. Because of their extensive use in brain-damaged populations, performance on many of these tests can lead to hypotheses about the locus of brain dysfunction. Thus, they provide a relatively non-invasive and inexpensive means of generating hypotheses about brain pathophysiology that can be tested using the more direct neuroimaging measures of brain structure and function.

In a review of neuropsychological studies, Nigg (2005) showed that ADHD was most consistently associated with deficits in vigilance-attention, cognitive control (i.e., executive functioning), and motivation (as assessed by the processing of

reinforcement and incentives). Another metaanalysis of neuropsychological studies concluded that patients with ADHD had deficits in several domains of executive functioning: response inhibition, vigilance, working memory, and planning (Willcutt et al., 2005). From these studies, we can safely conclude that patients with ADHD are at risk for a wide range of neuropsychological dysfunction. However, the differences between ADHD and non-ADHD subjects were not large, which suggests that such deficits are not uniformly seen in patients with ADHD and are not specific to the disorder. The executive function deficits of patients with ADHD lead to difficulties with planning, organization, and time management, which impair their ability to accomplish tasks and function effectively in school and occupational settings (Biederman et al., 2006).

The motivational deficits identified by metaanalysis are often conceptualized as an altered response to reinforcement (Luman et al., 2010). In practical terms, this means that children with ADHD are less able to delay gratification. For example, compared with non-ADHD children, they are more likely to choose small immediate rewards rather than large reward for which they must wait. In experimental paradigms using partial reinforcement, children with ADHD do not function as well as normal children. Attention deficit/hyperactivity disorder is also associated with impaired reinforcement-learning and deficits in the extinction of non-rewarded responses (e.g., Luman et al., 2010). Functional magnetic resonance imaging studies and event-related potential studies have reported altered brain activation in experimental paradigms involving the anticipation, receipt, or loss of rewards (Luman et al., 2010).

The wide range of neuropsychological deficits observed in patients with ADHD has motivated the development of several overarching theories that attempt to parsimoniously explain these deficits and ADHD symptoms. These include the Sergeant's Cognitive-Energetic model (Sergeant, 2005), Sonuga-Barke et al.'s (2010) triple pathway model, Tripp and Wickens' (2009) dopamine transfer deficit model, Sagvolden et al.'s (2005) Dynamic Developmental Theory, and Barkley's (1997) model of ADHD as a disorder of deficient self-regulation. We refer readers to the cited articles for further information.

Given that inattention is a hallmark of ADHD, neuropsychological studies of the disorder have focused on the assessment of attention. This led to many vigilance studies finding impaired continuous performance test (CPT) performance in children with ADHD. In these studies, subjects must sustain their attention to subtle sensory signals, avoid being distracted by irrelevant stimuli, and maintain alertness for the duration of the session.

Children with ADHD also perform poorly on tasks requiring inhibition of motor responses, organization of cognitive information, planning, complex problem solving, and the learning and recall of verbal material. Examples of tests that measure these functions are the Stroop test, the Wisconsin Card Sorting Test, the Rey-Osterrieth test, the Freedom from Distractibility factor from Wechsler's tests of intelligence, and the California Verbal Learning Test.

Some studies suggest that the impairments found in children with ADHD cannot be accounted for by psychiatric comorbidity and that the deficits continue through adolescence

into adulthood. Moreover, having a family history of ADHD may predict a greater degree of neuropsychological impairment. This latter finding suggests that familial ADHD and neuropsychological impairment identify a more biologically based type of ADHD. In contrast, non-familial cases of ADHD with lesser neuropsychological impairments may be caused by other etiological factors such as psychosocial adversity.

Our description of neuropsychological dysfunction in ADHD describes trends that have emerged in the research literature, not findings that have been consistently replicated. Although there are inconsistencies among studies, it is notable that the pattern of deficits that has emerged is similar to what has been found among adults with frontal lobe damage. Thus, the neuropsychological data tend to support the hypothesis that the frontal cortex or regions projecting to the frontal cortex are dysfunctional in at least some children with ADHD.

Because neuropsychological tests are only indirect measures of brain function, we must be cautious in using them to make inferences about the locus of brain impairment in ADHD. Nevertheless, many of these tests have been standardized on normative populations and administered extensively to brain-damaged populations. Hence, performance on many of these tests can lead to hypotheses about the functional integrity of certain brain regions.

With this caveat in mind, we view the pattern of neuropsychological impairment in children with ADHD as consistent with Satterfield and Dawson's (1971) idea that ADHD is associated with abnormalities of prefrontal cortex and/or its projections to subcortical structures. This inference derives from the clinical and behavioral features that have been linked to regions of the prefrontal cortex. Orbital frontal lesions predict social disinhibition and impulsivity and dorsolateral lesions affect organizational abilities, planning, working memory, and attention. Thus, the neuropsychological test data—along with the clinical features of the disorder—implicate both orbitofrontal and dorsolateral prefrontal dysfunction in ADHD. In contrast, the mesial prefrontal region, in which lesions predict dysfluency and the slowing of spontaneous behavior, is not implicated in ADHD.

Because of the complexity of prefrontal circuitry along with the limitations of neuropsychological inference, whether the “prefrontal” abnormalities in ADHD are owing to “lesions” of prefrontal cortex or to brain areas with prefrontal projections is not yet clear. Thus, the term fronto-subcortical, which denotes a behavioral or cognitive dysfunction that looks “frontal” but may be influenced by subcortical projections, provides a suitable neuropsychological description of ADHD.

It is likely that a network of interrelated brain areas is involved in the attentional-executive impairments of children with ADHD. The cingulate cortex plays a role in motivational aspects of attention and response selection and inhibition. A system mainly involving right prefrontal and parietal cortex is activated during sustained and directed attention across sensory modalities. The inferior parietal lobule and superior temporal sulcus are polymodal sensory convergence areas that provide a representation of extrapersonal space that play an important role in focusing on and selecting a target stimulus. The brainstem reticular activating system and reticular

thalamic nuclei, regulate attentional tone and filter interference, respectively. Working memory deficits implicate a distributed network, including anterior hippocampus, ventral anterior and dorsolateral thalamus, anterior cingulate, parietal cortex, and dorsolateral prefrontal cortex.

NEUROIMAGING STUDIES

To overcome the limitations of neuropsychological inference, researchers have turned to brain imaging studies. Because neuroimaging studies provide direct assessments of brain structure and function, they are ideal for testing hypotheses about the locus of brain dysfunction. We discuss three types of ADHD imaging studies. Structural studies ask if patients with ADHD show anomalies of brain structure as evidenced by increases or decreases on the volumes of brain regions. Functional studies ask if the brains of patients with ADHD function differently from the brains of non-ADHD people. Last, functional connectivity studies ask if ADHD is associated with abnormal neural connections among brain regions.

STRUCTURAL IMAGING STUDIES

A comprehensive view of structural brain anomalies in ADHD has been reported in two metaanalyses of studies that examined patients with ADHD with either computed tomography (CT) or magnetic resonance imaging (MRI). Valera et al. (2007) applied metaanalysis to 21 structural imaging studies. Their analysis including all brain regions found globally reduced brain volumes for ADHD subjects compared with controls. They found the largest differences between ADHD and control subjects for cerebellum (especially the posterior inferior region of the vermis) followed by the splenium, right and total cerebral volume, and the right caudate. For these regions, there was no evidence for publication bias, and influence analysis tests indicated that no single study accounted for the significant differences between ADHD and control subjects. Bilateral prefrontal gray matter and right globus pallidus were nominally significant but did not meet criteria for significance after correcting for multiple comparisons.

In another metaanalysis of structural imaging studies, Ellison-Wright et al. (2008) examined seven studies that used MRI, voxel-based morphometry to assess differences in gray matter density and reported the three-dimensional coordinates of brain changes in stereotactic space. This metaanalysis found a single cluster of gray matter decrease associated with ADHD located in the right putamen/globus pallidus region. There was no evidence for gray matter increases in any region to be associated with ADHD. A third metaanalysis of structural imaging data was provided by Nakao et al. (2011). They examined 14 data sets comprising 378 ADHD patients and 344 non-ADHD subjects. Patients with ADHD had significantly decreased global gray matter volumes. Regional analyses showed ADHD to be associated with smaller gray matter volumes in a large cluster in the right lentiform nucleus, which included the caudate nucleus. Attention deficit/hyperactivity disorder was also associated with larger gray matter volumes in the left posterior

cingulate cortex/precuneus. In a fourth metaanalysis of brain volumes, Frodl and Skokauskas (2012) examined eleven studies comprising 320 ADHD patients and 288 controls. Consistent with prior structural imaging metaanalyses, these authors reported that ADHD was associated with reduced volumes of the right globus pallidus and putamen as well as the bilateral caudate.

FUNCTIONAL IMAGING STUDIES

Functional imaging studies of ADHD are consistent with the structural studies in implicating fronto-subcortical systems in the pathophysiology of the disorder (Cubillo and Rubia, 2010). The most consistent findings from the functional studies suggest that ADHD is associated with reduced activation of inferior frontostriatal, temporoparietal, and cerebellar brain regions during tasks that require attention and inhibitory control. Dickstein et al. (2006) reported a metaanalysis of 16 fMRI studies, containing 134 foci of activation for patients with ADHD and 180 foci for controls. The authors concluded that ADHD is associated with widely distributed frontal hypoactivity affecting anterior cingulate, dorsolateral prefrontal, inferior prefrontal, and orbitofrontal cortices. They also implicated hypoactivity of the basal ganglia and parietal cortices.

Fassbender and Schweitzer (2006) have interpreted functional imaging studies of ADHD in a developmental context. They point out that patterns of functional brain activity become less diffuse and more focal with maturation. Likewise, for many functional imaging tasks, patients with ADHD activate a more diffuse set of brain regions compared with non-ADHD people. Their review suggested that, for functional imaging tasks requiring higher cognitive functions, ADHD patients activated regions typically associated with motor, visual, and spatial processing whereas, non-ADHD people were more likely to activate brain regions typically associated with executive functioning. Thus, it appears that ADHD brains attempt to solve functional tasks in a manner that is less efficient and less developmentally mature than non-ADHD people. Longitudinal structural MRI studies are also consistent with a developmental delay interpretation of neuroimaging data. Shaw et al. (2007) examined 223 children with ADHD and 223 controls. They indexed cortical maturation with the age of achieving peak cortical thickness. They reported a significant difference in the median age at which 50% of the cortical points achieved their peak thickness: 10.5 years for ADHD patients and 7.5 years for controls. This delay in cortical maturation was greatest for prefrontal regions. These developmental perspectives on ADHD brain imaging data are consistent with the hypothesis that the ADHD brain develops at a slower rate than the non-ADHD brain, which is also consistent with a metaanalysis of longitudinal studies, which reported that about one-third of patients with ADHD remit most signs of the disorder by young adulthood (Faraone et al., 2006). In another study, Shaw et al. (2011) compared 193 typically developing children with 389 longitudinal neuroanatomic magnetic resonance images with 197 children with ADHD having 337 longitudinal scans. This study found a quantitative effect of ADHD symptoms on cortical thinning. Subjects with higher

levels of hyperactivity/impulsivity had a slower rate of cortical thinning, with the slowest rate seen for the ADHD sample. For each increase of one point in the hyperactivity/impulsivity score (even among controls), the rate of cortical thinning decreased 0.0054 mm/year. The authors concluded that their data supported a dimensional view of ADHD because cortical thinning was associated with both the diagnosis of ADHD and with the number of ADHD symptoms among non-ADHD children.

Proton magnetic resonance spectroscopy (MRS) is an imaging method that detects neurometabolites in the brain. Perlov et al. (2009) presented a metaanalysis of 16 controlled MRS studies of patients with ADHD. The reviewed studies examined anterior cingulate cortex, prefrontal cortex, the basal ganglia (mostly striatum) and the fronto-striato-thalamo-frontal circuits. The authors concluded that choline compounds (*N*-acetyl-aspartate and glutamate/glutamine to creatine ratios) were abnormal in ADHD. These results differed somewhat for studies of children and adults. The studies of children provided evidence for increased choline signals in left striatum and right frontal lobe. For adults, increased choline signals were found in the right and left anterior cingulate cortex. The authors noted that these choline signals could implicate abnormal turnover of cell membranes, effects of energy metabolism, or anomalies of cholinergic neurotransmission.

Several studies have measured dopamine transporter (DAT) density in striatum by single photon emission computed tomography (SPECT) or PET. Based on a metaanalysis of nine SPECT and PET studies, Fusar-Poli et al. (2012) concluded that DAT density was 14% higher in patients with ADHD compared with controls. This finding is consistent with the mechanism of action of stimulants, which block the DAT.

Another line of neuroimaging research has examined the functional interregional connectivity between brain regions. These studies ask if ADHD is associated with aberrant neural connectivity. Studies that examine the brain at rest (i.e., while not engaged in a task) find that ADHD is associated with reduced functional connectivity in frontostriatal, frontoparietal, and frontocerebellar regions (Cubillo and Rubia, 2010).

One limitation of brain imaging studies is that many of the patients in these studies had been pharmacologically treated with ADHD, which makes it difficult to disentangle disorder effects from treatment effects. This issue was examined comprehensively in a metaanalysis by Frodl et al. (2012). This metaanalysis examined eleven studies comprising 320 ADHD patients and 288 controls. These authors showed that ADHD associated brain volume reductions in the right globus pallidus and putamen were greatest for those patients that had not received pharmacotherapy, which led them to conclude that pharmacotherapy tended to normalize brain structures. A similar conclusion was reached by the metaanalysis of Nakao et al. (2011), which included 14 data sets comprising 378 ADHD patients and 344 non-ADHD subjects. In that study, use of stimulant medication was associated with stimulant medication increased gray matter volume in the right basal ganglia and the right caudate. The authors concluded that treatment with stimulants may be associated with more normal striatal brain structure.

Paloyelis et al.'s (2007) review of fMRI studies concluded that the altered brain activation patterns in children with ADHD are not owing to the effects of long-term pharmacological treatment because many studies of treatment-naïve patients have demonstrated these effects. In the one study that directly compared stimulant treated and non-treated patients, few differences were found. When differences were found, the ADHD group that had received long-term treatment was more similar to the non-ADHD controls than to the untreated ADHD group, which led Paloyelis et al. to conclude that stimulant treatment may normalize neural functioning. This conclusion finds some support in fMRI studies of the acute effects of stimulant treatment. Clinical doses of stimulants boost brain activations in ADHD patients in regions that are typically underactivated in ADHD (i.e., caudate, prefrontal cortex, cingulate, cerebellum), with some studies suggesting normalization of functioning (e.g., Shafritz et al., 2004).

DIFFUSION TENSOR IMAGING STUDIES

Diffusion tensor imaging (DTI) examines the white matter tracts that connect cortical and subcortical structures. Fractional anisotropy assesses cumulative axonal membrane circumference, axonal density, and the thickness of the myelin sheath and is used as an indicator of axonal integrity and organization (Van Ewijk et al., 2012).

Van Ewijk et al. (2012) reported a metaanalysis of 15 DTI studies. They concluded that white matter integrity was reduced in children, adolescents, and adults with ADHD. Their work implicated several white matter regions and tracts: the inferior and superior longitudinal fasciculus, anterior corona radiata, corticospinal tract, cingulum, corpus callosum, internal capsule, caudate nucleus, cerebellum, uncinate fasciculus, forceps minor, areas within the basal ganglia, and widespread differences in the frontal, temporal, parietal, and occipital lobes.

Five clusters were reliably reported across studies of children: the right anterior corona radiate, forceps minor close to the genu of the corpus callosum, right and left internal capsule, and left cerebellar white matter. Studies investigating adolescents or adults did not find group differences in these areas, which led van Ewijk et al. (2012) to speculate that the myelination of these areas had been delayed in children with ADHD. Longitudinal studies are needed to better address this point. Studies focusing on white matter tracts in focused brain regions of interest found decreased fractional anisotropy to be associated with ADHD. In contrast, whole-brain studies identified increased fractional anisotropy. According to van Ewijk et al. (2012), the fact that whole-brain studies have identified increased as well as decreased fractional anisotropy might be owing to including those regions with much fiber crossing.

MODEL OF PATHOGENESIS

History shows that grand theories of psychopathology have short half-lives, but the facts of empirical research endure. Naturally, this leads us to emphasize the empirical generalizations that emerge from the work we have reviewed. All ADHD

researchers will agree that the disorder is clinically heterogeneous and most would interpret the variability of findings from neurobiological studies as support for the etiological and pathophysiological heterogeneity of the disorder. It is equally clear that aberrant genes create a vulnerability to the disorder that is not expressed in all environments. We do not know if environmental insults are necessary for the disorder to emerge, but we do know that many environmental agents have been implicated. These run the gamut from psychosocial stressors to toxic and physical assaults on the brain.

The genetic and environmental causes of ADHD most assuredly modify the developing brain, leading to a heterogeneous profile of neuropsychological, structural, and functional abnormalities. Although there is no single pathophysiological profile of ADHD, numerous data implicate dysfunction in the fronto-subcortical-cerebellar pathways that control attention and motor behavior. Moreover, the effectiveness of stimulants, along with animal models of hyperactivity, point to catecholamine dysregulation as at least one source of ADHD brain dysfunction.

Any model of pathogenesis must consider two key points: etiological heterogeneity and multifactorial causation.

ETIOLOGICAL HETEROGENEITY

To ground our work in the empirical realities of ADHD, our heuristic model begins with a nosological theory based on the conceptual framework developed by Robins and Guze, which has guided much empirical psychiatry during the past quarter century. That framework asks if an identified syndrome shows a characteristic course, outcome, family history, and pattern of clinical correlates. This approach has led us to the first proposition of our theory: Rather than being a unitary condition, ADHD is a heterogeneous disorder and its clinical heterogeneity is, in part, an expression of genetic heterogeneity.

To confirm etiological heterogeneity requires that patients with ADHD be separated into at least two classes having different known etiologies and, perhaps, different pathophysiological signatures. In contrast, the homogeneity hypothesis asserts that there is a single necessary and sufficient cause or configuration of causes of ADHD.

To assert either etiological heterogeneity or homogeneity implies that we can fully describe one or more mechanisms of etiology. Although there are many clues to the etiological puzzle, they do not allow a full description because the etiological mechanisms for ADHD have not been worked out in sufficient detail. This tempts researchers to examine descriptive, phenotypic data and infer the presence of one or more etiologies.

Unfortunately, the correspondence between etiology and clinical expression is not isomorphic. Differing etiologies may lead to similar clinical features. For example, Alzheimer's disease can arise from either genetic or non-genetic factors and genetic studies show that there are several genetic subforms. Although the observation of dissimilar phenotypes (clinical heterogeneity) may suggest etiological heterogeneity, such inferences are also limited because a single disease entity, with a homogeneous etiology can have variable expression owing to moderating factors. In genetics the term pleiotropy describes the situation in which a pathogenic genotype can express more

than one phenotype. Pleiotropy is not unusual for human genetic diseases and may be the rule rather than the exception for psychiatric disorders.

MULTIFACTORIAL CAUSATION

A simple multifactorial model posits all cases of ADHD to arise from a single pool of genetic and environmental variables—each of small effect—that act in an additive fashion to produce a vulnerability to ADHD. If an individual's cumulative vulnerability exceeds a certain threshold, he or she will manifest the signs and symptoms of ADHD. At lower thresholds, other disorders may be expressed (e.g., neuropsychological disorders). According to the multifactorial model, no single factor is a necessary or sufficient cause for ADHD and each of the etiological factors are interchangeable (i.e., it does not matter which factors one has; only the total number is important).

Multifactorial causation is sometimes viewed as an alternative to etiological heterogeneity, but we argue that both are relevant for the study of ADHD. As we have seen, the etiology of ADHD may involve at least four causal agents: genes, pregnancy and delivery complications, psychosocial adversity, and exposure to toxins. Notably, each of these putative causes is actually a class of potential causes.

The multifactorial model is usually considered a homogeneity model because it assumes that etiological factors are interchangeable. This makes sense for some multifactorial models but not others. For example, if there are 12 causes of ADHD and 11 are needed to develop ADHD, then there would be considerable etiological homogeneity among ADHD patients (i.e., most patients would share the same etiological factors). In contrast, if there were 35 etiological factors (e.g., 10 mutations, eight types of obstetric complications, seven environmental toxins and psychosocial stressors) and five were required to develop ADHD, then there would be considerable etiological heterogeneity. Some cases would be exclusively genetic, others exclusively owing to birth related complications, others would have a toxic etiology, some would be caused solely by psychosocial stress, and many would be caused by the simultaneous action of causes from more than one domain.

Because of these considerations, the second proposition of our theory is that etiotically homogenous subtypes will exist, but will be relatively rare. Most cases of ADHD share some sources of etiological variance with other cases.

IMPLICATIONS FOR PATHOGENESIS

The data we have reviewed provide some evidence for this modified multifactorial model. The genetic studies show that some relatively homogeneous subtypes do exist: Some cases of ADHD—albeit rare—are caused by gross abnormalities of chromosomes. We do not know if the smaller deletions and duplications known as CNVs are necessary and sufficient causes for rare cases of ADHD. As for the large majority of patients with ADHD, the available data reject the most parsimonious version of the hypothesis of etiological homogeneity, that all these cases are caused by the exact same pattern of genetic mutations and adverse environmental exposures.

Instead, there are likely to be several etiological profiles of ADHD. For example, the neuroimaging studies clearly show that there is no single brain lesion that causes ADHD. Instead, and articulated by Makris et al. (2009), ADHD can be viewed as a disorder of the neural networks that mediate attention, executive functions, motor regulation, and emotional regulation. Their model attributes the clinical manifestations of ADHD to four neuroanatomical networks. The first network mediates hyperactivity. It comprises connections among dorsolateral prefrontal cortex, caudate, dorsal anterior cingulate cortex, cerebellum, and the supplementary motor area. The second network mediates inattention and executive dysfunction. It comprises connections among the cerebellar hemisphere, dorsal anterior cingulate cortex, dorsolateral prefrontal cortex, thalamus, and inferior parietal lobule. The third network mediates impulsivity. It comprises connections among cerebellar vermis, perigenual anterior cingulate cortex, orbital frontal cortex, and nucleus accumbens. The fourth network mediates deficient emotional self-regulation. It comprises cerebellar vermis, perigenual anterior cingulate cortex, frontoorbital cortex, and amygdala. Although we cannot say for certain why these brain networks are affected in ADHD, given that the risk factors identified to date are primarily genetic or environmental exposures during fetal development, it is reasonable to speculate that the brains of patients with ADHD are mis-wired during development as opposed to having been subjected to an environmental insult subsequent to the neurodevelopment that occurs *in utero* and early childhood. This suggests a strategy for clarifying the pathophysiology of ADHD. Instead of studying heterogeneous samples of patients with ADHD, neurobiological studies should focus on subgroups that are putatively more homogeneous.

Unraveling these complexities will be a difficult task for ADHD researchers. Technological developments in neuroscience and molecular genetics are moving at a rapid pace. The next decade of work should provide us with more accurate assessments of the brain along with a complete sequence of the human genome. These advances should set the stage for breakthroughs in our understanding of the neurobiology of ADHD and our ability to treat affected individuals.

DISCLOSURES

In the past year, Dr. Faraone received consulting income and/or research support from Shire, Otsuka, Akili, and Alcobra, and research support from the National Institutes of Health (NIH). In previous years, he received consulting fees or was on advisory boards or participated in continuing medical education programs sponsored by Shire, McNeil, Janssen, Novartis, Pfizer, and Eli Lilly. Dr. Faraone receives royalties from books published by Guilford Press: *Straight Talk about Your Child's Mental Health*, and Oxford University Press: *Schizophrenia: The Facts*. Dr. Joseph Biederman is currently receiving research support from the following sources: Elminda, Janssen, McNeil, and Shire. In 2012, Dr. Joseph Biederman received an honorarium from the MGH Psychiatry Academy and the Children's Hospital of Southwest Florida/Lee Memorial Health System

for tuition-funded CME courses. In 2011, Dr. Biederman gave a single unpaid talk for Juste Pharmaceutical Spain, received honoraria from the MGH Psychiatry Academy for a tuition-funded CME course, and received honoraria for presenting at international scientific conference on ADHD. He also received an honorarium from Cambridge University Press for a chapter publication. Dr. Biederman received departmental royalties from a copyrighted rating scale used for ADHD diagnoses, paid by Eli Lilly, Shire, and AstraZeneca; these royalties are paid to the Department of Psychiatry at MGH. In 2010, Dr. Biederman received a speaker's fee from a single talk given at Fundación Dr. Manuel Camelo A.C. in Monterrey Mexico. Dr. Biederman provided single consultations for Shionogi Pharma, Inc. and Cipher Pharmaceuticals, Inc.; the honoraria for these consultations were paid to the Department of Psychiatry at the MGH. Dr. Biederman received honoraria from the MGH Psychiatry Academy for a tuition-funded CME course. In previous years, Dr. Biederman received research support, consultation fees, or speaker's fees from the following additional sources: Abbott, Alza, AstraZeneca, Boston University, Bristol Myers Squibb, Celltech, Cephalon, Eli Lilly and Co., Esai, Fundacion Areces (Spain), Forest, Glaxo, Gliatech, Hastings Center, Janssen, McNeil, Medice Pharmaceuticals (Germany), Merck, MMC Pediatric, NARSAD, NIDA, New River, NICHD, NIMH, Novartis, Noven, Neurosearch, Organon, Otsuka, Pfizer, Pharmacia, Phase V Communications, Physicians Academy, the Prechter Foundation, Quantia Communications, Reed Exhibitions, Shire, the Spanish Child Psychiatry Association, the Stanley Foundation, UCB Pharma Inc., Veritas, and Wyeth.

79 | TOURETTE SYNDROME AND TIC DISORDERS

KYLE WILLIAMS, MICHAEL H. BLOCH, MATTHEW W. STATE,
AND CHRISTOPHER PITTENGER

Tourette syndrome (TS) was first characterized as a disorder of episodic tics, distinguished from dystonic movements by their spasmodic nature, by the French neurologist Gilles de la Tourette in 1885. Tourette syndrome was long thought to be rare, with a prevalence estimated, as recently as the 1960s, at one case per 2,500 individuals. In recent decades, however, it has been recognized as a far more common condition, affecting between 0.3% and 1% of the population (Robertson et al., 2009). Moreover, it has now been well established that TS is characterized by symptomatology that extends well beyond the pathognomonic motor and vocal tics.

The last 10 years have witnessed striking advances in TS research, with the discovery of rare genetic variants contributing to risk, the emergence of novel insights into the functional and structural neuroanatomy of the syndrome, the identification of specific neuropathological abnormalities in postmortem brains, and the development of new synthetic pathophysiological hypotheses. This chapter presents a summary of these recent advances, addresses current models of TS pathogenesis, reviews available treatments and their putative mechanisms of action, and describes the challenges that lie ahead in developing a deeper understanding of the etiology, natural history, and treatment of TS and related conditions.

PHENOMENOLOGY AND DESCRIPTION OF TIC DISORDERS

Tourette syndrome is a chronic, sometimes disabling disorder, beginning in childhood, that is characterized by stereotyped motor movements and vocalizations termed tics. Tics are discrete, repetitive, involuntary (or semivoluntary) movements or vocalizations. For both diagnostic and treatment purposes tics are described as either motor or phonic. Motor tics may be further classified as either simple, involving a single muscle group (e.g., blinking, sniffing), or complex, involving multiple muscle groups simultaneously with coordinated movement (e.g., head turning, kicking). Phonic tics are similarly classified into simple (e.g., grunting, throat clearing) or complex (e.g., yelling, swearing), based largely on whether or not they result in the production of language.

Tourette syndrome is the most severe end of a spectrum of tic disorders that are hierarchically classified according to both chronicity and tic symptomatology. As outlined in the DSM-IV-TR, and in the proposed classification for the forthcoming DSM-5, a diagnosis of Tourette syndrome requires the

presence of both a motor and a phonic tic for at least one year, in the absence of any identifiable medical condition responsible for the tics (e.g., stroke, medication). Individuals who display motor tics, phonic tics, or both for less than one year meet criteria for transient tic disorder. Patients who display either motor or phonic tics, but not both, for one year are diagnosed with chronic tic disorder. Finally, individuals with tics who do not meet criteria for a specific tic disorder but do suffer impairment are given the diagnosis of tic disorder not otherwise specified.

Although the specific characteristics of tics differ substantially among individuals, certain trends are broadly recognizable. For example, motor tics manifest more frequently in the muscles of the face and upper limbs than the torso or legs, and, overall, the frequency of simple phonic tics greatly exceeds that of complex phonic tics. One example of a complex phonic tic is coprolalia, or the involuntary yelling of obscenities; this is widely recognized and sometimes described in the lay press as synonymous with TS, but such tics are estimated to occur at some point during the course of the syndrome in only 15% to 20% of patients with TS (Freeman et al., 2009). Recent investigations have outlined the complexity of sensory and motoric processes that are hypothesized to underlie tic symptomatology. Ninety percent of adult patients with TS report premonitory “urges” before a tic (Du et al., 2010), and although tics are ultimately involuntary, many patients report an ability to transiently suppress them. Moreover, sensory processing appears to be more generally disrupted in at least some cases of TS. For example, patients often describe either difficulty screening out minor, distracting stimuli and/or the presence of “sensations without sources.”

EPIDEMIOLOGY, NATURAL HISTORY, AND COMORBIDITY

Tic disorders are the most common form of movement disorders among children, with an estimated prevalence of 5% (Dooley, 2006). Estimates of the frequency of specific tic disorders vary considerably, and large-scale, well-controlled epidemiological studies are sorely needed; TS itself has an estimated prevalence of 0.6% to 1% of school-aged children (Cavanna and Termine, 2012). Tic disorders in aggregate display a marked gender bias, with boys outnumbering girls 4:1, although this ratio approaches equality when a broader phenotype encompassing both TS and OCD is considered (State, 2011).

By definition, TS onset occurs before adulthood; most patients have an onset of tics between the ages of three and eight, with the highest rate of TS diagnoses occurring from age six to ten (Cavanna and Termine, 2012). Simple motor tics such as eye-blinking or grimacing are generally observed before other tic symptoms, with phonic tics emerging several years following the onset of motor tics. Similarly, simple tics typically precede the onset of complex tics by a number of years (Du et al., 2010).

The clinical course of tic disorders is variable. Tic severity and frequency typically peak at 10 years of age (Jankovic and Kurlan, 2011). Symptoms are dynamic, such that new tics frequently develop or disappear over the course of illness, and their severity and frequency waxes and wanes over weeks to months. Tics are influenced by external factors; they may be exacerbated during periods of stress or fatigue and mitigated during concentration (Du et al., 2010). Most patients experience a significant reduction in tic symptoms with age, with roughly 75% of patients with TS demonstrating improvement by adolescence and as many as one-third displaying complete remission by adulthood (Bloch and Leckman, 2009).

Any description of the clinical phenomenology of tic disorders is incomplete without a discussion of the frequent psychiatric comorbidities observed in affected individuals. Comorbid psychopathology, which Gilles de la Tourette first described as “mental tics,” is now appreciated to be the rule rather than the exception, with 60% to 90% of children presenting for evaluation and/or treatment of TS meeting criteria for at least one additional psychiatric disorder. The most frequent comorbidity in clinical populations with tic disorders is attention deficit/hyperactivity disorder (ADHD), with an estimated prevalence of 50% in patients with transient or chronic tic disorders and between 60% and 75% in patients with TS (Du et al., 2010). Similarly high rates of comorbidity are found for obsessive-compulsive disorder (OCD), with an estimated 30% to 50% of patients with TS meeting lifetime diagnostic criteria (Bloch and Leckman, 2009). Finally, the majority of patients with TS also suffer from mood and impulse-control disorders. A recent longitudinal study of TS found 61% of patients to meet criteria for depression by 18 years of age, along with high rates of learning disorders (41%), conduct disorder (23%), and non-OCD anxiety disorders (40%) (Gorman et al., 2010).

Comorbidity can influence the presentation and complicate treatment. Selective serotonin reuptake inhibitor (SSRI) treatment of OCD symptoms is less effective in individuals with a comorbid tic disorder than in those without (March et al., 2007). Psychostimulants, a first-line treatment for ADHD, are no longer contraindicated in patients with tic disorders, as they once were, but are nonetheless thought by many clinicians to exacerbate symptoms in some individuals. A recent metaanalysis failed to support an association, however (Bloch et al., 2009). Comorbid OCD and ADHD diagnoses have been shown to negatively affect quality of life, psychosocial stress, and global functioning in those with TS (Lebowitz et al., 2012). Indeed, comorbid diagnoses may often have a greater impact on quality of life than tics themselves (Bernard et al., 2009), further complicating the long-term treatment of tic disorders and TS.

The frequent comorbidity among OCD, ADHD, and TS has led to the hypothesis that in some individuals these disorders share a common genetic etiology. This hypothesis is indirectly supported by the observation that rates of OCD (or obsessive-compulsive behaviors) and ADHD are higher in relatives of patients with TS than in the general population (O'Rourke et al., 2011). A study using latent-class analysis, a type of structural equation modeling, has reported a highly heritable subclass of comorbid TS + OCD + ADHD in a familial study of TS probands (Grados and Mathews, 2008), although additional studies suggest the shared genetic risk may be related to independent associations between TS + OCD and OCD + ADHD, rather than all three conditions together (Mathews and Grados, 2011). These three disorders all are thought to involve dysfunction of the same basal ganglia circuitry, described in detail in the following, making shared causality quite plausible.

GENETICS

Family studies dating back to the 1970s provide consistent, if indirect, evidence for a genetic contribution to TS. The rate at which first-degree relatives of probands with TS are affected has been found to be on the order of 5% for females and 10% for males, representing an approximately 10-fold increase compared with the general population. Moreover, although relatively small in scale, twin studies have demonstrated that monozygotic twins share a diagnosis of TS much more frequently than do dizygotic twins (State, 2011), suggesting that the observed familial clustering is owing largely to genetic factors.

The earliest studies of TS pedigrees in the mid-1980s were interpreted to suggest that this genetic risk was transmitted as a Mendelian single-gene autosomal-dominant trait with partial and sex-limited penetrance (State, 2011). However, over the subsequent decade, despite intensive efforts, no single genomic locus or gene was identified carrying risk. Given the increasing yield of gene discovery efforts in Mendelian disorders through the 1990s, the continued difficulties in mapping a TS gene, and the completion of additional segregation analyses, it became clear that, like other psychiatric conditions, TS was likely transmitted as a complex trait (Deng et al., 2012) involving multiple genes and their interactions with environmental factors.

This reevaluation led to a series of case control studies focusing on common polymorphisms (typically defined as $\geq 5\%$ allele frequency in the population) in and around biologically plausible candidate genes. This approach was based on the widely held hypothesis that common genetic variation would underlie common complex disorders. With regard to TS, specific genes interrogated included those encoding dopamine receptors (*DRD2*, *DRD3*, *DRD4*), the dopamine transporter (*DAT*), dopamine beta hydroxylase (*DBH*), catechol-*O*-methyltransferase (*COMT*), noradrenergic receptors (*ADRA1C*, *ADRA2A*, *ADRA2C*), monoamine oxidase A (*MAO-A*), tyrosine hydroxylase, and several molecules involved in serotonergic neurotransmission (*TPH2*, *5HT3*, *5HTTLR*) (Deng et al., 2012; Du et al., 2010).

Although this candidate gene approach was popular and relatively easy to implement, such studies generally failed to yield reproducible results in any area of medicine (Hirschhorn and Altshuler, 2002); TS was no exception. More recently, insights into methodological confounds attending hypothesis-driven common variant approaches, combined with key technological advances, have resulted in a shift toward genome-wide association studies (GWAS). This unbiased, genome-wide interrogation of alleles has proved to be a highly reliable means of identifying common variants contributing to common disease. Very recently, the Tourette Syndrome Association International Consortium for Genetics completed a GWAS involving 1496 TS cases and 5249 controls (Scharf et al., 2012). Unfortunately, no locus reached accepted genome-wide thresholds for statistical significance. A likely explanation is that common polymorphisms contributing to TS, like other neuropsychiatric conditions, individually carry very small effects (State, 2011). Consequently, although large relative to other TS genetic efforts, this study was still most likely underpowered to detect common variants influencing risk. Samples on order of magnitude larger than this have played an essential role in identifying common variation contributing to schizophrenia and bipolar disorder (Bergen and Petryshen, 2012).

Although analyses of common variations have generally predominated the field, studies aimed at identifying the contribution of rare mutations have provided important insights. In contrast to the earliest efforts in TS genetics, these more recent rare variant investigations conceptualize the disorder as genetically complex and highly heterogeneous, presupposing that multiple rare mutations, in multiple different genes, may converge on a final common clinical phenotype. Pursuit of this “rare variant, common disease” model has been highly productive in other neurodevelopmental disorders, including autism and schizophrenia (Malhotra and Sebat, 2012).

As early as the mid-1990s, rare chromosomal abnormalities were reported in TS probands or families mapped using traditional and molecular cytogenetic methods, identifying several candidate genes and regions, including 2p12, 3p21.3, 7q35-36, 8q21.4, 9pter, 13q31, and 18q22.3 (Deng et al., 2012). Three results from this work stand out. Verkerk and colleagues reported a complex rearrangement in a father with TS as well as his affected children, disrupting the gene encoding *Contactin-Associated Protein-like 2 (CNTNAP2)*, which is also associated with a rare recessive form of autism and epilepsy and is thought to contribute to common forms of social disability, language delay, and possibly schizophrenia. Lawson-Yuen et al. reported a family with tics and TS transmitting an exonic deletion of the *Neurologin 4, X-linked (NLGN4X)*, in which rare mutations also cause autism (State, 2011). These studies point to the now well-established phenomenon of rare variants in a single gene or region leading to highly divergent developmental and neuropsychiatric phenotypes, as has been demonstrated for autism, schizophrenia, epilepsy, and intellectual disability (Malhotra and Sebat, 2012). As discussed in the following, recent studies of structural variation in TS lead to the same conclusion, that variants in the same genes or genomic regions can lead both to TS and other neuropsychiatric conditions.

A third cytogenetic finding has garnered attention because it was the first to lead to the identification of a protein-disrupting rare mutation in a nearby gene. A *de novo* chromosome 13 inversion was identified in a simplex family with TS to a region upstream of the gene *SLITRK1 (Slit and Trk-like Family Member 1)*. Sequencing of a cohort of 179 unrelated affected individuals revealed a frame-shift deletion in the gene in a small pedigree segregating TS and trichotillomania. In addition, two independent instances of a single, very rare single base mutation (var321) were identified in the 3' untranslated region (UTR) corresponding a micro-RNA (miR-189) binding site. Additional screening for this mutation turned up no additional observations in 4,296 control chromosomes, leading to a significant association with TS ($p = 0.0056$) (State, 2011).

Follow-up studies have yielded mixed results. Sequencing of more than 300 TS subjects has not identified any clearly pathogenic coding mutations in *SLITRK1*, but several putatively disruptive variants were found in a small sample of individuals with trichotillomania. Two candidate gene studies of common variation at the *SLITRK1* locus have supported association, but as noted, neither this locus nor any others reached genome-wide significance in GWAS studies of TS. Two studies specifically focused on the 3' UTR var321 and raised the possibility that this finding may have been the result of occult differences in ancestry among cases and controls (i.e., population stratification). However, the authors of the original paper provided further data and analysis arguing against this interpretation (State, 2011).

A mouse knockout of *SLITRK1* has been described (Aruga et al, 2010). Knockout mice show an anxiety phenotype and increased levels of noradrenaline and its metabolites, mirroring earlier finding in human studies of cerebrospinal fluid in TS (Leckman et al., 1995). Biochemical analyses have demonstrated that *SLITRK1* binds to 14-3-3 molecules and regulates neurite outgrowth (Deng et al., 2012), and a mouse knockout of a closely related molecule, *SLITRK5*, shows abnormal corticostriatal dendritic morphology and a rare repetitive grooming/obsessive compulsive phenotype (Shmelkov et al., 2010). Collectively these studies have yielded provocative data; however, the role of *SLITRK1* in TS remains an open question. Given the experience with similarly early rare mutation findings in other areas of psychiatric genetics, such as autism, it is likely that this will only be clarified as larger-scale studies are completed.

The emergence of microarray technology in the early 2000s led to the systematic detection of submicroscopic variations in chromosomal structure called copy number variants (CNVs). These have now been widely studied in a range of disorders, including autism, schizophrenia, bipolar disorder, and others (Malhotra and Sebat, 2012). Two CNV analyses in TS have been reported to date. The first included 111 affected subjects and 73 controls and highlighted the overlap of risks with schizophrenia and autism based on the observation of CNVs in the genes *Neurexin 1 (NRXN1)* and *Catenin, alpha 3 (CTNNA3)* (Sundaram et al., 2010). There was no detectable increase in the overall rate of CNVs in cases versus controls, although the power to detect an increase of plausible scale was limited by the small sample size. A later study of 460 TS subjects and 1131

controls similarly found no significant difference in the number of rare CNVs in cases versus controls, though the burden of *de novo* rare exonic variants among 148 TS trios (2.7%) versus 436 control trios (0.7%) approached significance ($p = .07$) (Fernandez et al., 2012). Extrapolating from recent evidence from other disorders, it is likely that a markedly larger sample of affected trios will be required to confirm or refute a significant contribution of *de novo* CNVs to TS. Interestingly, this CNV study provided statistical support for the reported overlap of genes mapping within rare CNVs in TS and ASD. In addition, three large, likely pathogenic *de novo* CNVs were identified, including one disrupting multiple gamma-aminobutyric acid (GABA) receptor genes (Fernandez et al., 2012).

Finally, a recent report of a two-generation family with nine affected members (Ercan-Sencicek et al, 2010) was the first genetic study to suggest a link between TS and histaminergic neurotransmission. The pedigree was found to segregate a rare nonsense mutation in the *HDC* (*L-histidine decarboxylase*) gene, the rate-limiting enzyme in histamine (HA) biosynthesis. In combination with the results of a pathway analysis in the aforementioned CNV study (Fernandez et al., 2012), which found enrichment in CNVs affecting histamine signaling, the finding highlighted a potential role for striatal HA in the genesis or modulation of tics.

Overall, the accumulated evidence demonstrates a critical role for genetic contributors in the etiology of TS, and a series of recent findings have generated intriguing hypotheses

regarding molecular pathophysiological mechanisms and the possible overlap of TS risks with other complex neuropsychiatric conditions. Although gene discovery efforts have been less revealing than in other disorders, such as autism and schizophrenia, the prospects for the future are nonetheless extremely bright. Recent studies in autism, schizophrenia, ADHD, and bipolar disorder have all demonstrated that the key to progress is the consolidation of very large samples and the pursuit of studies that address, in an unbiased fashion, the potential contribution of the entire range of allele frequencies, from rare and *de novo* mutations to common polymorphisms (Fig. 79.1). The rapid maturation of genomic technologies, the development of highly reliable analytical methods and the dramatic progress in other complex neuropsychiatric disorders resulting from samples approaching this size point to a clear path forward for TS genetics, one that promises new insights into molecular and cellular mechanisms, and the development of novel and more effective therapeutics.

CORTICOBASAL GANGLIA CONNECTIONS: CORE CIRCUITRY AND CELLULAR COMPONENTS

Dysregulation of the basal ganglia loops connecting the cerebral cortex, striatum (caudate and putamen), globus pallidus, and thalamus—collectively termed the cortico-striato-thalamo-cortical (CSTC) circuitry (Fig. 79.2)—is hypothesized to be

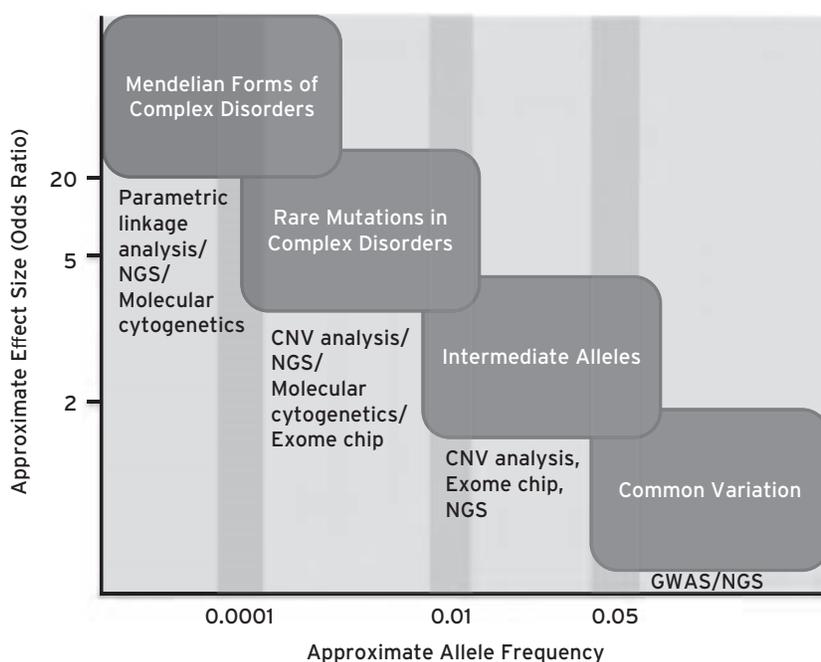

Figure 79.1 Methodological tools for the discovery of disease-associated alleles of different frequency and effect size. Genetic variation that contributes to disease extends on a continuum of allele frequency and the effect size of disease-associated mutations. These tend to be inversely correlated, as disease alleles of large effect size, particularly for developmental disorders, are subject to purifying selection. Different technologies and analytic approaches are appropriate to characterize alleles at different points along this continuum (as described in the text below the boxes). There is strong evidence for the contribution to TS risk of rare Mendelian forms of TS (e.g., *HDC* mutations), rare, non-Mendelian mutations (e.g., copy number variation), and common variation. It is very likely that mutations spanning this frequency and effect size spectrum will be found to contribute to both risk and resilience in TS. With the application of the methods noted in the figure, investigations of sufficiently large populations should reveal the genetic architecture of TS in dramatically increased detail over the coming years. Exome-chip, a microarray enriched for probes of recurrent alleles represented at low frequency in the population; NGS, next generation sequencing including whole genome and whole exome analysis. Allele frequencies and effect sizes are approximate and are intended for illustrative purposes.

central to the pathogenesis of TS. This circuitry is implicated in movement disorders such as Parkinson disease, Huntington disease, and dystonia (Albin et al., 1989). Several lines of evidence suggest that abnormalities in this circuitry also contribute to TS. For example, focal insults to the striatum can produce tics and tic-like phenomenology, as in patients with discrete striatal strokes who may present with motor or phonic tics (Kwak and Jankovic, 2002). Similarly, monkeys develop focal motor tics after local disinhibition of the striatum through injection of the GABA_A antagonist bicuculine (McCairn et al., 2009).

The basal ganglia have been described, to a first approximation, as a series of loops from the cortex, through the striatum and globus pallidus, to the anterior thalamus, and back to the cortex (Alexander et al., 1986). Loops connecting to different cortical regions are hypothesized to quasi-independently process different types of information, although connections between different circuits allow for interactions between domains (Haber et al., 2000). The basal ganglia are unusual in that most of their long-range projections are inhibitory, rather than excitatory. GABAergic medium spiny neurons (MSNs) of the striatum receive excitatory input from the cortex and project through several synapses to the thalamus following two parallel routes, the *direct* (or *striatonigral*) pathway and the *indirect* (or *striatopallidal*) pathway (see Fig. 79.1). A more recently described third route, the *hyperdirect* pathway constituted by

direct cortical projections to the subthalamic nucleus, serves as a reminder that the focus on these two pathways is a convenient simplification.
